Dedication

To my wife, Deborah, whose love, patience and understanding makes my work possible.
In 1940, Emil Novak published the first edition of what has been known as “Novak's Textbook.” Dr. Novak was a mentor and exemplar to so many of those of us who studied gynecology and gynecologic pathology. He clearly saw the importance of this study and this field of medicine, and he provided each of us who have followed in his footsteps with a wonderful example. To us, Emil Novak was the ultimate doctor, a man who saw the study of medicine as a way to provide aid to those who suffered illness. We are indebted to him for having begun this work, taught so many who have worked in this specialty, and provided the means by which his textbook could carry on his work.

It is a pleasure and a privilege to have been asked to pen this foreword, as it has been my pleasure and privilege to have worked on this textbook and to have as colleagues in this endeavor so many superb physicians. Dr. Novak would endorse and be thankful that the text is being updated for your use. He knew, as we do, that the pursuit of academic medicine is imperative to the development of medicine in general and our field in particular. In order to provide you with the same superb resource that Emil Novak began 55 years ago, Novak's *Textbook of Gynecology* must be updated, and a new generation of men and women must accept his challenge.

Medicine as a profession has changed and will continue to change, but the basic message that Emil Novak presented in the first textbook is the same: doctors must be concerned with the welfare of patients, and in order to accomplish this task, they must have access to the latest and best information and training. Jonathan Berek and his colleagues are well schooled in the legacy of Emil Novak and all of those who have worked on this book. It is with confidence in the quality of their work that I endorse this 12th edition of *Novak's Gynecology*.

J. Donald Woodruff, MD
Richard W. TeLinde Professor Emeritus
Johns Hopkins University School of Medicine
Baltimore, Maryland

Dr. J. Donald Woodruff passed away in 1996. He was a particularly gifted teacher and clinician who helped guide the development of our specialty. I feel it is important to retain the thoughtful comments he contributed to our twelfth edition for this edition of *Novak's Gynecology*.

Jonathan S. Berek
Preface to the Thirteenth Edition

Novak’s Gynecology, 13th edition, has been thoroughly updated and revised to be certain that its contents and bibliography are current and accurate. Its essence is the same as the original—a comprehensive general textbook in gynecology. The substance reflects the wealth of information that has emerged and evolved during the 62 years since the inception of Novak’s Textbook of Gynecology. It is an honor to have been asked to continue to shepherd this important book and I hope will retain its value to inform and assist our colleagues for many years.

The textbook, originated by the faculty of the Johns Hopkins University School of Medicine, continues to reflect the contributions of that great institution. The book was inaugurated by Dr. Emil Novak, a pioneer in gynecology and pathology. After the fifth edition and subsequent death of Dr. Novak in 1957, many physicians on the faculty of Johns Hopkins, and subsequently some members of the Vanderbilt faculty, have helped carry the torch—Dr. Edmund R. Novak through the ninth edition in 1979; Drs. Howard W. Jones, Jr. and Georgeanna Seegar Jones through the tenth edition in 1981; and Drs. Howard W. Jones, III, Lonnie S. Burnett, and Anne Colston Wentz through the 11th edition in 1988. These editors, assisted by many contributors who have been faculty at Johns Hopkins, especially Drs. J. Donald Woodruff and Conrad G. Julian, have helped define the specialty of gynecology over the latter half of the 20th century. These physicians and authors are responsible for the ideas that shaped the specialty of gynecology as we know it today—its surgical and medical therapies, reproductive endocrinology, assisted reproductive technologies, gynecologic oncology, urogynecology, and infectious diseases. As a graduate of Johns Hopkins University School of Medicine, I am proud to contribute to that rich tradition.

Starting with the twelfth edition, this textbook utilized a new format. The design of the book was established by Dr. Leon Speroff and his colleagues in the textbook Clinical Gynecologic Endocrinology and Infertility and was adapted for the book Practical Gynecologic Oncology. This presentation style should facilitate the study of gynecology for the student as well as the specialist.

Novak’s Gynecology, 13th edition, is presented in six sections. The first, “Principles of Practice,” includes the initial assessment of the gynecologic patient, the history and physical examination, and communication skills. This section addresses ethical principles of patient care, quality assessment and improvement, and the epidemiology of gynecologic conditions. The second section, “Basic Sciences,” summarizes the scientific basis for the specialty—anatomy and embryology, molecular biology and genetics, and reproductive physiology. The third section, “Preventive and Primary Care,” reflects the importance of primary health care for women, which has evolved to address preventive care, screening, family planning, sexuality, and common psychiatric problems. The fourth section, “General Gynecology,” reviews benign diseases of the female reproductive tract, the evaluation of pelvic infections, pain, intraepithelial diseases, the management of early pregnancy loss and ectopic pregnancy, the evaluation of benign breast disease, and the operative management of benign gynecologic conditions. The fifth section, “Reproductive Endocrinology,” summarizes the major disorders affecting the growth, development, and function of women from puberty through menopause. The sixth section, “Gynecologic Oncology,” covers malignant diseases of the female reproductive tract and breast cancer.

I have purposely abbreviated the discussion of the historical development of the subjects in each chapter. Space limitations have required a shift in emphasis from the achievements of the past to the relevant issues of the present.

I am especially grateful to the many individuals who contributed to this book. Rebecca Rinehart provided superb editorial assistance, manuscript review, and revision. Drs. Paula Hillard and Eli Adashi served as excellent Assistant Editors. Tim Hengst, an outstanding medical illustrator, designed and created the original artwork. At the publishers, Lippincott Williams & Wilkins, Ms. Lisa McAllister supported the editorial process with great enthusiasm. Working with her, Ray Reter, Steven Martin and the rest of their team skillfully produced the manuscript. Expert secretarial support was provided by Kevin Wong and Sergio Huidor.

I acknowledge the efforts of my mentors and colleagues—Dean Sherman Mellinkoff, Drs. J. Donald Woodruff, Kenneth J. Ryan, Isaac Schiff, J. George Moore, William J. Dignam, Gautum Chaudhuri, and Neville F. Hacker. Each of these physicians and scholars provided me with guidance, wisdom, and encouragement during the years we shared at our respective university medical schools.

My thanks to Nicole Kidman, the chair of the advisory board for the UCLA Women's Reproductive Cancer Program—whose support and friendship has helped stimulate this project.

I hope that this book will be a useful resource for my colleagues and for students of the specialty of gynecology. I look forward to the continued impact of the specialty on the enhancement of health care for women throughout the world.

Jonathan S. Berek
Since the plan and scope of this book represent something of a departure from those followed in other textbooks of gynecology, the author feels impelled to state the ideas which furnished the incentive for the preparation of this work, and which dictated its character and scope.

First of all, no especial apology seems necessary for the combined title. While gynecology was formerly often spoken of as a branch of surgery, this is certainly not its present status. Only a small proportion of gynecological patients require surgical treatment. On the other hand, the biological aspects of gynecology have assumed vast importance, chiefly because of the amazing developments in the field of reproductive physiology and endocrinology. Many of these advances find daily application in the interpretation and management of functional disorders in women. In other words, female endocrinology is now an integral and important part of gynecology and it is so considered in this book.

Second, it has always seemed to me that the great majority of readers of textbooks on gynecology must be not at all interested in the details of operative technique, to the consideration of which most authors have devoted many pages. Certainly this applies to the general practitioner, while medical educators are now generally agreed that the medical student should not be burdened with such details in his undergraduate years. Since this book is designed for these two groups primarily, the indication seemed clear to omit the consideration of operative details. The plan followed is to carry the patient up to the point of operation, and to discuss the indications, scope and purpose of the latter, without going into descriptions of the technique itself.

Diagnosis and treatment have been accentuated throughout the book, as I believe most readers would wish. The traditional chapters on anatomy, history-taking, and methods of examination have been boiled down to the essentials. On the other hand, functional disorders, including especially the large group of gynecological endocrinopathies, have been treated rather elaborately, in keeping with the avowed plan of covering the combined fields of gynecology and female endocrinology. The list of references appended to each chapter makes no pretense of exhaustiveness, and preference has been given to publications most worth while, those most recent, and those written in English. The pathological aspects of gynecological disease, so fundamental to a proper understanding of the whole subject, have received adequate but not disproportionate consideration.

In the consideration of various endocrine disorders a disturbing problem presented itself. In the discussion of endocrine preparations which might be indicated in treatment, there is no doubt that the mention of various products by their commercial names would have had some advantages. On the other hand, these have appeared to be definitely outweighed by the disadvantages of such a plan, apart from its questionable delicacy. These proprietary preparations are constantly multiplying, and their commercial names are being changed from day to day. For example, there are now well over forty estrogenic preparations on the market. It would be almost impossible, in any enumeration of such therapeutic products, to avoid omission of some of them, and this might be very unfair to products perhaps just as effective as those which might be included. A complete list published today is quite likely to be very incomplete within a few months.

The sensible plan seemed to be to rely on the intelligence and initiative of the reader, who should have no difficulty in ascertaining good commercial preparations of estrogen, progesterone, chorionic hormone or any other hormone principle to which reference is made in the treatment of various disorders.

It will be noted that the work is devoted to “straight” gynecology and male endocrinology and that it does not include a consideration of disorders in allied fields which concededy obstruct themselves frequently into the practice of the gynecologist. For example, many gynecologists include female urology in their practices, while anorectal and abdominal surgical problems are often encountered, as may be problems in any field of medicine. For textbook purposes, however, the line must be drawn fairly sharply, and the reader will naturally expect to go to the proper sources for information in any of these allied fields.

In short, the purpose of this book is to present to the reader as much information as is possible in as practical a fashion as possible on the subjects of gynecology and female endocrinology. Whether right or wrong, the ideas behind the book represent the crystallization of many years of teaching and practice in gynecology. The author’s goal has been to produce a book which would not only be suited to the needs of the medical student, but which could be carried with him into the practice of his profession.

It is a pleasant obligation to express my indebtedness to those who have been helpful to me in the preparation of this book. To a number of my friends, especially Dr. R.B. Greenblatt, of Augusta, Georgia, I am grateful for the loan of illustrations; to Dr. E.L. Krieg, for the excellent colored illustrations as well as for other photographic work; to Mr. Chester Reather, for most of the photomicrographs; to Miss Eva Hildebrandt, technician in the Laboratory of Gynecological Pathology at The Johns Hopkins Hospital and to Sister Mary Lucy, technician at Bon Secours Hospital for help in the preparation of sections for microscopic illustration; to my artist, Miss Frances Shultz, for many of the illustrations; and to my faithful secretary, Miss Helen L. Clayton, for much help throughout the project. For permission to use illustrations which have appeared in previously published articles of my own I am indebted to the publishers of the Journal of the American Medical Association; the American Journal of Obstetrics and Gynecology; Surgery, Gynecology and Obstetrics; and the Bulletin of The Johns Hopkins Hospital.

Certain illustrations which appeared in one of my previous books, Gynecological and Obstetrical Pathology, do not have a credit line in the caption. For permission to use these I wish to thank WB Saunders Company, the publishers.

Finally, it is a genuine pleasure to acknowledge the efficient and wholehearted cooperation of the publishers, Little, Brown and Co., throughout the preparation of this work.

The practice of gynecology requires many skills. In addition to medical knowledge, the gynecologist should develop interpersonal and communication skills that promote patient-physician interaction and trust. The assessment must be of the “whole patient,” not only of her general medical status. It should include any apparent medical condition as well as the psychological, social, and family aspects of her situation. Environmental and cultural issues that affect the patient must be taken into account to view her in the appropriate context. This approach is of value in routine assessments, providing opportunities for preventive care and counseling on a continuing basis, as well as in the assessment of medical conditions.

**Communication**

Good communication is essential to patient assessment and treatment. The patient-physician relationship is based on communication conducted in an open, honest, and careful manner so that the patient’s situation and problems can be accurately understood and effective solutions determined. Good communication requires patience, dedication, and practice.

The foundation of communication is based on key skills: empathy, attentive listening, expert knowledge, and rapport. These skills can be learned and refined (1). After establishing the initial relationship with the patient, the physician must vigilantly pursue interviewing techniques that create opportunities to foster an understanding of the patient’s concerns (2). Trust is the fundamental element that encourages the patient to communicate her feelings, concerns, and thoughts openly, without withholding information.

Although there are many styles of interacting with patients and each physician must determine the best way that he or she can relate to patients, physicians must convey that they are able and willing to listen and that they receive the information with utmost confidentiality (3). The Hippocratic oath demands that physicians be circumspect with all patient-related information.

**Variables that Affect Patient Status**

Many external variables exert an influence on the patient and on the care she receives. Some of these factors include the patient’s “significant others”—her family, friends, and personal relationships (Table 1.1). These external variables also include psychological, genetic, biologic, social, and economic issues. Factors that affect a patient’s perception of disease and pain and the means by which she has been taught to cope with illness include her education, attitudes, understanding of human reproduction and sexuality, family history of disease, and, in some cases, need for attention (3, 4, and 5). Cultural factors, socioeconomic status, religion, ethnicity, and sexual preference are important considerations in understanding the patient’s response to her care in both illness and health.

We are all products of our environment, our background, and our culture. The importance of ascertaining the patient’s general, social, and familial situation cannot be overemphasized (1). The context of the family can and should be ascertained directly. The family history, including a careful analysis of those who have had significant illnesses, such as cancer, must be obtained. The psychological and sexual practices of the patient should be understood, and her functional level of satisfaction in these areas should be determined. The physician must avoid being judgmental, particularly with respect to questions about sexual practices and preferences (see Chapter 11 and Chapter 12).
It is essential for the physician to communicate with a patient in a manner that allows her to continue to seek appropriate medical attention. Not only the words used, but also the patterns of speech, the manner in which the words are delivered, even body language and eye contact, are important aspects of the patient–physician interaction. The traditional role of the physician has been rather paternalistic, with the physician being expected to deliver direct commands and specific guidance on all matters (3). Patients are now demanding more balanced communication with their physicians, and although they do not in most cases command an understanding of medicine, they do expect to be treated with appropriate deference, respect for their intellect, and a manner more equal in stature with the physician (6). There is some evidence that giving the patient more control in the relationship with her doctor can lead to better health outcomes (3, 7, 8).

### Physician–Patient Interaction

The pattern of the physician's speech can influence interactions with the patient. Some important components of effective communication between patients and physicians are presented in Table 1.2. For this communication to be effective, the patient must feel that she is able to discuss her problems fully. In addition, if the patient perceives that she participates in the decision and that she is given as much information as possible, she will react to the proposed treatment with lower levels of anxiety and depression. There is ample evidence that patient communication and understanding and treatment outcome are improved when discussions with physicians are more dialogue than lecture. In addition, when patients feel they have some room for negotiation, they tend to retain more information regarding health care plans (9).

<table>
<thead>
<tr>
<th>Table 1.2 Important Components of Communication between the Patient and Physician: The Physician's Role</th>
</tr>
</thead>
<tbody>
<tr>
<td>The notion of collaborative planning between patients and physicians has developed (9). This means that the patient becomes more vested in the process of determining health care choices. For example, if the patient is informed about the risks and benefits of hormone replacement therapy and clearly understands them, she may be more likely to comply with the plan once it has been set jointly by she and her physician.</td>
</tr>
<tr>
<td>There is some evidence that when patients are heard, understood, more vocal, and more inquisitive, their health improves (2). Good communication is essential for the maintenance of a relationship between the patient and physician that fosters ongoing care. Health maintenance, therefore, can be linked directly to the influence of positive, genial interactions. Patients who are comfortable with their physician may be more likely to raise issues or concerns or convey information about potential health risks and may be more receptive to the physician's recommendations. This degree of rapport may promote the effectiveness of early interactions, including behavior modification. It also helps ensure that patients return for regular care because they feel the physician is genuinely interested in their welfare.</td>
</tr>
<tr>
<td>When patients are ill, they feel vulnerable, physically and psychologically exposed, and powerless. Because the physician has power by virtue of knowledge and status, this relationship can be intimidating. Therefore, it is essential that the physician be aware of this disparity so that the “balance of power” does not shift too far away from the patient. Shifting it back from the physician to the patient may help improve outcomes (3, 7, 8).</td>
</tr>
<tr>
<td>In assessing the effects of the patient–physician interaction on the outcome of chronic illness, three characteristics that are associated with better health care outcomes have been identified (8):</td>
</tr>
<tr>
<td>1. Empathetic physician and more patient control of the interview</td>
</tr>
<tr>
<td>2. Expression of emotion by both patient and physician</td>
</tr>
<tr>
<td>3. Provision of information by the physician in response to the patient’s inquiries</td>
</tr>
<tr>
<td>These findings related to the control of diastolic blood pressure and the reduction of hemoglobin A1c in patients with diabetes, who experienced improved function and subjective evaluation of health in the presence of these characteristics. The best responses were achieved when an empathetic physician provided as much information and clarification as possible, responded to the patients’ questions openly and honestly, and expressed a full range of emotions, including humor, and when the relationship was not entirely dominated by the physician (8).</td>
</tr>
<tr>
<td>In studies of gender and language, men tend to talk more than women, successfully interrupt women, and control the topics of the conversation (13). As a result, male physicians may tend to take control and be more assertive than female physicians. Men's speech tends to be characterized by interruptions, command, and lectures, and women's speech is characterized by silence, questions, and proposals (11, 12). Some patients may simply feel more reticent in the presence of a male physician, whereas others may be more forthcoming with a male than a female physician (19). Although these generalizations clearly do not apply to all physicians, they can raise awareness about the various styles of communication. These patterns indicate the need for all physicians, regardless of their gender, to be attentive to their style of speech because it may affect their ability to elicit open and free responses from their patients (14, 15). Women tend to speak openly in order to express their feelings and to have them validated and shared in an attempt to gain understanding of their concerns (9, 10 and 11).</td>
</tr>
<tr>
<td>With regard to communication relating to gynecologic issues, it is important to understand that different styles of communication may affect the physician's ability to perceive the patient's status and to achieve the ultimate goal of optimal assessment and compliance with medical and surgical therapies. The intimate and highly personal nature of many gynecologic conditions requires particular sensitivity to evoke an honest response.</td>
</tr>
</tbody>
</table>

#### Style

In general, the art of communication and persuasion is based on mutual respect and development of the patient’s understanding of the circumstances of her health (2). Insight is best achieved when the patient is encouraged to query her physician and when she is not pressured to make decisions (3). Patients who feel “backed into a corner” have the lowest compliance with recommended treatments (7).

Following are techniques to help achieve rapport with patients:

1. **Use positive language** (e.g., agreement, approval, and humor).
2. **Build a partnership** (e.g., acknowledgment of understanding, asking for opinions, paraphrasing, and interpreting the patient's words).
3. **Ask rephrased questions**.
4. **Give complete responses to the patient’s questions**.

The manner in which a physician guides a discussion with a patient will determine the patient's level of understanding and her compliance. For example, in providing a prescription, if a command is given to take the medication without a discussion of the rationale for it, patients may not comply, particularly if they become confused about the instructions (3). It is obviously inappropriate to prescribe hormone replacement therapy with a statement of simply, ‘Just take one of these pills every night.
The style of the presentation of information is key to its effectiveness. The physician should avoid “speaking down” to patients, both figuratively and literally. The latter occurs when discussions take place with the patient in the supine or the lithotomy position. Such a position creates a vulnerable situation in which the patient does not feel she is an equal partner in the relationship. Serious discussions about diagnosis and management strategies should be conducted when the patient is fully clothed and face-to-face with a doctor in a private room, with or without an intervening desk.

Body language is also important in interactions with patients. The physician should avoid an overly casual stance, which can communicate a lack of caring or lack of compassion. The patient should be viewed directly and spoken to with eye contact so that the physician is not perceived as “looking off into the distance” (3).

Laughter and Humor

Humor is an essential component that promotes open communication. It can be either appropriate or inappropriate. Appropriate humor allows the patient to diffuse anxiety and understand that (even in difficult situations) laughter can be healthy (16). Inappropriate humor makes the patient feel uncomfortable or seem disrespectful of her. Laughter can be used as an appropriate means of relaxing the patient and making her feel better.

Laughter is a “metaphor for the full range of the positive emotions” (15). It is the response of human beings to incongruities and one of the highest manifestations of the cerebral process. It helps to facilitate the full range of positive emotions—love, hope, faith, the will to live, festivity, purpose, and determination (16). Laughter is a physiologic response, a release that helps us all feel better and allows us to accommodate the collision of logic and absurdity. Illness, or the prospect of illness, heightens our awareness of the incongruity between our existence and our ability to control the events that shape our lives and our outcomes. We use laughter to combat stress, and stress reduction is an essential mechanism used to cope with illness.

Strategies for Improving Communication

All physicians should understand the art of communication during the medical interview. It is essential that interactions with patients are professional, honorable, and honest. Issues that are important to physicians regarding patient–physician interactions are presented in Table 1.3. Following are some general guidelines that can help to improve communication:

1. Listen more and talk less.
2. Encourage the pursuit of topics introduced by and important to patients.
3. Minimize controlling speech habits such as interrupting, issuing commands, and lecturing.
4. Seek out questions and provide full and understandable answers.
5. Become aware of discomfort in an interview, recognize when it originates in an attempt by the physician to take control, and redirect that attempt.
6. Assure patients that they have the opportunity to discuss their problem fully.

Recognize when patients may be seeking empathy and validation of their feelings rather than a solution. Sometimes all that is necessary is to be there as a compassionate human being.

In conducting interviews, it is important for the physician to understand the patient’s concerns. In studies of interviewing techniques, it has been shown that although clinicians employ many divergent styles, the successful ones tend to look for “windows of opportunity” (i.e., careful, attentive listening with replies or questions at opportune times) (2). This skill of communication is particularly effective in exploring psychological and social issues during brief interviews. The chief skill essential to allowing the physician to perceive problems is the ability to listen attentively.

An interview that permits maximum transmission of information to the physician is best achieved by the following approach (2):

1. Begin with an open-ended question.
2. As the patient begins to speak, pay attention not only to her answers but also to her emotions and general body language.
3. Extend a second question or comment, encouraging the patient to talk.
4. Allow the patient to respond without interrupting, perhaps by employing silence, nods, or small facilitative comments, encouraging the patient to talk while the physician is listening.
5. Summarize and express empathy and understanding at the completion of the interview.

Attention and rapport, and collaboration characterize good medical interviewing techniques. Open-ended questions are generally desirable, particularly coupled with good listening skills (“How are you doing?” “How does that make you feel?”). Premature closure of an interview and inability to get the complete information to the patient may occur for several reasons (2). It may arise from a lack of recognition of the patient’s particular concern, from not providing appropriate opportunity for discussion, from the physician’s becoming uncomfortable in sharing the patient’s emotion, or perhaps from the physician’s lack of confidence that he or she can deal with the patient’s concern. One of the principal factors undermining the success of the interview is lack of time. However, skilled physicians can facilitate considerable interaction even in a short time by encouraging open communication (2).

Many patients lack accurate information about their illness. Lack of full understanding of an illness can produce dissatisfaction with medical care, increased anxiety, distress, coping difficulties, noncompliance with treatment, and poor treatment response (16,19 and 20). As patients increasingly request more information about their illnesses and more involvement in decisions about their treatment, and as physicians attempt to provide more open negotiation, communication problems become more significant. Poor patient understanding stems from poor communication techniques, lack of consultation time, patient anxiety, patient denial, and in some cases, the withholding of information considered detrimental to patient welfare (16).

If clinical findings or confirmatory testing strongly suggest a serious condition (e.g., malignancy), the gravity and urgency of this situation must be conveyed in a manner that does not unduly alarm or frighten the individual. Honest answers should be provided to any specific questions the patient may want to discuss (19,20).

Allowing time for questions is important, and scheduling a follow-up visit to discuss treatment options after the patient has had an opportunity to consider the options and recommendations may be valuable (19,20). The patient should be encouraged to bring a partner or family member with her to provide moral support and to assist with questions. The patient should also be encouraged to write down any concerns she may have and bring them with her because important
issues may not come to mind easily during an office visit. If the patient desires a second opinion or if a second opinion is mandated by her insurance coverage, it should be facilitated.

Valuable information can be provided by interviews with ancillary support staff and by providing pamphlets and other materials produced for patient education. Some studies have demonstrated that the use of pamphlets is highly effective in promoting an understanding of the condition and treatment options. Others have shown that the use of audiotapes and videotapes has a positive impact on knowledge and can decrease anxiety (18).

There are numerous medicine websites on the Internet that can be accessed, although the accuracy of the information is variable and must be carefully reviewed by physicians before recommending to patients.

The relationship between the patient and her physician is subject to constant change, as is true of all features of social interchange. The state of our health is dynamic. Many of us are fortunate to be in a good state of health for much of our lives, but some are not so fortunate. The goal of open communication between patient and physician is to achieve maximum effectiveness in diagnosis, treatment, and compliance for all patients.

Talk to the heart, speak to the soul.

Look to the being and embrace the figure’s form.
Reach deeply, with hands outstretched.
Talk intently, to the seat of wisdom, as life resembles grace.
Achieve peace within a fragile countenance.
Seek the comfort of the placid hour.
Through joyous and free reflection
know the other side of the flesh’s frame.

JSB

History and Physical Examination

After a dialogue has been established, the patient assessment proceeds with obtaining a complete history and performing a physical examination. Both of these aspects of the assessment rely on good patient–physician interchange and attention to details. During the history and physical examination, the identification of risk factors that may require special attention should be sought. These factors should be reviewed with the patient in developing a plan for her future care (see Chapter 8).

Table 1.4 Technique of Taking the History of the Present Illness

Physical Examination

A thorough general physical examination should be performed during each patient assessment (Table 1.5). In addition to evaluation of the vital signs, examination of the breast, abdomen, and pelvis is an essential part of the gynecologic examination.

Table 1.5 Method of the Female Pelvic Examination

Abdominal Examination

With the patient in the supine position, an attempt should be made to have the patient relax as much as possible. Her head should be leaned back and supported gently by a pillow so that she does not tense her abdominal muscles.

The abdomen should be inspected for signs of an intraabdominal mass, organomegaly, or distention that would, for example, suggest ascites or intestinal obstruction. Initial palpation of the abdomen is performed to evaluate the size and configuration of the liver, spleen, and other abdominal contents. Evidence of fullness or mass effect should be noted. This is particularly important in evaluating patients who may have a pelvic mass and in determining the extent of omental involvement, for example, with metastatic ovarian cancer. A fullness in the upper abdomen could be consistent with an “omentum cake.” All four quadrants should be carefully palpated.
for any evidence of mass, firmness, irregularity, or distention. A systematic approach should be used (e.g., clockwise, starting in the right upper quadrant). Percussion should be used to measure the dimensions of the liver. The patient should be asked to inhale and exhale during palpation of the edge of the liver.

Auscultation should be performed to ascertain the nature of the bowel sounds. The frequency of intestinal sounds and their quality should be noted. In a patient with intestinal obstruction, "rushes," as well as the occasional high-pitched sound, can be heard. Bowel sounds associated with an ileus may be less frequent but at the same pitch as normal bowel sounds.

**Pelvic Examination**

The pelvic examination is typically performed with the patient in the dorsal lithotomy position (Fig. 1.1). The patient's feet should rest comfortably in stirrups with the edge of the buttocks at the lower end of the table so that the vulva can be readily inspected and the speculum can be inserted in the vagina without obstruction from the table.

![Figure 1.1 The lithotomy position for the pelvic examination.](image)

The vulva and perineal area should be carefully inspected. Evidence of any lesions, erythema, pigmentation, masses, or irregularity should be noted. The skin quality should be noted as well as any signs of trauma, such as excoriations or ecchymosis. The presence of any visible lesions should be quantitated and carefully described with regard to their full appearance and characteristics on palpation (i.e., mobility, tenderness, consistency). Ulcerative or purulent lesions of the vulva should be cultured as outlined in subsequent chapters, and biopsy should be performed on any lesions.

After thorough visualization and palpation of the external genitalia, including the mons pubis and the perianal area, a speculum is inserted in the vagina. In a normal adult who is sexually active, a Pederson or Graves speculum is used. The types of specula that are used in gynecology are presented in Fig. 1.2. In general, the smallest speculum necessary to produce adequate visualization should be used. The speculum should be warmed before it is inserted into the vagina, and warm water generally provides sufficient lubrication for this procedure. The patient should be alerted to the fact that the speculum will be inserted so that she is not surprised by its placement. After insertion, the cervix and all aspects of the vagina should be carefully inspected. Particular attention should also be paid to the vaginal fornices because lesions (e.g., warts) may be present in those areas and are not readily visualized unless care is taken to do so.

![Figure 1.2 Vaginal specula: 1, Graves extra long; 2, Graves regular; 3, Pederson extra long; 4, Pederson regular; 5, Huffman “virginal”; 6, pediatric regular; and 7, pediatric narrow.](image)

The appropriate technique for a Papanicolaou's (Pap) test is presented in Chapter 16. Any obvious lesions on the cervix or in the vagina should undergo biopsy. An endometrial biopsy is usually performed with a flexible cannula or a Novak curette (see Chapter 13). Any purulence in the vagina or cervix should be cultured (see Chapter 15).

After the speculum is removed and the pelvis palpated, the first and second fingers are inserted gently into the vagina after adequate lubrication has been applied to the examination glove. In general, in right-handed physicians, the right hand is inserted into the vagina and the left hand is used on the abdomen to provide counter pressure as the pelvic viscera are moved (Fig. 1.3). The vagina, its fornices, and the cervix are palpated carefully for any masses or irregularities. The fingers are placed gently into the posterior fornix so that the uterus can be moved. With the abdominal hand in place, the uterus can usually be palpated just above the surface pubis. In this manner, the size, shape, mobility, contour, consistency, and position of the uterus are determined.

![Figure 1.3 The bimanual examination.](image)

The adnexa are then palpated gently on both sides, paying particular attention to any enlargements. Again, the size, shape, mobility, and consistency of any adnexal structures should be carefully noted.
A rectal examination is suggested periodically in women 40 years of age and older (see American College of Obstetricians and Gynecologists guidelines, Chapter 8) and in all premenopausal women in whom there is any difficulty ascertaining the adnexal structures (Fig. 1.4). Rectovaginal examination should also be performed in these women to exclude the possibility of concurrent rectal disease (23). In postmenopausal women who undergo rectal examination, a stool guaiac test can be performed. During rectal examination, the quality of the sphincter muscles, support of the pelvis, and evidence of masses such as hemorrhoids or lesions intrinsic to the rectum should be noted.

**Figure 1.4 The rectovaginal examination.**

At the completion of the physical examination, the patient should be informed about the findings. When the results of the examination are normal, the patient can be reassured accordingly. When there is a possible abnormality, the patient should be informed immediately. A plan to evaluate the findings should be outlined briefly and in clear, understandable language. The implications of any proposed procedure (e.g., biopsy) should be discussed, and the patient should be informed when the results of any tests will be available.

### Pediatric Patients

A careful examination is indicated when a child presents with genitai complaints. The examiner should be familiar with the normal appearance of the prepubial genitalia. The normal unestrogenized hymenal ring and vestibule can appear mildly erythematous. The technique of examination is different from that used for examining an adult and may need to be tailored to the individual child based on her age, size, and comfort with the examiner. A young child can usually be examined best in a “frog-leg” position on the examining table. Some very young girls (toddlers or infants) do best when held in their mother’s arms. Sometimes, the mother can be positioned, clothed, on the examination table (feet in stirrups, head of table elevated) with the child on her lap, the child’s legs straddling her mother’s. The knee-chest position may also be helpful for the examination (22). The child who is relaxed and warned about touching will usually tolerate the examination satisfactorily. Some children who have been abused, who have had particularly traumatic previous examinations, or who are unable to allow an examination may need to be examined with the use of anesthesia, although a gentle office examination should almost always be attempted first. If no obvious case of bleeding is visible externally or within the distal vagina, an examination under anesthesia may be indicated to visualize the vagina and cervix completely. A hysteroscope, cystoscope, or other endoscopic instrument can be used to provide magnification and light source.

### Adolescent Patients

A pelvic examination may be less revealing in an adolescent than in an older woman, particularly if it is the patient’s first examination or if it takes place on an emergency basis. Although other diagnostic techniques (such as pelvic ultrasound) can supplement an inadequate or poorly revealing examination, an examination should usually be attempted. The keys to a successful examination lie in earning the patient’s trust, explaining the components of her examination, performing only the essential components, and using a very careful and gentle technique. It is important to ascertain whether the patient has had a previous pelvic examination.

An adolescent should have a pelvic examination if she has had intercourse, if the results of a pregnancy test are positive, if she has abdominal pain, if she is markedly anemic, or if she is bleeding heavily enough to compromise hemodynamic stability. The pelvic examination occasionally may be deferred in young teenagers who have a classic history of irregular cycles soon after menarche, who have normal hematocrit levels, who deny sexual activity, and who will reliably return for follow-up.

Before a first pelvic examination is performed, a brief explanation of the planned examination (which may or may not need to include a speculum), instruction in relaxation techniques, and the use of lidocaine jelly as a lubricant can be helpful. The patient should be encouraged to participate in the examination through voluntary relaxation of the introital muscles or by using a mirror if she wishes. If significant trauma is suspected or the patient finds the examination too painful and is truly unable to cooperate, an examination under anesthesia may occasionally be necessary. The risks of general anesthesia must be weighed against the value of information that would be obtained by the examination.

Confidentiality is an important issue in adolescent health care. A number of medical organizations, including the American Medical Association, the American Academy of Pediatrics, and the American College of Obstetrics and Gynecologists, have endorsed adolescents’ rights to confidential medical care. Particularly with regard to issues as sensitive as sexual activity, it is critical that the adolescent be interviewed alone, without a parent in the room. The patient should be asked if she has engaged in sexual intercourse, if she used any method of contraception, and if she feels there is any possibility of pregnancy.

### Follow-up

Arrangements should be made for the ongoing care of patients, regardless of their health status. Patients with no evidence of disease should be counseled regarding health behaviors and the need for routine care. For those with signs and symptoms of a medical disorder, further assessments and a treatment plan should be discussed. The physician must determine whether he or she is equipped to treat a particular problem or whether the patient should be directed to another health provider, either in obstetrics and gynecology or another specialty. If the physician believes it is necessary to refer the patient elsewhere for care, the patient should be reassured that this measure is being undertaken in her best interests and that continuity of care will be ensured.

### Summary

The management of patients’ gynecologic symptoms, as well as abnormal findings and signs detected during examination, requires the full use of a physician’s skills and knowledge and poses challenges to practice the art of medicine in a manner that leads to effective alliances between physicians and their patients. Physicians must listen carefully to what patients are saying about the nature and severity of their symptoms. The art of medical history taking must not be minimized. Physicians also must listen carefully for what patients may not be saying: their fears, anxieties, and personal experiences that lead them to react in a certain manner when faced with what is often, to them, a crisis (the diagnosis of an abnormality on examination, laboratory testing, or pelvic imaging).

Physicians must use their knowledge of gynecology gained through formal education, personal experience, teachers and mentors, and textbooks, always striving to have the latest information about a given problem. Patients often present a unique set of circumstances, medical issues, or combination of diseases. Today, the use of a textbook chapter is only a beginning. Computers have made the world of information management accessible. Physicians must learn to practice evidence-based medicine—based on the very latest of what is known, not just impressions, recollections, or advice of colleagues. Physicians need to search the medical literature to help discover what they do not know. Patients are searching the medical literature, using computer online services to gain access to medical subject talk-groups, research reports, and the same literature read by physicians. Knowledge derived from an evidence base must be applied, using the art of medicine, to interact with patients to maintain health, alleviate suffering, and manage and cure disease.

The practice of gynecology, as with all branches of medicine, is based on ethical principles that guide patient care. These principles and concepts create a framework for ethical decision making that applies to all aspects of practice:

- **Autonomy**: a person's right to self-rule, to establish personal norms of conduct, and to choose a course of action based on a set of personal values and principles derived from them
- **Beneficence**: the obligation to promote the well-being of others
- **Confidentiality**: a person's right to decide how and to whom personal medical information will be communicated
- **Informed Consent**: a binding agreement between two or more parties for the performance of some action
- **Fiduciary Relationship**: a relationship founded on faith and trust
- **Informed Consent**: the patient's acceptance of a medical intervention after adequate disclosure of the nature of the procedure, its risks, and benefits, and alternatives
- **Justice**: the right of individuals to claim what is due them based on certain personal properties or characteristics
- **Maleficence**: the act of committing harm (nonmaleficence obliges one to avoid doing harm)

### Patient and Physician

Health care providers fulfill a basic need—to preserve and advance the health of human beings. Despite the challenges imposed by the commercial aspects of the current medical environment, for most physicians, the practice of medicine remains very much a "calling," a giving of oneself to the greater good. Although much of medicine is contractual in nature, it cannot be understood in only those terms: "The kind of minimalism that a contractualist understanding of the professional relationship encourages produces a professional too grudging, too calculating, too lacking in spontaneity, too quickly exhausted to go the second mile with his patients along the road of their distress" (1). There is a relationship between physician and patient that extends beyond a contract and assumes the elements of a fiduciary relationship—a covenant between parties. The physician, having knowledge about the elements of health care, assumes a trust relationship with the patient whereby her interests are held paramount. Both the patient and the physician have rights and responsibilities in this relationship, and both are rewarded when those rights and responsibilities are upheld. Confidentiality and informed consent are two expressions of that trust or covenantal relationship.

### Confidentiality

The patient seeking assistance from a health professional has the right to be assured that the information exchanged during that interaction is private. Privacy is essential to the trust relationship between doctor and patient. Discussions are privileged information. The right to privacy prohibits a physician from revealing information regarding the patient unless the patient waives that privilege. Privileged information belongs to the patient except when it impinges on the legal and ethical rights of institutions and society at large, regardless of the setting. In a court situation, for example, physicians cannot reveal information about their patients unless that privilege is waived by the patient. If privilege is waived, the physician may not withhold such testimony.

The privilege of privacy must be maintained even when it does not seem intrinsically obvious. A patient's family, friend, or spiritual guide, for example, has no right to medical information regarding the patient unless the patient specifically releases it. This may seem obvious but often can be overlooked, such as when a health care giver receives a call from a concerned parent, spouse, or relative inquiring about the status of a patient. The response may be a natural attempt to reassure and inform a caring individual about the patient's status. However, for her own reasons, the patient may not want certain individuals informed of her medical condition. Thus, confidentiality has been breached. It is wise to ask patients about who may be involved in decision making and who may be informed about their status. If a health care giver is unclear of the patient's wishes regarding the person requesting information, the reply should indicate that the patient's permission is necessary before discussing her status. Finally, when trying to contact individual patients for follow-up of medical findings, it is never appropriate to reveal the reason to an individual other than the patient.

### Record Keeping

Health care professionals are part of a record-keeping organization. Those records are used for multiple purposes in medicine and are a valuable tool in patient care. Unfortunately, there is an increasing tendency for ancillary organizations to collect, maintain, and disclose information about individuals to whom they have no direct connection (2). Given the present lack of universal and nondiscriminatory access to health insurance in the United States, physicians must be aware of this practice and its ramifications. Patients sign a document, often without understanding its meaning, upon registering with a health care institution or insurance plan. That document waives the patient's privilege to suppress access and gives access to the medical record to insurers and often other health care providers who request it. The consequences of such disclosure for patients can be significant in terms of insurance coverage and potential job discrimination (3). This concern must be weighed against the need for all health care providers involved with an individual to be informed about past or present diseases or activities that may interfere with or complicate management. The use of illegal drugs, a positive human immunodeficiency virus (HIV) test result, and even a history of cancer or psychiatric illness are all exceptionally important to health care providers in evaluating individual patients. When revealed to outside institutions, however, these factors may affect the patient's ability to obtain and keep medical coverage, insurance, or even credit. It is axiomatic that everything that is written in a patient's record should be important to the medical care of that patient and that extrinsic information should be avoided. Furthermore, it is appropriate for physicians to discuss with patients the nature of medical records and their release to other parties so that patients can make an informed choice about such release. Additional guidelines from the Department of Health and Human Services (DHHS) to protect the security of patient records, known as the Healthcare Information Privacy and Protection Act (HIPPA), will translate into additional requirements for access to these records for clinical research as well as guidelines for electronic medical records protections. The security of medical
Informed Consent

Informed consent is a process that involves an exchange of information directed toward reaching mutual understanding and informed decision making. Ideally, informed consent should be the practical manifestation of respect for patient preferences (autonomy) \(^{(5,6)}\). Unfortunately, an act of informed consent is often misunderstood as procurement of a signature on a document. Furthermore, the intent of the individual involved in the consent process often is the protection of the physicians from liability. Nothing could be further from either the legal or ethical meaning of this concept. Informed consent is a conversation between physician and patient that teaches the patient about the medical condition, explores her values, and informs her about the reasonable medical alternatives. Informed consent is an interactive discussion in which one participant has greater knowledge about medical individuals and the other is a patient and circumstance regarding the individual’s valued consent. For example, if the prevailing standard for decision making does not require an arduous lecture on the medical condition or extensive examination of the patient’s psyche, it does require adjustment of the information to the educational level of the patient and respectful elicitation of concerns and questions. It also requires acknowledgement of the various fears and concerns of both parties. Fear that the information may frighten patients, fear of hearing the information by the patient, lack of ability to decode technical information, and inability to express lack of comprehension are among the many barriers facing physicians and patients engaging in this conversation. Communication skills are part of the art of medicine and observation of good role models, practice, and good intent can help to instill this ability in physicians \(^{(7)}\).

Autonomy

Autonomy is not respect for a patient's wishes against good medical judgment. Consider the example of a patient with inoperable, advanced-stage cervical cancer who demands surgery and refuses radiation therapy. The physician's ethical obligation is to seek the best for the patient's survival (beneficence) and avoid the harm (maleficence) of surgery, even though that is what the patient wishes. Although physicians are not obligated to offer treatment that is of no benefit, the patient does have the right to refuse treatment if it does not fit into her values. Thus, this patient could refuse treatment for her cervical cancer, but she does not have the right to be given any treatment she wishes.

Surrogate Decision Makers

If the ability to make choices is diminished by extreme youth, mental processing difficulties, extreme medical illness, or loss of awareness, surrogate decision making may be required. In all circumstances, the surrogate must make every attempt to act as the patient would have acted \(^{(9)}\). The hierarchy of surrogate decision makers is specified by statutory law in each state and differs slightly from state to state. For adults, the first surrogate decision maker is a court-appointed guardian if one exists and second is a durable power of attorney, followed by relatives by degree of presumed familiarity (e.g., spouse, adult children, parents).

For children, parents are the surrogate decision makers, except in circumstances in which the decision is life-threatening and might not be the choice a child would make later, when adult beliefs and values are formed. The classic example of this is the Jehovah's Witness parents who refuse life-saving transfusions for their child \(^{(10)}\). Although this case is the extreme, it illustrates that the basic principle outlined for surrogate decision making should also apply to parents. Bias that influences decision making (in protection of parental social status, income, or systems of beliefs) needs to be considered by physicians because the potential conflict may lead parents to decisions that are not in the best interest of the child. If there is a conflicting bias that does not allow decisions to be made in the best interest of the child or that involves a medical threat to a child, legal action to establish guardianship (normally through a child protective agency) may be necessary. This action can destroy not only the patient (child)--physician relationship but also the parent–physician relationship and may affect the long-term health and well-being of the child, who must return to the care of the parents. Such decisions should be made only after all attempts to educate, clarify, and find alternatives have been tried.

The legal age at which adolescents may make their own decisions regarding their health care varies by state \(^{(11)}\). However, there is a growing trend to increase the participation of adolescents who are capable of decision making in decisions about their health care. Because minors often have developed a value system and the capacity to make informed choices, their ability to be involved in decisions should be assessed individually rather than relying solely on the age criteria of the law and their parents' views.

A unique area for consideration of informed consent is in the international context, either conducting care or clinical research in foreign settings or caring for individuals from other countries with widely differing viewpoints regarding the individual’s valued consent. For example, if the prevailing standard for decision making by a woman is that her closest male relative makes it for her, how is that standard accommodated within our present autonomy-based system? In international research, these issues have presented major concerns when women were assigned to placebo or treatment groups and consent was accepted from male relatives \(^{(12)}\).

Furthermore, the coercive effect of access to health care through clinical trials when no other access to health care is available creates real questions about the validity and freedom of choice for participants in these studies \(^{(13)}\). Guidelines for limiting coercion and ensuring the ability to choose participation in research are being developed for international research. However, it is important to recognize that these same issues exist in a microcosm when caring for patients from certain cultures and foreign countries in daily practice. Ensuring that the patient can make the choice herself or freely chooses to have a relative make it for her remains an important element of informed consent between individual physicians and individual patients.

Beneficence and Nonmaleficence

The principles of beneficence and nonmaleficence are the basis of medical care—the “to do good and no harm” of Hippocrates. However, these issues are often clouded by other decision makers, consultants, family pressures, and sometimes financial constraints or conflicts of interests. Of all the principles of good medical care, benefit is the one that continually must be reassessed. Simple questions often have no answers. What is the medical indication? How does the proposed therapy address this issue? How much will this treatment benefit the patient? How much will it extend the patient's life? Furthermore, when confronted with multiple medical problems and consultants, physicians should ask how much treatment will be of benefit given all the patient's problems (e.g., failing kidneys, progressive cardiomyopathy, HIV-positive status, and respiratory failure) rather than necessarily attempting intubation and respiratory support to treat the immediate problem.
The benefit or futility of the treatment, along with quality-of-life considerations, should be considered in all aspects of patient care. It is best to weigh all of the relevant issues in a systematic fashion. Some systematic approaches depend on a sequential gathering of all the pertinent information in four domains: medical indications (benefit and harm), patient preferences (autonomy), quality of life, and contextual issues (justice) (5). Other approaches identify decision makers, followed by facts, and then ethical principles. It is important for physicians to select an ethical model of analysis with which to practice so that, when faced with troubling and complex decisions, a system is available to help clarify the issues.

Medical Futility

The essence of good medical care is to attempt to be as clear as possible about the outcomes of the proposed interventions. If the proposed intervention (e.g., continued respiratory support or initiating support) has a very low or highly unlikely chance of success, intervention might be considered futile. Physicians have no obligation to continue or initiate therapies of no benefit (14). The decision to withdraw or withhold care, however, is one that must be accompanied by an effort to ensure that the patient or her surrogate decision maker is educated about the decision and agrees with it. Other issues, such as family concerns, can and should modify decisions if the overall well-being of the patient and of the family is best served. For example, waiting (within reason) to withdraw life support may be appropriate to allow a family to reach consensus or a distant family member to see the patient for a last time.

Quality of Life

Quality of life is a much used, often unclear term. In the care of patients, quality of life is the effect of therapy on the patient's experience of living based on her perspective. It is perilous and wholly speculative to assume that physicians know what quality of life represents for a particular patient judging from a personal reaction. It is instructive, however, to attempt to guess what it means and then seek the patient's perspective. The results may be surprising. For example, when offered a new drug for ovarian cancer, a patient might prefer to decline the treatment because the side effects may not be acceptable even when there may be a reasonable chance that her life may be slightly prolonged. In some instances, the physician may not believe that further treatment is justified but the patient finds joy and fulfillment in preserving her existence as long as possible.

Controversy exists regarding whether currently available quality-of-life measurement systems will provide information to help patients make decisions (15). Information from quality-of-life studies might be judged by criteria that include whether the measured aspects of the patient's life were based on the patient's views or the physician's clinical experience (16). Informing patients of others' experiences with alternative treatments may help in their decision making, but it is never a substitute for the individual patient's decision.

Professional Relations

Conflict of Interest

All professionals have multiple interests that affect their decisions. Contractual and covenantal relationships between physician and patient are intertwined and complicated by health care payers and colleagues, which creates considerable pressure. The conflict with financial considerations directly influences how patients' lives are affected, often without their consent. Rennie (17) described that pressure eloquently: "Instead of receiving more respect (for more responsibility), physicians feel they are being increasingly questioned, challenged, and sued. Looking after a patient seems less and less a compact between two people and more a match in which increasing numbers of spectators claim the right to interfere and referee." An honest response to this environment is for the physician to attempt to protect his or her efforts by assuming that the physician–patient relationship is contractual, and only contractual, in nature. This allocation of responsibility and authority for the contract precludes the existence of the covenantal relationship between the physician and patient. For example, a contract, insurance, or managed care plan may discourage referral to a more knowledgeable specialist, removing the physician's responsibility. Thus, the contract establishes the extent of the physician–patient relationship. All health care providers must decide whether they will practice within a covenantal or contractual relationship and whether the relationship they develop remains true to this decision. In either setting, a reasonable perception of that relationship is "one that allows clients as much freedom as possible to determine how their lives are affected as is reasonably warranted on the basis of their ability to make decisions" (18).

Health Care Payers

An insurance coverage plan may demand that physicians assume the role of gatekeeper and administrator. Patients can be penalized for a lack of knowledge about their future desires or needs and the lack of alternatives to address the changes in those needs. Patients are equally penalized when they develop costly medical conditions that would not be covered if they moved from plan to plan. These situations often place the physician in the position of being the arbiter of patients' coverage rather than acting as an advocate and adviser. It is an untenable position for physicians because they often cannot change the conditions or structure of the plan but are made to be the administrators of it.

In an effort to improve physician compliance with and interest in decreasing costs, intense financial conflicts of interest can be brought to bear on physicians by health care plans. If a physician's profile on costs or referral is too high, he or she might be excluded from the plan, thus decreasing his or her ability to earn a living or to provide care to patients with whom a relationship has developed. Conversely, a physician may receive a greater salary or bonus if the plan makes more money. The ability to earn a living and to see patients in the future is dependent on maintaining relationships with various plans and other physicians. These are compelling loyalties and conflicts that cannot be ignored (19,20 and 21).

These conflicts are substantially different from those of older fee-for-service plans, although the ultimate effect on the patient can be the same. In fee-for-service plans, financial gain may result in failure to refer a patient, or referral is restricted to those cases in which the financial gain is derived by return referral of other patients (22). Patients may be unaware of these underlying conflicts, a situation that elevates conflict of interest to an ethical problem. A patient has a right to know what her plan covers, to whom she is being referred and why, and the credentials of those to whom she is referred. The reality is that health care providers make many decisions under the pressure of multiple conflicts of interest. Physicians are potentially caught between self-interest and professional integrity. Whether it is the more blatant lying about indications for a procedure in order to receive reimbursement or a more subtle persuasion to sign up for a certain protocol because of points earned for a study group, the outcome for individual and society's relationship with health care providers is damaged by failure to recognize and specifically address conflicts of interest that impede decision making (23). Focusing clearly on the priority of the patient's best interest and responsibly rejecting choices that compromise the patient's needs are ethical requirements.

Institutions, third-party payers, and legislatures have avoided accountability for revealing conflicts of interest to those to whom they offer services. The restrictions of health care plans are never placed in an equally prominent a position as the coverage. The coverage choices can be quite arbitrary, and there is rarely an easily accessible and usable system for challenging them. The social and financial conflicts of interest of these payers can directly affect the setting and nature of the relationship between physician and patient. To deal with ambiguous and sometimes capricious decision making, revelation of the conflicts of interest and accountability for choices should be demanded by physician and patient (24).

Legal Problems

Abuses of the system (e.g., referral for financial gain) have led to proposals and legislation, often referred to as Stark I and II, affecting physicians' ability to send patients to local laboratories and facilities in which they have a potential for financial gain. Although there have been clearly documented abuses, the same legislation would affect rural clinics and laboratories in which the only capital available is obtained through the rural physicians. States vary on the statutory legislation regarding this issue. Regardless of the laws, however, it is ethically required that financial conflicts of interest be revealed to patients (25,26,27 and 28).

Another abuse of the physician–patient relationship caused by financial conflicts of interest is fraudulent Medicare and Medicaid billings. This activity resulted in the Fraud and Abuse Act of 1987 (42. U.S.C. at 1320a–7b), which prohibits any individual or entity making false claims or soliciting or receiving any remuneration in cash or any kind, directly or indirectly, overtly or covertly, to induce a referral. Indictments under these laws are felonies, with steep fines, jail sentences, and loss of the license to practice medicine. Physicians should be aware of the legal ramifications of their referral and billing practices (29,30).

Harassment

The goal of medicine is excellence in the care of patients and, often, research and education that will advance the practice of medicine. Thus, everyone involved in the process should be able to pursue the common goal on equal footing and without harassment that interferes with employees’ or colleagues’ ability to work or be equally promoted in that environment. Every office and institution must have written policies on discrimination and sexual harassment that detail inappropriate behavior and state specific steps to be taken to correct an inappropriate situation. The legal sanction for this right is encoded in both statutory law through the Civil Rights Act of 1964 [42 U.S.C.A. at 2000e–2000e–17 (West 1981 and Supp. 1988)] and reinforced with judicial action (case or precedential law) by state and U.S. Supreme Court decisions. In particular, charges of sexual harassment can be raised as a result of unwelcome sexual conduct or a hostile workplace (such as areas of medicine that have been known for antifeminist attitudes in the past). As stated in one legal case, “a female does not assume the risk of harassment by voluntarily entering an abusive, antifemale environment” (Barbetta v. Chemlawn Service Co., 669 F. Supp. 569, WDNY, 1989). The environment must change; it is not acceptable to expect the men or women to adapt because “they knew what it would be like.” The tension in the legal debate regarding harassment (sexual, racial, disability) always hinges on the weight of protection of free speech and the right of the individual to equality and a nonhostile work environment.

**Stress Management**

There is little doubt that the day-to-day stress of practicing medicine is significant. Besides the acknowledged stress of the time pressures and responsibility of medicine, the current health care environment has had a detrimental effect on physicians’ job security, with concurrent health risks (30). Stress takes a toll not only on cardiac function (31) but also on the practice of medicine and life outside of medicine (32).

Responding to stress through drug or alcohol abuse increases overall health and marital problems and decreases effectiveness in practice. In a long-term prospective study of medical students, individuals with high-risk (e.g., volatile, argumentative, aggressive) temperaments have been shown to have a high rate of premature death (particularly before 55 years of age) (33). Adequate sleep, reasonable working hours, exercise, and nutritional balance have been shown to be directly related to decreases in psychological distress (33). Simple relaxation training has been shown to decrease gastroesophageal reflux in response to stress (35).

The pace that physicians maintain has a seductive quality that can easily mask the need for stress reduction by means of good health practices, exercise, and relaxation training. The answer to increased stress is not to work harder and extract the time to work harder from the relaxing and enjoyable pursuits that exist outside medicine. The outcome (in terms of psychological and physical optimal functioning) of that strategy is in neither the physician’s nor the patient’s best interest. Both the welfare of the patient and the welfare of the physician are enhanced by a planned strategy of good health practices and relaxation. Furthermore, such a strategy is important to all members of the health care team. By providing such leadership, physicians can contribute to a better work and health care environment for everyone.

**Society and Medicine**

**Justice**

Some of the ethical and legal problems in the practice of gynecology relate to the fair and equitable distribution of burdens and benefits. How benefits are distributed is a matter of great debate. There are various methods of proposed distribution:

- Equal shares (everyone has the same number of health care dollars per year)
- Need (only those people who need health care get the dollars)
- Queuing (the first in line for a transplant gets it)
- Merit (those with more serious illnesses receive special benefits)
- Contribution (those who have paid more into their health care fund get more health care)

Each of these principles could be appropriate as a measure of just allocation of health care dollars, but each will affect individual patients in different ways. Only recently has just distribution become a major issue in health care. The principles of justice apply only when the resource is desired or beneficial and to some extent scarce (36).

The traditional approach to medicine has been for practitioners to accept the intense focus on the individual patient. However, the current changes in medicine will alter the focus from the patient to a population (37)—“in the emerging medicine, the presenting patient, more than ever before, will be a representative of a class, and the science that makes possible the care of the patient will refer prominently to the population from which that patient comes.” Physicians are increasingly bound by accumulating outcomes data (population statistics) to modify the treatment of an individual in view of the larger population statistics. If, for example, the outcome of liver transplantation is only 20% successful in a patient with a certain set of medical problems, that transplant may instead be offered to someone who has an 85% chance of success. Theoretically, the former individual might have a successful transplant and the procedure might fail in the latter, but population statistics have been used to allocate scarce resources. The benefit has been measured by statistics that predict success, not by other forms of justice allocation by need, queuing, merit, or contribution. This approach represents a major change in the traditional dedication of health care to the benefits of individual patients. With scarce resources, the overall benefits for all patients are considered in conjunction with the individual benefits for one patient.

There has always been an inequity in the distribution of health care access and resources. This inequity has not been seen by many health care providers who do not care for those patients who are unable to gain access, such as those who lack transportation or live in rural areas or where limits are imposed by lack of health care providers, time, and financial resources. Social discrimination sometimes leads to inequity of distribution of health care. Minorities are less likely to see private physicians or specialists, regardless of their income or source of health care funding (38,39) and 40). Thus, health care is rationed by default.

Health care providers must shift the paradigm from the absolute “do everything possible for this patient” to the proportionate “do everything reasonable for all patients” (41). To reform the health care system requires not just judicial, legislative, or business mandates but also attention to the other social components that can pose obstacles to efforts to expand health care beyond a focus on individual patients.

**Health Care Reform**

The tension between understanding health as an inherently individual matter (in which the receipt of health care is critical to individual well-being) and as a communal resource (in which distribution of well-being throughout society is the goal) underpins much of the political and social debate surrounding health care reform (41). The questions of health care reform are: What is the proper balance between individual and collective good? and Who will pay for basic health care? Because much of health care reform requires a balancing of competing goals, legislation should specifically address how this balance can be achieved. The role of government would be the following:

- Regulating access of individuals to health care
- Regulating potential harms to the public health (e.g., smoking, pollution, drug use)
- Promoting health practices of benefit large populations (e.g., immunization, fluoridation of water)

Decisions regarding both the amount and distribution of resources are often made by health care payers, not individual providers. The health insurance industry determines what are “reasonable and customary” charges and what will be covered. The government decides (often with intense special-interest pressure) what will be covered by Medicare and Medicaid (42,43). These decisions directly affect patient care. For that reason, health care providers cannot ethically remain silent when the health and well-being of their individual patients and their communities are adversely affected by health care reform decisions. Health care providers should assess proposed reforms in light of their value to the community and to individual patients and then formulate their own criteria for judging proposals for health care reform (44,45,46, and 47). Furthermore, initiation and support of research focused on the outcomes of care delivered by gynecologists (financial aspects, quality-of-life measures, survival, morbidity, and mortality) will allow the discipline to have a real voice in determining what choices are made for health care for women.

**References**

For more than 20 years, the need to maintain or increase the quality of health care while controlling its cost has stimulated a great deal of interest and activity in quality assessment and performance improvement. A report from the Institute of Medicine (IOM) on patient safety has generated intense public interest and concern about the high estimated number of preventable deaths caused by medical errors (1). Although the conclusions of this report are controversial, it raises fundamental and disturbing questions about health care quality and performance.

The annual United States per capita expenditure for health care (in constant dollars) had risen steadily from about $950 in 1970 to about $3,400 in 1992 (about 12% increase per year). Although efforts in the 1990s to “manage” care and its costs were reasonably successful in slowing annual health care cost increases, they have recently been returning to double digits. Currently, annual United States per capita expenditure is estimated to exceed $4,500 (about 3.2% increase per year since 1992). The “political” failure and public distrust of 1990s-style managed care has resulted in predictions of its demise despite well-documented economic success (2). Before the mid-1990s, much of the increase in health care costs had been shifted from individuals to state and federal governments and to employers (Fig. 3.1). More recently, employers have been setting limits on their contributions to health care benefits and shifting more of the increased costs to their employees. Currently, the United States spends more on health care (about 14% of gross domestic product) than on education and defense combined. Despite this enormous outlay of resources, there is concern about the overall quality of health care (3,4). The health status of U.S. residents (in terms of life expectancy, neonatal mortality, and rates of illness and disability) is poorer than that of people living in most European and Scandinavian countries, the United Kingdom, Japan, and Canada, although these countries spend far less per capita on health care. Quality improvement programs in other industries have shown that management methods can both increase quality and reduce costs. Because of concerns about quality, cost, and safety, patients, as well as private and public third-party payers, are demanding ongoing quality assessment and performance improvement programs in health care delivery systems.

Figure 3.1 Sources of spending in U.S. health care, 1960–1990. Note that third-party payment steadily replaced direct payment during this interval. After a long decline, out of pocket spending is expected to rise. (Data from U.S. Congressional Budget Office, 1992).

Quality Assurance

The medical profession traditionally has focused its efforts on assessing and improving the quality of health services through internal, self-imposed, retrospective peer review. Examples of such mechanisms are morbidity and mortality (M&M) conferences, medical society-sponsored and state-legislated peer-review programs, surgical case reviews (tissue committees), and the specialty board certification processes. These programs review adverse occurrences retrospectively (e.g., assessment of medical and surgical complications and review of misdiagnoses). Although useful as part of the peer-review process, these quality assurance (QA) programs are not aimed at prevention of errors and are not designed to assess and improve the effectiveness of health care services and procedures (5).

The differences between traditional QA programs and newer performance improvement and quality management programs, such as continuous quality improvement (CQI) or total quality management (TQM), are presented in Fig. 3.2. QA programs are designed to identify and eliminate the small percentage of substandard care represented on the left side of the normal curve (the “bad apple” approach). Most “standard” care occurs in the middle of the curve, however, and is the focus of newer programs like CQI. Such programs are designed to study prospectively the processes of care based on need and to improve outcomes by the reduction of unintended variation (6). The right side of the curve represents state-of-the-art practice usually performed under protocols at universities and other large centers of excellence that are monitored by institutional review boards and national research groups such as the National Cancer Institute and the Gynecologic Oncology Group. As more emphasis is placed on quality management programs in health care, innovations should come from both traditional research and performance improvement efforts.
Quality means different things in different situations. The concept of quality in products (e.g., consumer goods and state-of-the-art machinery) is different than that of complex services (e.g., health care delivery to people). However, many of the principles of quality assessment and improvement that have been shown to improve the quality of consumer goods and services can also be applied to the evaluation and improvement of health services. There are certain principles of quality assessment that should be considered when attempting to measure and improve health care quality.

**Efficacy, Effectiveness, and Efficiency**

*Efficacy and effectiveness* are similar terms that are often used interchangeably to describe evaluations of outcomes of health care services and procedures. As defined by the Institute of Medicine, *efficacy* refers to what an intervention or procedure can accomplish under ideal conditions and when applied to appropriate patients (19). *Effectiveness* refers to the actual performance in customary practice of an intervention or procedure. An example of this difference is the theoretical success rate (efficacy) of oral contraception used for one year (99% successful at preventing pregnancy) versus the actual or use-rate, effectiveness, usually reported to be 93% to 97%. Most health care decisions have been based on efficacy rates obtained from controlled clinical trials rather than the actual effectiveness of such decisions. One of the major challenges for quality assessment and management programs is to develop and use measurements that reflect the actual, or real-life, success rates of treatment options so that evidence-based decision making can replace authority-based decision making. Also, strategies need to be developed to improve patient compliance rates in order to increase the likelihood that the actual effectiveness is as close as possible to theoretical efficacy (13).

*Efficiency* describes the relative “waste” or resource use (complications and costs) of alternative effective interventions. To realize meaningful improvements in health services, health professionals and organizations must develop more efficient interventions (e.g., medical therapy or expectant management versus surgical treatment for abnormal bleeding) when appropriate. The goal of health care quality improvement is optimal value. *Value* is defined as quality divided by the cost, or as the quotient of outcomes (benefits) divided by resources used:

\[
\text{Value} = \frac{\text{outcomes}}{\text{resource use}}
\]

**Optimal versus Maximal Care**

The assessment of the quality of health care depends on whether the goal of the system is to provide maximally effective or optimally effective care (14). Figure 3.3 shows a theoretical representation of the difference between maximally effective health care (Point B), in which every conceivably intervention is offered regardless of cost to those who can afford it, and optimally effective health care (Point A), in which resources are used in a manner that will provide the most good for as many people as possible. Maximized health care emphasizes individual intervention, whereas optimized care emphasizes public health care and prevention. When optimal health care becomes the goal of a health care system, conflicting individual and societal needs must be resolved.

Assessing Outcomes

A widely accepted system for assessing the quality of health care is based on the measurement of indicators of structure, process, and outcome (15). Structure includes the resources, equipment, and people who provide health care. Process is the method by which a procedure or course of action is executed. Outcome includes the complications, adverse events, and short-term results of interventions, as well as the patient's health status and
health-related quality of life after treatment, which reflects the effectiveness of the intervention.

Evaluation of health care structure involves the assessment of the stable and tangible resources needed to provide care, such as safe and adequately sized operating rooms and properly functioning equipment. Other examples of structural elements include the aspects of the medical staff's qualifications, such as school accreditation, licensure, continuing medical education credits, and specialty board certification. Although these elements form the foundation of a health care organization or system, there is a weak correlation between structural assessment and other measures of the quality of care, such as clinical outcomes (16).

Therefore, many health services researchers believe that organizations need to measure clinical outcomes directly (including not only death and short-term morbidity but also disability and health-related quality-of-life issues) if they hope to improve both the effectiveness and efficiency of health care delivery. Their research also emphasizes measurement of clinical or health outcomes that are defined as those that patients can experience and value without the interpretation of a health care provider. Examples of clinical or health outcomes and their corresponding intermediate or surrogate end points are presented in Table 3.1. Ultimately, longevity and quality-of-life factors may be the only relevant outcomes of health care.

### Table 3.1. Clinical and Health Outcomes and Their Corresponding Intermediate or Surrogate Endpoints: Some Examples

| In the past, traditional quality assessment programs have tended to focus on the assessment of short-term risks and the confirmation of pathologic diagnoses. This effort has usually been limited to quantification of mortality and major morbidity—such as infection, blood transfusion, and reoperation—occurring while the patient was hospitalized and verified by tissue diagnosis. Most standardized lists of clinical QA indicators are from the medical model of outcomes assessment. Although the importance of these kinds of indicators seems obvious, many of these indicators may have little or no relevance to the more fundamental question of actual effectiveness of a procedure in terms of preserving or enhancing quality of life. For example, if a patient with pelvic pain undergoes a hysterectomy for leiomyomas, experiences no short-term complications, and has a diagnosis that is confirmed histologically, the procedure may be considered successful from the standpoint of surgical risk management, short-term outcome, and histologic verification. However, if the patient continues to experience pain and has no improvement in the quality of her life, the surgery has been, in reality, unsuccessful. Short-term risk indicators often have little or no bearing on whether the procedure actually works. | Efforts to measure the success or the effectiveness of health care procedures in the United States are based on the traditional medical model in which a patient is evaluated for a symptom, diagnosed as having a condition, and treated for that condition. A procedure is usually considered successful if the diagnosis is confirmed. Medicine has traditionally relied on short-term risk indicators and histologic confirmation because these measurements seem more objective and quantifiable. Death and infection rates, blood loss, and rates of histologic verification can all be measured and expressed numerically. Crucial to the application of a more predictive behavioral model in clinical outcomes research are several statistically valid and reliable methods to measure health-related quality of life. Many measures have been developed and validated, but few are used in clinical practice (17). Using the behavioral model of effectiveness, the concept of quality-adjusted life-years (QALY) has been proposed to measure the benefit, in both quantity and quality of life, of a health care procedure (19). The number of QALYS is determined by combining the extra years of life that a procedure offers with a validated measure of eight categories of disability and four measures of distress. The use of this methodology allows standardized comparison of the cost of entirely different health care procedures. Despite its inadequacies, the medical model has been the standard, but the behavioral model of outcomes is now becoming incorporated into health care evaluation and research (19). Scales of health-related quality-of-life issues, called the SF-36 and the SF-12 (short form 36 and short form 12, the health-status tool derived from the RAND Medical Outcomes Survey), have been developed (20). | Most methods for the assessment of the quality of health care and the delivery of health services have been based on the premise that quality is the sole responsibility of the health care practitioner. Because the practitioner's technical skills, knowledge, and interpersonal interactions are the basis for quality of patient care and its delivery, many regulatory agencies [e.g., the Joint Commission on the Accreditation of Health Care Organizations (JCAHO)] and hospitals have created traditional QA models that focus mostly on the practitioner. However, quality of care is determined by many interacting forces, and the practitioner clearly does not deliver care in isolation. The delivery of health care requires the integration and management of many processes. The practitioner's ability to deliver care is influenced by the environment, the ability and skill of support staff, policies and procedures, facilities, governing processes, methods of work, and equipment and materials available, as well as innumerable patient variables such as severity of illness, concurrent illness (comorbidity), and social support. Historically, QA efforts attempted to monitor these processes to document bad outcomes. However, this approach has not proved to be adequate in improving the quality of care (21). Regulatory agencies and hospitals are now focusing on the overall performance of health care organizations in terms of clinical or health outcomes. Performance improvements in health care have been based on knowledge that physicians and other health care professionals acquired in medical and other professional schools. Improvements have been brought about by clinicians applying knowledge developed by discipline-specific experts (22). The recent national emphasis on health care reform is an indication that the past rate of improvements is not sufficient to meet the financial needs and expectations of society. Performance improvements in efficiency must be made at a faster pace because consumers are seeking greater value for and access to health care services. A theoretical basis for organizational change that promotes continuous improvement includes knowledge of a system, knowledge of variation, and the theory of knowledge (23,24). | The first component of continuous performance improvement is knowledge of a system. A system is defined as a network of interdependent components that work together to accomplish its aim. A system does not exist without an aim and is only capable of improving if there is a connection between the aim, the means of production, and the means of improving. An open system is one that permits continued access from outside the system. Because health care organizations are accountable to patients and to the community as a whole, they are considered open systems. The aim of an organization involves the integration of the knowledge of the social needs and the needs of patients. Knowledge of a system includes the following aspects: Customer knowledge. This is the basis of an organization's aim. The aim is derived by identifying the organization's customers and by understanding the measures used to judge quality. Meeting patient expectations is one of the most accurate ways to define quality. How the organization provides its services. This is the means of producing a service, which involves knowledge of what is delivered, the processes or steps taken
to deliver the services, the information and materials used to provide services, and the suppliers.

How the organization improves what it delivers. This involves knowledge of the aim and identification of areas for improvement that are likely to have the greatest impact.

Understanding the interrelationships between the aim, the customers, the primary areas for improvement, and the specific processes that can be improved is known as systems thinking. When a health care organization is focused on providing as many services as possible without consideration for the needs of the community and their customers, it will eventually fail to deliver quality services. Proper perspective for customer needs and preferences gained through a process called strategic planning may even lead to a competitive advantage for a health care organization (25).

Knowledge of Variation

Another element of continuous improvement is knowledge of variation. Variation is present in every aspect of our lives. Variation is inherent to everyone's behavior, learning styles, and ways of performing a task. Although the presence of variation, or uniqueness, can be considered a kind of quality, most services are judged on the basis of predictability and a low level of variation. When a service is thought to be of high quality, we expect it to be exactly the same each time, and if there is to be any variation, it must be better.

To improve health products and services continually, it is necessary to know the customers, their needs, and how they judge the quality of health services. The processes by which health services are delivered must be understood and unintended variations reduced. If an organization is to improve and be innovative, it must plan changes that are based on knowledge of what can be better. Two types of variation found in production processes are those that occur by chance (common cause) and those due to assignable causes (special causes) (26). The ability to differentiate between these two types of variation is essential to making improvements in health care.

Clinicians regularly make decisions in their practices based on variation. For example, a physician making frequent rounds may note a change in a patient's temperature and may decide to treat or to observe the patient based on the temperature change and on experience (i.e., judgment). If the temperature variation is seen as special cause (i.e., infection), a decision may be made to add an antibiotic. However, if the change or variation is interpreted as common cause variation in temperature due to short-term, normal changes or chance, it may be ignored. If this happens often, the physician may alter the frequency of observation, thereby making an improvement to the monitoring process. Frequently, however, common cause variation is not recognized in health care, and the variation is acted on prematurely, resulting in the overuse of resources and a lower quality of care (27). If the approach is to measure and change, too many costly changes might be made.

Learning how to respond appropriately to variation in health care processes is a major challenge. Understanding and controlling variation in health care services should be the main emphasis of quality management. The notion of controlling variation, however, causes concern and skepticism in many health care professionals. Physicians who fear any effort to control variation are worried about the loss of options and about restrictions on their judgment. As Berwick points out (7), however, "The (problem) is not considered, intentional variation, but rather unintended or misinterpreted variation in the work of health care. Unintended variation is stealing health care blind today. In controlling it, the health care system could potentially recover a bounty in wasted resources that would dwarf the puny rewards of cost-containment to date."

Variation in Utilization

One of the earliest and most compelling influences on modern health care quality assessment in the United States was a series of investigations that demonstrated a wide variation in the use of health care procedures (27). Although previous investigations had documented a twofold to fourfold difference in the rates of selected procedures both within the United States and between the United States and other industrialized countries, these variations usually were disregarded as secondary to population differences. However, a small-area analysis documented similar or even greater magnitudes of variation within small (25 to 50 miles) geographic regions that could not be explained by differences in patient characteristics or appropriate differences in standards of care (28).

Variations in utilization have now been analyzed for virtually all major surgical procedures, including hysterectomy and cesarean delivery (29,30). Also, variation in the performance of medical procedures, such as those used in the management of acute myocardial infarction and sepsis, have been identified (31). On the basis of these analyses, significant variation has been documented in utilization and in important outcomes such as complications, cost, and derived benefit (32). This type of analysis does not usually allow accurate assessment of which rate of utilization or outcome is appropriate. However, it can help to focus attention on the quality of health services and the complexities of using statistically valid methods to measure health care quality.

Variation in utilization of health care services can be categorized as follows:

1. Necessary and intended variation because of well-recognized patient differences such as severity of illness, comorbidity, and legitimate patient preferences
2. Acceptable but reducible variation because of uncertainty and lack of accurate information about outcomes
3. Unacceptable variation because of nonclinical factors, such as habitual differences in practice style, which are not grounded in knowledge or reason

Most of the differences in utilization rates of many health care procedures result from the last two categories.

Variation in Women's Health Care

Overall, the rate of inpatient surgery for females aged 15 to 44 years is more than 3 times that of males, excluding vaginal deliveries. The most commonly performed major surgical procedure in the United States is cesarean delivery, with about 950,000 procedures performed annually in the United States. Rates of cesarean delivery vary by region, state, and small geographic areas. Overall, the rate of cesarean deliveries is 12% to 40%, and the national mean is about 23%. Comparative rates for the United Kingdom are 6% to 12%.

Hysterectomy is the second most frequent inpatient surgical procedure in the United States. The total annual occurrence of hysterectomy for all ages, all indications, and all institutions (federal and nonfederal) in the United States is about 550,000. Hysterectomy rates in the southern and western United States are 50% to 75% higher than those in the Midwest and New England. A twofold to fivefold variation in utilization rates has been documented within states and small geographic areas within the United States (29). National rates in the United States are twice those in the United Kingdom and more than 3 times the rates in Sweden and Norway (33).

Hysterectomy utilization in the United States varies by both provider and patient characteristics. Studies of utilization patterns have demonstrated that older physicians are more likely to recommend hysterectomy than are younger physicians and that (when controlled for age) gender does not appear to influence hysterectomy decision making (33). With respect to patient variables, although hysterectomy utilization is similar among African American women and white women (35,36), low income and low educational level are risk factors for hysterectomy (37). By 65 years of age, the prevalence of hysterectomy is 40% for women with a high school education and 20% for women with a college education.

Short-term outcomes of hysterectomy vary significantly by race. African American women have a substantially higher relative risk (RR) for morbidity and in-hospital mortality (RR = 3.1) compared with age- and condition-matched white women (38). The reasons for this variation are not known. Quality management techniques are being applied to research in an attempt to reduce these wasteful variations.

The Theory of Knowledge

The final component of knowledge for improvement is the theory of knowledge. The theory of knowledge refers to the need for the application of a scientific method for improving performance. One model for testing small-scale change is called the Plan, Do, Study, Act (PDSA) method (24). Unlike the ideal scientific method recommended for clinical trials, the PDSA method does not include a control group. Although randomized controlled trials have been considered to be the best way to determine the value of health care interventions, they have two distinct disadvantages: they are expensive, and they tend to define the efficacy of an intervention such as a drug or a surgical procedure. Because efficacy is the way an intervention works under ideal conditions, compared with effectiveness, which is the way an intervention works in everyday practice, health services researchers now recognize that it may not be possible to generalize about an intervention's effectiveness.
based on its efficacy as measured in a randomized trial. Also, it is too expensive to perform randomized trials in all situations in which the effectiveness of health care services need to be improved.

The PDSA cycle has been modified as the Find a process, Organize a team, Clarify the process, Understand the variation, and Select an improvement (FOCUS). The PDSA cycle has tested FOCUS for application to health care improvements (25). In this model, the P stands for identifying a change that might lead to improvement and then testing the change on a small scale. During this phase, who will do what, when the change will occur, and how the change will be communicated to those who will be affected are detailed. The D stands for doing or implementing the plan (change to the process) and collecting the data. The C stands for checking the data to determine whether the change to the process represents an improvement, and the A stands for acting or incorporating the change into the process if it is found to be an improvement. A new cycle with another change is started if an improvement was not recognized.

Health care organizations are seeking efficient ways to optimize their delivery of and to improve health care services. The notion that high-quality health care automatically means high cost is no longer accepted without question. At a time when many businesses have transformed themselves by using newer methods of quality management, enabling them to deliver high-quality goods and services at reasonable costs, health care professionals and organizations are beginning to test these improvement methods in medical and surgical practice.

**Newer Methods for Improving Performance**

Health services researchers and clinicians are beginning to develop and validate newer methods for the measurement and improvement of health care quality. For example, there is a need to make valid comparisons of quality between divergent populations and to correlate clinical performance with measurable processes of care. The goal of a new branch of investigation called clinical outcomes sciences is to obtain valid measures of relevant outcomes that are correlated with measurable processes of care so that changes in process can be identified, thereby improving outcomes. This discipline incorporates methodologies from divergent areas, such as epidemiology, clinical research, management, engineering, economics, and behavioral sciences.

Statistical adjustments are used to allow clinically dissimilar populations, such as high-risk and low-risk patients and those with complicated and uncomplicated conditions, to be compared. This procedure is called case-mix adjustment and controls for severity of illness and comorbidity (38,40). Outcomes that are assessed include traditional (medical model) measures, such as complications and adverse occurrences, as well as newer, well-validated measures of satisfaction, health, and functional status.

Concurrently, the processes of care are assessed. This would include measurement of resources used during an episode of care (e.g., supplies, medications, specialized personnel) and practice parameters (e.g., physician orders and nursing practices).

Measurement of the processes and outcomes of health care can be prohibitively expensive if this measurement is not integrated into the daily clinical care. For this reason, another goal of clinical quality outcomes research is to develop and incorporate methods of quality assessment into routine practice. This mechanism could be accomplished, for example, by using the SF-36 as a standard nursing intake form at the time of admission.

Analytic methods in clinical outcomes science rely heavily on multivariate statistics and iterative outcomes databases to provide valid correlations between measurable (and changeable) processes and outcomes. However, the mere identification of process changes that would improve outcomes does not ensure that they will, in fact, be used. For this reason, process and outcomes data must be linked to methods that will allow this information to be incorporated into clinical and operational decision making if they are to change behavior and improve outcomes. These analyses must be readily available both geographically and temporally at the point of care (the place and time that the decision is made) if they are to improve outcomes.

One approach to QA, performance improvement, and medical decision making that has been recommended (the PREPARED system) uses a checklist to analyze the value of a health care procedure before it is performed (84,41). The purpose is to review sequentially the critical data categories of information, each represented by a letter in the word PREPARED, that should be used to determine the most appropriate course of action or choice (45).

- **P**: Procedure & the course of action being considered
- **R**: Reason & the indication or rationale
- **E**: Expectation & the chances of benefit and failure
- **P**: Preferences & patient-centered priorities (utilities) affecting choice
- **A**: Alternatives & other reasonable options
- **R**: Risks & the potential for harm from procedures
- **E**: Expenses & all direct and indirect costs
- **D**: Decision & fully informed collaborative choice

Standardized procedural analysis using this sequenced checklist has been shown to improve health care decision making by increasing patient satisfaction and self-efficacy, thereby facilitating patient choice. It has the potential to improve the assessment of the quality and appropriateness of both provider and patient decision making.

**Outcomes Research and Outcome-derived Clinical Guidelines**

In the past, clinical practice guidelines or parameters have been largely derived by expert opinion and consensus. A major goal of clinical outcomes science is to allow for the development of guidelines based on actual measured outcomes that could self-adjust based on performance and newer methods of diagnosis and treatment. One such approach for incorporating outcomes data into clinical practice is the critical pathway–case management method (43). In this method, consensus practice parameters for a given condition (e.g., management of preterm labor) are initially developed by a multidisciplinary team consisting of all professional, allied, and support services involved in the care of the target population. This list of parameters is called a critical path or clinical map. The critical path details all laboratory, dietary, consultative, medical, teaching, and nursing activities that are thought to be necessary to obtain specific clinical outcomes. Outcomes of care, as well as variations from the "path," are monitored and collected continuously.

Positive and negative outcomes are then analyzed and correlated with variances from the critical pathway. These data are then returned to the multidisciplinary team, which recommends changes in the entire path based on the outcomes and variance analyses.

In one pilot study of a critical pathway method for cesarean delivery, length of stay and cost were reduced by 13% and 14%, respectively. Additionally, five of seven measurements of satisfaction, including quality of care, were improved, and health status was unchanged (43). A relatively new federal government agency, the Agency for Healthcare Research and Quality (AHRQ), formerly known as the Agency for Health Care Policy and Research (AHCPPR), is responsible for funding developmental efforts, collecting information about clinical care guidelines, and disseminating information.

**Managed Care**

Measuring and improving health care quality and performance have received progressively greater support and validation. Health care reform activity and rapidly changing reimbursement patterns are moving away from traditional fee-for-service plans toward negotiated fee-for-service plans, prospective payment, and capitation-based contracting. This trend has led to a rapid application of modern quality management techniques and performance improvement activity aimed at reducing costs. Managed care contracts are being awarded on the basis of both clinical outcomes and cost.

Many states and federal agencies have enacted legislation that requires health care providers to collect and disseminate comparative outcomes data in their practices. The National Committee on Quality Assurance (NCQA), which is sponsored by managed care organizations, has mandated the collection of quality performance indicators, referred to as HEDIS, which stands for Healthplan and Employer Data Information Set. If data are collected and analyzed appropriately, these initiatives could improve health care quality and reduce costs by facilitating rational decision making by consumers, providers, and third-party payers. If done hastily or inappropriately, efforts to use outcomes data, although well intended, could undermine these goals. For these reasons, standardized and validated methods for measuring the processes and outcomes of health care must be developed and integrated into daily clinical and operational practice (44).
Patient safety

Patient safety has been identified by the IOM as one of the most important dimensions of health care QA and performance improvement. According to a recent report from the IOM, it is estimated that between 44,000 and 98,000 preventable deaths may be due to medical error (1). Although there continues to be controversy about the validity of methods used in these analyses, critics admit that even if the actual number of preventable deaths from error is much smaller than estimated, efforts should be made to eliminate as many as possible.

Patient safety has its roots in traditional risk management (RM) but there are important conceptual differences between the two (Fig. 3.4). RM is retrospective and is focused on individual outliers. It is also outcomes oriented and addresses significant adverse (sentinel) events. The goals of RM include sanctions for substandard providers with far less attention to finding systems-oriented improvements that could prevent recurrent medical errors. Patient safety initiatives are prospective, interdisciplinatory, and focused on health care process in addition to outcomes. They are designed to be nonpunitive and to recognize that most adverse outcomes are because of systems deficiencies and not individual error. Therefore, system changes in the overall process of delivery of care are necessary to prevent future problems. For example, when the wrong extremity is removed during a therapeutic amputation, RM efforts usually focus on legal liability issues, holding surgeons and operating room personnel accountable. A patient safety initiative would ideally study the entire process of care using a root-cause analysis approach (Fig. 3.5). All of the members of the health care team, from admission to discharge, would be involved in order to identify and implement preventive measures. This “going beyond blame” approach was a significant recommendation in the IOM report, and it is the approach that is commonly used in other industries, such as aviation safety (3).

Process changes and improvements, such as having the patient and surgeon sign the correct extremity using indelible ink at the time of admission and sharing the responsibility during the process so that several individuals (operating room personnel, anesthesia personnel, and members of the surgical team) would verify that the correct extremity is prepared and eventually removed. This team accountability approach is now being applied in all specialties, including obstetrics and gynecology.

The JCAHO has been very active and influential in the evolution of patient safety activities. Starting with an initial requirement that all significant (sentinel) events be reported, it now requires that root-cause(s) analysis be used to investigate the incident, identify contributing factors, and improve the process of care (45). Starting with all JCAHO surveys performed after June 2001, the Joint Commission requires documented evidence that a health care organization being reviewed has invested in a “top-down” commitment to patient safety improvement.

Business and government are also interested in promoting patient safety activities. A business committee called the Leapfrog Group representing the National Business Roundtable and corporations such as General Electric, General Motors, and Verizon have announced that they will give purchasing preference to health care organizations that have at least the following three patient safety programs that have been shown to improve performance: (a) 24-hour, 7 days per week in-house coverage by intensive care specialists; (b) computerized physician-order systems; and (c) high volume, optimal outcomes, and low complication rates for high-risk care organizations that have at least the following three patient safety programs that have been shown to improve performance: (a) 24-hour, 7 days per week in-house coverage by intensive care specialists; (b) computerized physician-order systems; and (c) high volume, optimal outcomes, and low complication rates for high-risk procedures such as cardiovascular and transplant surgeries. There are currently several legislative bills before the United States congress addressing patient safety issues, such as practice reform and confidentiality. In addition, government programs such as Medicare and Medicaid are putting into place financial and other incentives for patient safety initiatives.

Leaders in health care assessment and performance improvement have recommended five principles to help make health systems safer:

1. Leadership should commit to patient safety in the organization to provide the necessary personnel and financial resources.
2. System design should recognize human limitations. The noted health care improvement researcher, David Eddy, has stated that “the complexity of modern medicine exceeds the limitations of the unaided human mind.” The one-person (“captain-of-the-ship”) accountability of the past may actually lead to more errors in the current health care system.
3. Working and training in teams can help deliver safer care and more dependable accountability.
4. Training should anticipate the unexpected.
5. The organization should foster a learning environment for continual improvement of patient safety.

There is a growing consensus that there will need to be a nonpunitive reporting system to identify not only errors but also “near misses” and other hazards so that they may be corrected before the patient is harmed. The aviation industry is a prime example of how measures can be taken to improve safety. Operations are simplified and standardized. Crew resource management empowers the most appropriate individual to correct a problem, even if that person is not the pilot. Simulators and team training are widely employed. The industry has a system, the airline safety reporting system (ASRS), for reporting actual incidents and near misses. Furthermore, this system is confidential and separated from the Federal Aviation Agency (their main regulatory body) by the National Aviation and Space Agency (NASA).

Summary

Quality assessment and performance improvement activities are becoming increasingly important components of health care delivery. Although retrospective peer review and other QA efforts are still necessary, newer, prospectively focused methods to improve performance are being introduced. In the past, managing the cost of health care has been a major rationale for quality assessment and performance improvement programs. Recently, however, concerns about patient safety and deficiencies in quality have been prompted by several IOM reports (1,3). The complexity of modern health care delivery now requires a multidisciplinary team...
approach to effective systems approach to improve health care quality and safety significantly.

References

Epidemiology is the study of the occurrence of health events in human populations. Epidemiologic studies may encompass broad topics, such as how birth or death rates vary among people of different nationalities, or more narrow topics, such as how risk for a specific disease changes after a specific exposure. A common theme of most epidemiologic studies is the relationship between disease and exposure, but the design, strengths, weaknesses, and validity of epidemiologic studies vary considerably (1,2,3,4,5 and 6).

Some definitions that are commonly used in epidemiology are as follows:

- **Attributable risk**: the difference between the occurrence measure in the exposed and the unexposed cohort
- **Bias**: a systematic error in the design, conduct, or analysis of a study
- **Clinical trial**: a prospective cohort study to evaluate treatments for disease in humans
- **Confounder**: an extraneous variable that accounts for the apparent effect of the study variable or masks the true association
- **Confidence interval (CI)**: a component of statistical inference in which an interval is provided to give the reader some idea of the range in which the “true” statistical measure calculated (e.g., mean, proportion, and relative risk) is expected to occur
- **Incidence**: the rate of occurrence of new cases of a disease or condition over a specific time interval
- **Prevalence**: the existing number of cases at a specific point in time
- **Specificity**: the proportion of persons with a true negative screening result out of all those who do not have the disease
- **Sensitivity**: the proportion of persons with a true positive screening result out of all those who have the disease
- **Relative risk**: the occurrence in the exposed cohort divided by occurrence in the nonexposed cohort
- **Relative risk**: the occurrence in the exposed cohort divided by occurrence in the nonexposed cohort
- **Recall bias**: a type of information bias that may occur if cases are more likely than controls to remember or to reveal past exposures
- **Relative risk**: the occurrence in the exposed cohort divided by occurrence in the nonexposed cohort
- **Sensitivity**: the proportion of persons with a true positive screening result out of all those who do not have the disease
- **Statistical significance**: the application of a statistical method to test the null hypothesis (i.e., the hypothesis that two or more factors are not associated)
- **Yield**: the exposure odds ratio (or simply odds ratio) in a case-control study (i.e., the ratio of exposed cases to unexposed cases divided by the ratio of exposed to unexposed controls)

### Study Designs

Epidemiologic studies are primarily descriptive or analytic (i.e., designed to test a hypothesis about an association). This distinction is important in evaluating a medical study.

#### Descriptive Studies

Studies in which the characteristics of a disease are described are among the most common type of study. **The two principal types of descriptive studies are case series and cross-sectional studies.**

#### Case Reports or Series

A simple type of study is the case report or case series in which the characteristics of individuals who have a particular disease are described. Hypotheses about the cause of the disease or its treatment are frequently developed from case series and then explored in analytic studies. For example, a link between oral contraceptives and thromboembolism was first suggested by case reports (7) and later confirmed in a case-control study (8). Occasionally, when case series describe the co-occurrence of rare exposures and rare diseases, they are compelling enough on their own to suggest a cause-and-effect relationship. Links between thalidomide and fetal limb reduction (9), the Dalkon shield intrauterine device and septic abortion (10), and sequential oral contraceptives and premenopausal endometrial cancer (11) emerged through case series that were persuasive enough to initiate public health action without the performance of formal epidemiologic studies. In general, however, just because a high number of members of a case series share a particular characteristic, one cannot assume that there is a cause-and-effect relationship. A number of selection factors could have contributed to the observation.

Because of their potential importance, attention should be paid to details of the case selection in case reports or series (e.g., incident or prevalent cases, record-based or personal contact with patients). Investigators should strive to be sure that clear criteria exist for the definition of disease or study variables and that identification of cases was complete. Case series that extend over a long period may suffer from changes in the diagnosis or treatment of the condition that may confound objectives. Interobserver or reviewer reliability may need to be assessed. Careful assembly of a case series is the first step in performing a case-control study as the logical extension of a case series.

A case series does not usually yield any formal epidemiologic measures other than estimates of the frequency of a particular characteristic among members of the case series. This is often referred to as the incidence of a particular characteristic among cases, but prevalence is usually the more appropriate term.

#### Cross-sectional Studies
Design

Cross-sectional studies are larger in scope than case series and generally do not focus on a particular disease. Individuals are surveyed to provide a “snapshot” of health events in the population at a particular time. The U.S. Census Bureau counts the population by categories of age, sex, and ethnicity. The U.S. National Center for Health Statistics compiles a wide variety of data on the health of the population, such as occurrence of hospitalization for various conditions. State health departments are required to count the number of births and deaths annually in their population, and some maintain registries to count the number of individuals who have cancer.

Yield

**Incidence** is the rate of occurrence of new cases of diseases or conditions over a specific time. Cross-sectional studies often yield incidence rates in which births, new disease cases, or deaths are counted annually for a specified census region and divided by the population size to yield events per population per year. The rate is usually multiplied by a base (1,000, 10,000, or 100,000) to give numbers that can more easily be tabulated. Incidence is an important concept in epidemiology and is often used to calculate other measures of disease frequency, such as prevalence and lifetime risk.

**Age-specific incidence** refers to the number of new events occurring in 5- or 10-year age groups per year. Because of marked differences by age for most illnesses, age-specific incidence rates are the best way to describe event occurrence in a population. If the incidence rate is not specified with regard to age, it is described as “crude.”

**Prevalence** is the existing number of cases at a specific point in time. Prevalence is another measure frequently developed from cross-sectional studies. For example, in 1988, the Family Growth Survey Branch of the National Center for Health Statistics interviewed a sample of married couples and found the prevalence of infertility among married women younger than 45 years of age in the United States to be about 8.0% (12). Because prevalence measures disease status in a population rather than events occurring over time, prevalence is a proportion.

Although cross-sectional studies are primarily descriptive, they may contribute information on the cause of a disease by showing how that disease varies by age, sex, race, or geography. In ecologic studies, disease rates in various populations are correlated with other population characteristics (e.g., endometrial cancer rates worldwide are positively correlated with per capita fat consumption and negatively correlated with cereal and grain consumption) (13). Such observations are valuable in suggesting topics for analytic studies or supporting the consistency of an association.

**Analytic Studies**

The purpose of an analytic epidemiologic study is to test a hypothesis about and to measure an association between exposure (or treatment) and disease occurrence (or prevention) (Fig. 4.1). Analytic studies may be subdivided into nonexperimental and experimental studies.

![Figure 4.1](image)

**Figure 4.1** The essential design of an epidemiologic study showing the relationship between exposure (or treatment) and disease.

Nonexperimental analytic studies include cohort and case-control studies and take advantage of “natural experiments” in which individuals do or do not have a particular disease and have or have not had an exposure of potential interest. Experimental studies, such as clinical trials, should meet more rigid criteria than nonexperimental studies. Features they should include are randomization (in which participants are randomly assigned to exposures) and measures to ensure unbiased assessment of outcome.

**Nonexperimental Studies**

**Cohort Studies**

Design A cohort is a group of people who have some factor in common. In the context of a survival analysis, the cohort begins with a population that is 100% well at a particular time and is followed over time to calculate the percentage of the cohort still well at later times. Survival analysis describes mortality after disease (i.e., cancer patients who died within 5 years) but can be adapted to other events (e.g., the percentage of women who continue to menstruate after 50 years of age or the percentage of infertile women who conceive after therapy).

A cohort is defined by subsets of a population who are, have been, or may in the future be exposed to factors hypothesized to influence the occurrence of a given disease (Fig. 4.2). The exposed and nonexposed subjects are observed long enough to generate person-years as the denominator for incidence or mortality rates in exposed and nonexposed subsets.

![Figure 4.2](image)

**Figure 4.2** The format and calculations for a cohort study design.

Cohort studies are also called follow-up, longitudinal, or prospective studies. Although these terms suggest that the exposure is identified before outcome, a retrospective cohort study may also be performed in which the exposure and outcome have already occurred when the study is begun. For example, studies of radiation and subsequent cancer are often based on records of patients who received radiation therapy many years previously. Medical records and death certificates
are used to determine whether a second cancer occurred after the radiation therapy.

**Yield** Cohort studies may yield two measures of an association between exposure and illness. These measures are an attributable risk and a relative risk.

**Attributable risk** is the difference between the occurrence measure in the exposed and the unexposed cohort. The null value is zero—a positive number indicates how many cases of disease may be caused by the exposure, and a negative number indicates how many cases of disease may be prevented by the exposure.

**Relative risk** divides occurrence in the exposed cohort by occurrence in the nonexposed cohort. The null value for the relative risk is 1. A value greater than 1 indicates that exposure may increase risk for the disease (i.e., a relative risk of 1.5 indicates that exposed individuals had 1.5 times, or 50% greater, the risk for disease as unexposed individuals). A value less than 1 indicates that exposure may decrease risk for disease (i.e., a relative risk of 0.5 indicates that the rate in exposed individuals was half that of the rate in the nonexposed individuals).

**Strengths and Weaknesses** The ability to obtain both attributable and relative risks is a strength of cohort studies. In addition, cohort studies are less susceptible to selection and recall bias. Misclassification of exposure and confounding variables can occur, however. Disadvantages of a cohort study generally include higher cost and longer time for completion. Cohort studies are most useful for examining the occurrence of common diseases after a rare exposure. For rare exposures, an investigator may use the general population as the unexposed group. In this type of study, the observed number of cases in the exposed cohort is divided by the number of cases expected if general population rates had prevailed in the exposed cohort. This comparison is called the standardized morbidity or mortality ratio (SMR) and is equivalent to relative risk.

**Case-control Studies**

**Design** A case-control study starts with the identification of individuals with a disease or outcome of interest and a suitable control population without the disease or outcome of interest. The relationship of a particular attribute or exposure to the disease is studied by comparing how the cases and controls differed in that exposure. An alternate term frequently used to describe a case-control study is retrospective because the exposures are assessed after the disease has occurred.

**Yield** The yield of a case-control study is the exposure odds ratio. It is the ratio of exposed cases to unexposed cases divided by the ratio of exposed to unexposed controls. If an entire population could be characterized by its exposure and disease status, the exposure odds ratio would be identical to the relative risk obtainable from a cohort study of the same population. Although it is not feasible to survey the entire population, so long as the sampling of cases or controls from the population was not influenced by their exposure status, the exposure odds ratio will approximate the relative risk. Attributable risk is not directly obtainable in a case-control study (Fig. 4.3).

![Case-control study design](image_url)

**Figure 4.3** The case-control study design.

**Strengths and Weaknesses** The advantages of case-control studies are that they are generally lower in cost and easier to conduct than other analytic studies. Case-control studies are most feasible for examining the association between a relatively common exposure and a relatively rare disease. Disadvantages include greater potential for selection bias, information bias, and confounding variables.

Because an investigator must assign exposures according to a strict protocol, human experimental studies are limited to the study of measures that will prevent disease or the consequences of disease. Examples of experimental studies are clinical trials and field and community intervention trials.

**Experimental Studies**

**Clinical Trials**

The clinical trial is a prospective cohort study to evaluate treatments for disease in humans. Randomization of the treatment assignment is the cornerstone of a good clinical trial because it minimizes bias, which can result from confounding variables or preferential assignment of treatment based on patient characteristics. Evidence must be provided that factors that might influence outcome, such as stage of disease, were similar in patients assigned to the study protocol compared with patients assigned to placebo or traditional treatment. Criteria for successful treatment must be clearly defined. Blinding the subject and clinician to the treatment modality may help ensure unbiased assessment of the outcome. A properly designed clinical trial will have a sufficient number of subjects enrolled to ensure that a “negative” study is powerful enough to rule out a treatment effect.

**Field and Community Intervention Trials**

Field and community intervention trials evaluate measures that may prevent disease, such as vaccines, dietary interventions, or screening procedures. In a field trial, the intervention is applied to individuals. In a community intervention trial, the intervention (e.g., water fluoridation) is applied on a community-wide basis rather than to individuals. Both types of studies include subjects who do not yet have disease and may require large numbers of participants, especially for studies of screening procedures to prevent cancer. In the latter context, issues related to the validity of screening tests (i.e., sensitivity, specificity, and predictive value) are quite important.

![Table 4.1](image_url)

**Table 4.1. Measures of Validity for a Screening Procedure**
Features

Features of an analytic study that are considered in judging its scientific validity include statistical significance, biases, dose response, consistency, and biologic credibility.

Statistical significance is determined by application of a statistical method to test the null hypothesis (i.e., the hypothesis that two or more factors are not associated).

The degree of conflict between the test result and the result predicted by the null hypothesis is indicated by the \( p \) value. Typically, \( p < 0.05 \) is used to determine statistical significance and indicates a 5% chance of incorrectly rejecting the null hypothesis.

Confidence Interval

The confidence interval (CI) is a component of statistical inference in which an interval is provided to give the reader some idea of the range in which the true statistical measure calculated (e.g., mean, proportion, and relative risk) is expected to occur. A 95% CI implies that, if a study were to be repeated many times within the same population, the measures assessed would be expected to fall in this interval 95% of the time. Confidence intervals of 95% for an odds ratio that includes the null value of 1 would not be statistically significant.

Bias

Bias is a systematic error in the design, conduct, or analysis of a study. Such errors result in a mistaken conclusion and can take various forms.

Information Bias

Information bias occurs when subjects are classified incorrectly with respect to exposure or disease. This may occur if records are incomplete or if the criteria for exposure or outcome were poorly defined, leading to misclassification.

Recall bias is another type of information bias that may occur if cases are more likely than controls to remember or to reveal past exposures. In addition to adequate criteria and complete records, information bias may be reduced by making interviewers unaware of the status of the subjects or the purpose of the study.

Selection Bias

Selection bias may occur when correlates of the exposure or outcome influence sampling from the larger population of potentially eligible subjects. An example of selection bias that may arise in a hospital-based case-control study occurs when the combination of the disease under study and a particular exposure is more likely to lead to hospital admission. Using incident cases from more than one hospital, obtaining high participation rates, and attempting to describe nonparticipants are several ways to reduce or at least evaluate the potential for selection bias.

Confounding

A third source of potential error is confounding. A confounder is an extraneous variable that accounts for the apparent effect of the study variable or masks the true association. When a factor differs between cases and controls or cohort members and is associated with both the study exposure and the study outcome, a distortion of the true association between the exposure and the disease may be produced. Age, race, and socioeconomic status are likely confounders; results must be adjusted for these variables by using statistical techniques such as stratification or multivariate analysis. Stratification involves examining the association of interest only within groups that are similar with respect to a potential confounder. Multivariate analysis is a statistical technique commonly used in epidemiologic studies that controls a number of confounders simultaneously. After an analysis to control for confounding variables, the investigator presents the adjusted risk ratio that presumably reflects an association free of confounding.

Dose Response

Dose response means that a change in the amount, intensity, or duration of an exposure is associated with either a consistent increase or decrease in risk for a specified disease or outcome. Trend tests are used to determine whether a dose response exists.

Consistency and Metaanalysis

Consistency between findings in different populations, at different times, and by different methods or investigators is an important criterion used to judge whether there is likely to be a causal relationship. A formal method for studying consistency and pooling results from different studies is metaanalysis.

Metaanalysis is the process of combining results from several independent studies examining the same exposure (or treatment) and same outcome in order to conduct a more powerful test of the null hypothesis. A metaanalysis is conducted by assembling measures of the association from different studies, such as relative risks, weighting them by the variance of the measure, and taking an overall average. In the weighting process, the studies with the largest sample size contribute the greatest information. A properly performed metaanalysis also has a qualitative component that establishes criteria for acceptance of a study (e.g., only randomized studies might be chosen for a metaanalysis of the effect of a particular treatment on a particular disease).

Biologic Credibility

Biologic credibility means that an association is plausible, taking into consideration all aspects of what is known about the natural history or demographics of a disease or what has been observed in relevant experimental models. Whereas an imaginative epidemiologist can find an explanation for any single association, a key issue is whether a model can be proposed accounting for a variety of exposures as well as experimental data and cross-sectional observations.

Gynecologic Considerations

In epidemiologic terms, exposure refers to events that could be linked to an increased risk of disease. Exposures that are important to women’s health are either gynecologic exposures that affect common diseases or common exposures that affect gynecologic diseases.

Reproductive Events

Age at menarche, characteristics of menstrual cycles, number of pregnancies, contraceptives or hormones used, and age at menopause are important events that may have broad impact on many diseases, including endometriosis, fibroids, heart disease, osteoporosis, and cancers of the breast, endometrium, or ovary. Gynecologists should maintain careful records of reproductive landmarks, both for their potential usefulness in advising patients and for their relevance to clinical research.

Contraception and Sterilization

Barrier Contraception

A protective effect of barrier contraception against pelvic inflammatory disease (PID), tubal infertility, ectopic pregnancy, and cervical cancer has been consistently observed.
Intrauterine Devices

Current or past use of an intrauterine device (IUD) has been linked with risk for PID (26), ectopic pregnancy (27), and tubal infertility (28). It is likely that these risks could be reduced by restricting IUD use to women at low risk for genital infections (e.g., parous women in a monogamous relationship).

Oral Contraceptives

Early epidemiologic literature on oral contraceptives (OCs) focused on adverse events, including thromboembolism (particularly with high-dose formulations) (29), hypertension (30), myocardial infarction (especially in women older than 40 years of age who also smoked) (31), and liver adenomas (32). Protective effects of OCs have more recently been appreciated, including lower risk for benign breast disease (33), ovarian cysts (34), ovarian cancer (35), and PID (36). Controversy exists concerning the relationship between OC use and cervical and breast cancer. Progression of intraepithelial cervical lesions may be more rapid among OC users (37). A large case-control study of breast cancer in England suggested use of preparations containing 50 mg or more of estrogen may increase the risk for breast cancer (38). However, the possible increased risk associated with past OC use for developing breast cancer at an early age may be more than offset by a decreased risk for developing breast cancer at an older age (39).

Sterilization

Concerns that sterilization might induce early menopause (40) have not been proved. An unexpected protective effect of female sterilization has been suggested for ovarian cancer (41). This protection may derive from the reduction of uterine growth factors that reach the ovary as a result of the interruption of the uteroovarian circulation or from closure of the female tract, which would prevent substances in the vagina or uterus from reaching the ovaries (42).

Hormone Replacement Therapy

Similar to early studies of OCs, studies of menopausal hormones focused on adverse events, including endometrial cancer, associated with unopposed estrogen use (43). This association has likely been obviated by the use of combined estrogen-progesterone regimens (44). More recent studies suggest protective effects on heart disease (45), osteoporosis (46), and even Alzheimer’s disease (47). The association between menopausal hormones and breast cancer continues to be debated. However, a recent metaanalysis of studies of menopausal hormone use and breast cancer provided reassurance that the effect of such agents on breast cancer risk is modest (48).

Sexually Transmitted Disease

Worldwide, sexually transmitted diseases are possibly the most important preventable cause of morbidity in women. This morbidity includes not only PID from gonorrhea and chlamydia but also chronic disease from syphilis and genitaly transmitted viruses, including hepatitis, human papillomavirus, and human immunodeficiency virus (HIV). The importance of public health measures to prevent the spread of sexually transmitted diseases, especially the use of barrier contraception, cannot be overemphasized because the morbidity from these infections may carry over to the offspring of those infected.

Lifestyle

Factors relating to an individual’s lifestyle can increase the risk for potential problems. Often, the risk can be minimized by identifying these factors and altering behavior.

Smoking

Adverse effects of smoking on the lungs and heart are well known; however, it is less widely appreciated that smoking may be linked to tubal infertility (49), ectopic pregnancy (50), cervical cancer (51), and early menopause (52).

Alcohol

In moderation, alcohol use is associated with decreased risk for cardiovascular disease (53), which may come at the expense of an increased risk for breast cancer (54). It is possible that both of these effects are mediated by the ability of alcohol to retard the metabolism of estrogen, thereby leading to higher circulating levels of estrogen (55).

Exercise and Nutrition

Although aspects of exercise and nutrition cannot be fairly summarized in a single paragraph, it can be stated that gynecologic problems can occur at either extreme. The lean athlete in training who becomes amenorrheic may lose bone mass because of a lack of estrogen, as might the patient with anorexia (18). In obese women, menstrual difficulties may occur that are related to higher estrogen levels, which may, in the longer term, be associated with a higher risk for endometrial cancer (56).

Talc

Use of talc in genital hygiene is an exposure emphasized as a potential risk factor for ovarian cancer (57). Because there are no benefits of genital talc use, other than aesthetic, this practice should be discouraged.

Illnesses

Many gynecologists are primary care providers for women, and they may increasingly assume this role in the future. It is important, therefore, for gynecologists to have an overview of the major causes of mortality in women. Reliable incidence data for gynecologic cancers and benign gynecologic problems are sometimes difficult to find, but statistics are available to guide clinical interventions.

Table 4.2 shows the 10 leading causes of death in 1998 for females in the United States by age from the National Center for Health Statistics data (58). Heart disease remains the major cause of death in women overall, but there is considerable age variation. Accidents, homicides, and suicides are most important at ages younger than 40 years, and cancer is most important at ages 40 to 79 years.

Table 4.2. Reported Deaths for the 10 Leading Causes of Death by Age, United States, 1998
Table 4.3 shows the five leading causes of cancer mortality in women by various ages. In women, lung cancer now accounts for more deaths than breast cancer. Colon and rectal cancers are second overall, highlighting the importance of colon cancer screening in women older than 50 years of age. Pancreatic and ovarian cancers occur with about equal frequency, and both remain elusive to screening.

Table 4.3. Reported Deaths for the Five Leading Cancer Sites for Females by Age, United States, 1998

Figure 4.4 illustrates the age-specific incidence of genital malignancies in all females in the United States around 1991. The incidence of invasive cervical cancer remains steady across all ages, whereas ovarian and endometrial cancer increase markedly during the perimenopausal years and predominate after 50 years of age. The sharp increase in endometrial and ovarian cancer rates around the time of menopause may reflect anovulatory cycles associated with unopposed estrogen and increased levels of gonadotropins. Although ovarian cancer appears to rank second to endometrial cancer in terms of incidence, mortality from ovarian cancer currently exceeds the combined mortality of endometrial and cervical cancer.

The estimated number of hospital admissions listing various benign gynecologic conditions as a discharge diagnosis, shown in Table 4.4, is based on data collected by the National Hospital Discharge Survey for 1988 to 1990 and by the Division of Reproductive Health of the Centers for Disease Control and Prevention. These data pertain to women 15 to 45 years of age and are based on discharges from nonmilitary hospitals. PID is the most frequent discharge diagnosis, with nearly 300,000 women hospitalized annually. Of almost equal frequency are hospitalizations for benign ovarian cysts, endometriosis, and fibroids, each of which accounts for the hospitalization of almost 200,000 women annually.

Table 4.4. Estimated Number of Annual Hospitalizations among Women of Reproductive Age in the United States

The estimated age-specific incidence of PID, ovarian cysts, fibroids, and endometriosis is shown in Figure 4.5. Notable are the higher incidence of PID in women in their 20s and the increasing incidence of endometriosis and fibroids into the 40s. The high frequency of the latter two conditions, combined with a lack of information on their cause, suggests that these conditions should be targets for more epidemiologic research.

Figure 4.5 Age-specific incidence of hospitalization for various benign gynecologic conditions around 1990. (From Velebil P, Wingo PA, Xia A, et al. Rate of hospitalization for gynecologic disorders among reproductive-age women in the United States. Obstet Gynecol 1995;86:764–769, with permission.)
In 1989, there were about 88,400 ectopic pregnancies in the United States, with a rate of about 16.0 per 1,000 reported pregnancies, compared with 4.5 per 1,000 in 1970 (56). In 1970, however, the case-fatality rate was 35.5 per 10,000 ectopic pregnancies, compared with 3.8 per 10,000 ectopic pregnancies in 1989, which accounted for 13% of all maternal deaths that year. Ectopic pregnancy continues to contribute to maternal mortality, particularly among nonwhite populations.

Gynecologic exposures and gynecologic diseases have always been major foci for epidemiologic research. However, gynecologists have infrequently been involved in the design and interpretation of such studies, and therefore, the physiologic and clinical relevance of various associations often have been inadequately discussed. Even if the gynecologist does not actually perform epidemiologic research, an understanding of epidemiologic principles allows for a more critical reading of the medical literature and sharpens the practice of preventive medicine in gynecology.

Pelvic Structure

Bony Pelvis

The skeleton of the pelvis is formed by the sacrum and coccyx and the paired hipbones (coxal, innominate), which fuse anteriorly to form the symphysis pubis. Figure 5.1 illustrates the bony pelvis as well as its ligaments and foramina.

Figure 5.1 The female pelvis. The pelvic bones (the innominate bone, sacrum, and coccyx) and their joints, ligaments, and foramina.

Sacrum and Coccyx

The sacrum and coccyx are an extension of the vertebral column resulting from the five fused sacral vertebrae and the four fused coccygeal vertebrae. They are joined by a symphyseal articulation (sacroccygeal joint), which allows some movement.

The essential features of the sacrum and coccyx are as follows:

1. Sacral promontory—the most prominent and anterior projection of the sacrum, this is an important landmark for insertion of a laparoscope. It is located at the level of bifurcation of the common iliac arteries.
2. Four paired anterior and posterior sacral foramina—exit sites for the anterior and posterior rami of the corresponding sacral nerves; anterior foramina are also traversed by the lateral sacral vessels.
3. Sacral hiatus—results from incomplete fusion of the posterior lamina of the fifth sacral vertebra, offering access to the sacral canal, which is clinically important
The paired os coxae, or hipbones, have three components: the ilium, the ischium, and the pubis. These components meet to form the acetabulum, a cup-shaped cavity that accommodates the femoral head.

**Ilium**

1. **Iliac crest**—provides attachments to the iliac fascia, abdominal muscles, and fascia lata.
2. **Anterior superior and inferior spine**—superior spine provides the point of fixation of the inguinal ligament.
3. **Posterior superior and inferior spine**—superior spine is the point of attachment for the sacrotuberous ligament and the posterior sacral iliac ligament.
4. **Arcuate line**—marks the pelvic brim and lies between the first two segments of the sacrum.
5. **Ilipectineal eminence (linea terminalis)**—the line of junction of the ilium and the pubis.
6. **Iliac fossa**—the smooth anterior concavity of the ilium, covered by the iliacus muscle.

**Ischium**

1. **Ischial spine**—delineates the greater and lesser sciatic notch above and below it. It is the point of fixation for the sacrospinous ligament; the ischial spine represents an important landmark in the performance of pudendal nerve block and sacrospinosus ligament vaginal suspension; vaginal palpation during labor allows detection of progressive fetal descent.
2. **Ischial ramus**—joins that of the pubic rami to encircle the obturator foramen; provides the attachment for the inferior fascia of the urogenital diaphragm and the perineal musculofascial attachments.
3. **Ischial tuberosity**—the rounded bony prominence upon which the body rests in the sitting position.

**Pubis**

1. **Body**—formed by the midline fusion of the superior and inferior pubic rami.
2. **Symphysis pubis**—a fibrocartilaginous symphyseal joint where the bodies of the pubis meet in the midline; allows for some resilience and flexibility, which is critical during parturition.
3. **Superior and inferior pubic rami**—join the ischial rami to encircle the obturator foramen; provide the origin for the muscles of the thigh and leg; provide the attachment for the inferior layer of the urogenital diaphragm.
4. **Pubic tubercle**—a lateral projection from the superior pubic ramus, to which the inguinal ligament, rectus abdominis, and pyramidalis attach.

**Pelvic Bone Articulations**

The pelvic bones are joined by four articulations:

1. **Two cartilaginous symphyseal joints**—the sacroccyegeal joint and the symphysis pubis—these joints are surrounded by strong ligaments anteriorly and posteriorly, which are responsive to the effect of relaxin and facilitate parturition.
2. **Two synovial joints**—sacroiliac joints—these are stabilized by the sacroiliac ligaments, the iliolumbar ligament, the lateral lumbosacral ligament, the sacrotuberous ligament, and the sacrospinous ligament.

The pelvis is divided into the **greater and lesser pelvis** by an oblique plane passing through the sacral promontory, the **linea terminalis (arcuate line of the ilium)**, the pectineal line of the pubis, the pubic crest, and the upper margin of the symphysis pubis. This plane lies at the level of the superior pelvic aperture (pelvic inlet) or pelvic brim. The inferior pelvic aperture or pelvic outlet is irregularly bound by the tip of the coccyx, the symphysis pubis, and the ischial tuberosities.

The dimensions of the superior and inferior pelvic apertures have important obstetric implications.

**Ligaments and Foramina**

Four ligaments of the bony pelvis are of special importance to the gynecologic surgeon.

**Inguinal Ligament**

The inguinal ligament is important Surgically in the repair of inguinal hernia. The inguinal ligament:

1. Is formed by the lower border of the aponeurosis of the external oblique muscle folded back upon itself.
2. Is fused laterally to the iliacus fascia and inferiorly to the fascia lata.
3. Flattens medially into the lacunar ligament, which forms the medial border of the femoral ring.

**Cooper's Ligament**

Cooper's ligament is used frequently in bladder suspension procedures. Cooper's ligament:

1. Is a strong ridge of fibrous tissue extending along the pectineal line—also known as the pectineal ligament.
2. Merges laterally with the ilipectineal ligament and medially with the lacunar ligament.

**Sacrospinosus Ligament**

The sacrospinosus ligament is often used for vaginal suspension. This ligament offers the advantage of a vaginal surgical route. The sacrospinosus ligament:

1. Extends from the ischial spine to the lateral aspect of the sacrum.
2. Is separated from the rectovaginal space by the rectal pillars.
3. Lies anterior to the pudendal nerve and the internal pudendal vessels at its attachment to the ischial spine.
4. The inferior gluteal artery, with extensive collateral circulation, is found between the sacrospinous and sacrotuberous ligaments and may be injured during sacrospinosus suspension (2).

**Sacrotuberous Ligament**

The sacrotuberous ligament is sometimes used as a point of fixation for vaginal vault suspension. The sacrotuberous ligament:

1. Extends from the ischial tuberosity to the lateral aspect of the sacrum.
2. Merges medially with the sacrospinosus ligament.
3. Lies posterior to the pudendal nerve and the internal pudendal vessels.

The bony pelvis and its ligaments delineate three important foramina that allow the passage of the various muscles, nerves, and vessels to the lower
Greater Sciatic Foramen

The greater sciatic foramen transmits the following structures: the piriformis muscle, the superior gluteal nerves and vessels, the sciatic nerve along with the nerves of the quadratus femoris, the inferior gluteal nerves and vessels, the posterior cutaneous nerve of the thigh, the nerves of the obturator internus, and the internal pudendal nerves and vessels.

Lesser Sciatic Foramen

The lesser sciatic foramen transmits the tendon of the obturator internus to its insertion on the greater trochanter of the femur. The nerve of the obturator internus and the pudendal vessels and nerves reenter the pelvis through it.

Obturator Foramen

The obturator foramen transmits the obturator nerves and vessels.

Muscles

The muscles of the pelvis include those of the lateral wall and those of the pelvic floor (Fig. 5.2; Table 5.1).

Figure 5.2 The pelvic diaphragm. A: A view into the pelvic floor that illustrates the muscles of the pelvic diaphragm and their attachments to the bony pelvis. B: A view from outside the pelvic diaphragm illustrating the divisions of the levator ani muscles (superficial plane removed on the right). C: A lateral, sagittal view of the pelvic diaphragm.

Levator Ani

The levatores ani are composed of the pubococcygeus (including the pubovaginalis, pubourethralis, puborectalis, and the iliococcygeus). It is a broad, curved sheet of muscle stretching from the pubis anteriorly and the coccyx posteriorly and from one side of the pelvis to the other. It is perforated by the urethra, vagina, and anal canal. Its origin is from the tendinous arch extending from the body of the pubis to the ischial spine. It is inserted into the central tendon of the...
perineum, the wall of the anal canal, the anococcygeal ligament, the coccyx, and the vaginal wall.

The levator ani assists the anterior abdominal wall muscles in containing the abdominal and pelvic contents. It supports the vagina, facilitates defecation, and aids in maintaining fecal continence. During parturition, the levator ani supports the fetal head while the cervix dilates. The levator ani is innervated by S3 to S4, the inferior rectal nerve.

Urogenital Diaphragm

The muscles of the urogenital diaphragm reinforce the pelvic diaphragm anteriorly and are intimately related to the vagina and the urethra. They are enclosed between the inferior and superior fascia of the urogenital diaphragm. The muscles include the deep transverse perineal and sphincter urethrae (Table 5.1).

Blood Vessels

The pelvic blood vessels supply genital structures as well as the following:

- Urinary and gastrointestinal tracts.
- Muscles of the abdominal wall, pelvic floor and perineum, buttocks, and upper thighs.
- Fasciae, other connective tissue, and bones.
- Skin and other superficial structures.

Classically, vessels supplying organs are known as visceral vessels and those supplying supporting structures are called parietal vessels.

Major Blood Vessels

The course of the major vessels supplying the pelvis is illustrated in Fig. 5.4; their origin, course, branches, and venous drainage are presented in Table 5.2. In general, the venous system draining the pelvis closely follows the arterial supply and is named accordingly. Not infrequently, a vein draining a particular area may form a plexus with multiple channels. Venous systems, which are paired, mirror each other in their drainage patterns, with the notable exception of the ovarian veins. Unusual features of venous drainage are also listed in Table 5.2.

Figure 5.4 The blood supply to the pelvis. A: The sagittal view of the pelvis without the viscera. B: The blood supply to one pelvic viscera.

Table 5.2. The Major Blood Vessels of the Pelvis

General Principles

“Control blood supply” and “maintain meticulous hemostasis” are two of the most common exhortations to young surgeons. In developing familiarity with the pattern of blood flow in the pelvis, several unique characteristics of this vasculature should be understood and may have implications for surgical practice:

1. The pelvic vessels play an important role in pelvic support. They provide condensations of endopelvic fascia that act to reinforce the normal position of pelvic organs [3].

2. There is significant anatomic variation between individuals in the branching pattern of the internal iliac vessels. There is no constant order in which branches divide from the parent vessel; some branches may arise as common trunks or may spring from other branches rather than from the internal iliac. Occasionally, a branch may arise from another vessel entirely (e.g., the obturator artery may arise from the external iliac or inferior epigastric artery). This variation may also be found in the branches of other major vessels; the ovarian arteries have been reported to arise from the renal arteries or as a common trunk from the front of the aorta on occasion. The inferior gluteal artery may originate from the posterior or the anterior branch of the internal iliac (hypogastric) artery (2). Patterns of blood flow may be asymmetric from side to side, and structures supplied by anastomoses of different vessels may show variation from person to person in proportion of vascular support provided by the vessels involved. The pelvic surgeon must be prepared for deviations from “textbook” vascular patterns.

3. The pelvic vasculature is a high-volume, high-flow system with enormous expansive capabilities throughout reproductive life. Blood flow through the uterine arteries increases to about 500 mL/min in late pregnancy. In nonpregnant women, certain conditions, such as uterine fibroids or malignant neoplasms, may be associated with neovascularization and hypertrophy of existing vessels and a corresponding increase in pelvic blood flow. Understanding of the volume and flow characteristics of the pelvic vasculature in different clinical situations will enable the surgeon to anticipate problems and take appropriate preoperative and intraoperative measures (including blood and blood product availability) to prevent or manage hemorrhage.

4. The pelvic vasculature is supplied with an extensive network of collateral connections (Fig. 5.5) that provides a rich anastomotic communication between different major vessel systems. This degree of redundancy is important to ensure adequate supply of oxygen and nutrients in the event of major trauma or other vascular compromise. Hypogastric artery ligation continues to be used as a strategy for management of massive pelvic hemorrhage when other measures have failed. Bilateral hypogastric artery ligation, particularly when combined with ovarian artery ligation, dramatically reduces pulse pressure in the pelvis, converting flow characteristics from that of an arterial system to a venous system and allowing use of collateral channels of circulation to continue blood supply, other areas. The significance of collateral blood flow is demonstrated by reports of successful pregnancies occurring after bilateral ligation of both hypogastric and ovarian arteries (4). Table 5.3 lists the collateral channels of circulation in the pelvis.
Special Vascular Considerations

When inserting a laparoscopic trocar into the anterior abdominal wall, the gynecologic surgeon must keep in mind certain anatomic relationships in order to avoid injury to vascular structures and resultant hemorrhage. The inferior epigastric artery is a branch of the external iliac artery, arising from the parent vessel at the medial border of the inguinal ligament and coursing cephalad lateral to and posterior to the rectus sheath at the level of the arcuate line. It lies about 1.5 cm lateral to the medial umbilical fold, which marks the site of the obliterated umbilical artery. The aortic bifurcation occurs at the level of L4 to L5, just above the sacral promontory. Palpation of the sacral promontory to guide trocar insertion allows the surgeon to avoid the major vascular structures in this area (see Fig. 21.4 in Chapter 21).

Lymphatics

The pelvic lymph nodes are generally arranged in groups or chains and follow the course of the larger pelvic vessels, for which they are usually named. Smaller nodes that lie close to the visceral structures are usually named for those organs. Lymph nodes in the pelvis receive afferent lymphatic vessels from pelvic and perineal visceral and parietal structures and send efferent lymphatics to more proximal nodal groups. The number of lymph nodes and their exact location is variable; however, certain nodes tend to be relatively constant:

1. Obturator node in the obturator foramen, close to the obturator vessels and nerve.
2. Nodes at the junction of the internal and external iliac veins.
3. Ureteral node in the broad ligament near the cervix, where the uterine artery crosses over the ureter.
4. The Cloquet or Rosenmüller node—the highest of the deep inguinal nodes that lies within the opening of the femoral canal.

Figure 5.6 illustrates the pelvic lymphatic system. Table 5.4 outlines the major lymphatic chains of relevance to the pelvis and their primary afferent connections from major pelvic and perineal structures. There are extensive interconnections between lymph vessels and nodes; more than one lymphatic pathway is usually available for drainage of each pelvic site. Bilateral and crossed extension of lymphatic flow may occur, and entire groups of nodes may be bypassed to reach more proximal chains.

Figure 5.6 The lymphatic drainage of the female pelvis. The vulva and lower vagina drain to the superficial and deep inguinal nodes, sometimes directly to the iliac nodes (along the dorsal vein of the clitoris) and to the other side. The cervix and upper vagina drain laterally to the parametrial, obturator, and external iliac nodes and posteriorly along the uterosacral ligaments to the sacral nodes. Drainage from these primary lymph node groups is upward along the infundibulopelvic ligament, similar to drainage of the ovary and fallopian tubes to the paraaortic nodes. The lower uterine body drains in the same manner as the cervix. Rarely, drainage occurs along the round ligament to the inguinal nodes.
Table 5.4. Primary Lymph Node Groups Providing Drainage to Genital Structures

The natural history of most genital tract malignancies directly reflects the lymphatic drainage of those structures, although the various interconnections, different lymphatic paths, and individual variability make the spread of malignancy somewhat unpredictable. Regional lymph node metastasis is one of the most important factors in formulation of treatment plans for gynecologic malignancies and prediction of eventual outcome.

Nerves

The pelvis is innervated by both the autonomic and somatic nervous systems. The autonomic nerves include both sympathetic (adrenergic) and parasympathetic (cholinergic) fibers and provide the primary innervation for genital, urinary, and gastrointestinal visceral structures and blood vessels.

Somatic Innervation

The lumbosacral plexus (Figs. 5.7) and its branches provide motor and sensory somatic innervation to the lower abdominal wall, the pelvic and urogenital diaphragms, the perineum, and the hip and lower extremity. The nerves originating from the muscles, the lumbosacral trunk, the anterior divisions of the upper four sacral nerves (sacral plexus), and the anterior division of the coccygeal nerve and fibers from the fourth and fifth sacral nerves (coccygeal plexus) are found on the anterior surface of the piriformis muscle and lateral to the coccyx, respectively, deep in the posterior pelvis. Table 5.5 lists each major branch by spinal segment and structures innervated. In addition to these branches, the lumbosacral plexus includes nerves that innervate muscles of the lateral pelvic wall (obturator internus, piriformis), posterior hip muscles, and the pelvic diaphragm. A visceral component, the pelvic splanchnic nerve, is also included.

Figure 5.7 The sacral plexus. (Modified from Kamina P. Anatomie gynécologique et obstétricale. Paris: Maloine Sa Éditeur, 1984:90, with permission.)

Table 5.5. Lumbosacral Plexus

Nerves supplying the cutaneous aspects of the anterior, medial, and lateral lower extremities, as well as the deep muscles of the anterior thigh, primarily leave the pelvis by passing beneath the inguinal ligament. Nerves supporting the posterior cutaneous and deep structures of the hip, thigh, and leg lie deep in the pelvis and should not be vulnerable to injury during pelvic surgery. The obturator nerve travels along the lateral pelvic wall to pass through the obturator foramen into the upper thigh, and it may be encountered in more radical dissections involving the lateral pelvic wall and in paravaginal repairs.

The pudendal nerve crosses over the piriformis to travel with the internal pudendal vessels into the ischiorectal fossa, where it divides into its three terminal branches to provide the primary innervation to the perineum. Other nerves contribute to the cutaneous innervation of the perineum:

1. The anterior labial nerve branches of the ilioinguinal nerve—these nerves emerge from within the inguinal canal and through the superficial inguinal ring to the mons and upper labia majora.
2. The genital branch of the genitofemoral nerve—this branch enters the inguinal canal with the round ligament and passes through the superficial inguinal ring to the anterior vulva.
3. The perineal branches of the posterior femoral cutaneous nerve—after leaving the pelvis through the greater sciatic foramen, these branches run in front of the ischial tuberosity to the lateral perineum and labia majora.
4. Perforating cutaneous branches of the second and third sacral nerves—these branches perforate the sacrotuberous ligament to supply the buttocks and contiguous perineum.
5. The anococygeal nerves—these nerves arise from S4 to S5 and also perforate the sacrotuberous ligament to supply the skin overlying the coccyx.

Autonomic Innervation

Functionally, the innervation of the pelvic viscera may be divided into an efferent component and an afferent, or sensory, component. In reality, however, afferent and efferent fibers are closely associated in a complex interlacing network and cannot be separated anatomically.

Efferent Innervation

Efferent fibers of the autonomic nervous system, unlike motor fibers in the somatic system, involve one synapse outside the central nervous system, with two neurons required to carry each impulse. In the sympathetic (thoracolumbar) division, this synapse is generally at some distance from the organ being innervated; conversely, the synapse is on or near the organ of innervation in the parasympathetic (craniosacral) division.

Axons from preganglionic neurons emerge from the spinal cord to make contact with peripheral neurons arranged in aggregates known as autonomic ganglia. Some of these ganglia, along with interconnecting nerve fibers, form a pair of longitudinal cords called the sympathetic trunks. Located lateral to the spinal column from the base of the cranium to the coccyx, the sympathetic trunks lie along the medial border of the psoas muscle from T12 to the sacral prominence and then pass behind...
the common iliac vessels to continue into the pelvis on the anterior surface of the sacrum. On the anterolateral surface of the aorta, the aortic plexus forms a lacy network of nerve fibers with interspersed ganglia. Rami arising from or traversing the sympathetic trunks join this plexus and its subsidiaries.

The ovaries and part of the fallopian tubes and broad ligament are innervated by the ovarian plexus, a network of nerve fibers accompanying the ovarian vessels and derived from the aortic and renal plexuses. The inferior mesenteric plexus is a subsidiary of the celiac plexus and aortic plexus and is located along the inferior mesenteric artery and its branches, providing innervation to the left colon, sigmoid, and rectum.

The superior hypogastric plexus (presacral nerve) (Fig. 5.8) is the continuation of the aortic plexus beneath the peritoneum in front of the terminal aorta, the fifth lumbar vertebra, and the sacral promontory, medial to the ureters. Embedded in loose areolar tissue, the plexus overlies the middle sacral vessels and is usually composed of two or three incompletely fused trunks. It contains preganglionic fibers from lumbar nerves, postganglionic fibers from higher sympathetic ganglia and from the sacral sympathetic trunks, and visceral afferent fibers.

![Figure 5.8 The presacral nerves.](image)

Just below the sacral promontory, the superior hypogastric plexus divides into two loosely arranged nerve trunks, the hypogastric nerves. These nerves course inferiorly and laterally with the inferior hypogastric plexuses (pelvic plexuses) (Fig. 5.8), which are a dense network of nerves and ganglia that lie along the lateral pelvic sidewall overlying branches of the internal iliac vessels.

The inferior hypogastric plexus includes efferent sympathetic fibers, afferent (sensory) fibers, and parasympathetic fibers arising from the pelvic splanchnic nerves (S2 to S4, nervi erigentes).

This paired plexus is the final common pathway of the pelvic visceral nervous system and is divided into three portions, representing distribution of innervation to the viscera:

1. **Vesical plexus**
   - Innervation: bladder and urethra
   - Course: along vesical vessels
2. **Middle rectal plexus (hemorrhoidal)**
   - Innervation: rectum
   - Course: along middle rectal vessels
3. **Uterovaginal plexus (Frankenhäuser ganglion)**
   - Innervation: uterus, vagina, clitoris, vestibular bulbs
   - Course: along uterine vessels and through cardinal and uterosacral ligaments; sympathetic and sensory fibers derive from T10, L1; parasympathetic fibers derive from S2 to S4.

**Afferent Innervation**

Afferent fibers from the pelvic viscera and blood vessels traverse the same pathways to provide sensory input to the central nervous system. They are also involved in reflex arcs needed for bladder, bowel, and genital tract function. The afferent fibers reach the central nervous system to have their first synapse within posterior spinal nerve ganglia.

Presacral neurectomy, in which a segment of the superior hypogastric plexus is divided and resected in order to interrupt sensory fibers from the uterus and cervix, has been associated with relief of dysmenorrhea secondary to endometriosis in about 50% to 75% of cases in which it has been employed (5,6). Because efferent fibers from the adnexa travel with the ovarian plexus, pain originating from the ovary or tube is not relieved by resection of the presacral nerve. Because this plexus also contains efferent sympathetic and parasympathetic nerve fibers intermixed with afferent fibers, disturbance in bowel or bladder function may result. An alternative surgical procedure advocated in recent years is resection of a portion of the uterosacral ligaments; because they contain numerous nerve fibers with more specific innervation to the uterus, it is postulated that bladder and rectal function is less vulnerable to compromise.

An anesthetic block of the pudendal nerve is performed most often for pain relief with uncomplicated vaginal deliveries but may also provide useful anesthesia for minor perineal surgical procedures. This nerve block may be accomplished transvaginally through the perineum. A needle is inserted toward the ischial spine with the tip directed slightly posteriorly and through the sacrospinous ligament. As anesthetic agent is injected, frequent aspiration is required to avoid injection into the pudendal vessels, which travel with the nerve.

**Pelvic Viscera**

**Embryonic Development**

The female urinary and genital tracts are closely related, not only anatomically but also embryologically. Both are derived largely from primitive mesoderm and endoderm, and there is evidence that the embryologic urinary system has an important inductive influence on the developing genital system. About 10% of infants are born with some abnormality of the genitourinary system, and anomalies in one system are often mirrored by anomalies in another system (7).

Developmental defects may play a significant role in the differential diagnosis of certain clinical signs and symptoms and have special implications in pelvic surgery (7,8,9,10, and 11). This is important for the practicing gynecologist to have a basic understanding of embryology.

Following is a presentation of the urinary system, internal reproductive organs, and external genitalia in order of their initial appearance, although much of their development proceeds concurrently. The development of each of these three regions proceeds synchronously at an early embryologic age (Table 5.6).
Table 5.6. Development of Genital and Urinary Tracts by Embryologic Age

**Urinary System**

**Kidneys, Renal Collecting System, Ureters**

The kidneys, renal collecting system, and ureters derive from the longitudinal mass of mesoderm (known as the nephrogenic cord) found on each side of the primitive aorta. This process gives rise to three successive sets of increasingly advanced urinary structures, each developing more caudal to its predecessor. The pronephros, or “first kidney,” is rudimentary and nonfunctional; it is succeeded by the “middle kidney,” or mesonephros, which is believed to function briefly before regressing. Although the mesonephros is transitory as an excretory organ, its duct, the mesonephric (wolffian) duct, is of singular importance for the following reasons:

1. It grows caudally in the developing embryo to open, for the first time, an excretory channel into the primitive cloaca and the “outside world.”
2. It serves as the starting point for development of the metanephros, which becomes the definitive kidney.
3. It ultimately differentiates into the sexual duct system in the male.
4. Although regressing in female fetuses, there is evidence that the mesonephric duct may have an inductive role in development of the paramesonephric or müllerian duct.

Development of the metanephros is initiated by the ureteric buds, which sprout from the distal mesonephric ducts; these buds extend cranially and penetrate the portion of the nephrogenic cord known as the metanephric blastema. The ureteric buds begin to branch sequentially, with each growing tip covered by metanephric blastema. The metanephric blastema ultimately form the renal functional units (the nephrons), whereas the ureteric buds become the collecting duct system of the kidneys (collecting tubules, minor and major calyces, renal pelvis) and the ureters. Although these primitive tissues differentiate along separate paths, they are interdependent on inductive influences from each other—neither can develop alone.

The kidneys initially lie in the pelvis but subsequently ascend to their permanent location, rotating almost 90 degrees in the process as the more caudal part of the embryo in effect grows away from them. Their blood supply, which first arises as branches of the middle sacral and common iliac arteries, comes from progressively higher branches of the aorta until the definitive renal arteries form; previous vessels then regress.

**Bladder and Urethra**

The cloaca forms as the result of dilation of the opening to the fetal exterior. The cloaca is partitioned by the mesenchymal urorectal septum into an anterior urogenital sinus and a posterior rectum. The bladder and urethra form from the most superior portion of the urogenital sinus, with surrounding mesenchyme contributing to their muscular and serosal layers. The remaining inferior urogenital sinus is known as the phallic or definitive urogenital sinus.

Concurrently, the distal mesonephric ducts and attached ureteric buds are incorporated into the posterior bladder wall in the area that will become the bladder trigone. As a result of the absorption process, the mesonephric duct ultimately opens independently into the urogenital sinus below the bladder neck.

The allantois, which is a vestigial diverticulum of the hindgut that extends into the umbilicus and is continuous with the bladder, loses its lumen and becomes the fibrous band known as the urachus or median umbilical ligament. In rare instances, the urachal lumen remains partially patent, with formation of urachal cysts, or completely patent, with the formation of a urinary fistula to the umbilicus.

**Genital System**

Although genetic sex is determined at fertilization, the early genital system is indistinguishable between the two sexes in the embryonic stage. This is known as the “indifferent stage” of genital development, during which both male and female fetuses have gonads with prominent cortical and medullary regions, dual sets of genital ducts, and external genitalia that appear similar. Clinically, gender is not apparent until about the twelfth week of embryonic life and depends on the elaboration of testis-determining factor (TDY) and, subsequently, androgens by the male gonad. Female development has been called the “basic developmental path of the human embryo,” requiring not estrogen but the absence of testosterone.

**Internal Reproductive Organs**

The primordial germ cells migrate from the yolk sac through the mesentery of the hindgut to the posterior body wall mesenchyme at about the tenth thoracic level, which is the initial site of the future ovary (Fig. 5.9 and Fig. 5.10). Once the germ cells reach this area, they induce proliferation of cells in the adjacent mesonephros and celomic epithelium to form a pair of genital ridges medial to the mesonephros. The development of the gonad is absolutely dependent on this proliferation because these cells form a supporting aggregate of cells (the primitive sex cords) that invest the germ cells and without which the gonad would degenerate.
Because of the intertwined development of these two systems, it is easy to understand how abnormalities in one may be associated with abnormalities in the other.

Developmental abnormalities of the urinary and genital systems can be explained and understood by a consideration of female and male embryologic development.
Urinary System

Urinary tract anomalies arise from defects in the ureteric bud, the metanephric blastema, or their inductive interaction with each other.

Renal Agenesis
Renal agenesis occurs when one or both ureteric buds fail to form or degenerate, and the metanephric blastema is therefore not induced to differentiate into nephrons. Bilateral renal agenesis is incompatible with postnatal survival, but infants with only one kidney usually survive, and the single kidney undergoes compensatory hypertrophy. Unilateral renal agenesis is often associated with absence or abnormality of fallopian tubes, uterus, or vagina—the paramesonephric duct derivatives.

Abnormalities of Renal Position
Abnormalities of renal position result from disturbance in the normal ascent of the kidneys. A malrotated pelvic kidney is the most common result; a horseshoe kidney, in which the kidneys are fused across the midline, occurs in about 1 in 600 individuals and also has a final position lower than usual because its normal ascent is prevented by the root of the inferior mesenteric artery.

Duplication of the Upper Ureter and Renal Pelvis
Duplication of the upper ureter and renal pelvis are relatively common and result from premature bifurcation of the ureteric bud. If two ureteric buds develop, there will be complete duplication of the collecting system. In this situation, one ureteric bud will open normally into the posterior bladder wall, and the second bud will be carried more distally within the mesonephric duct to form an ectopic ureteral orifice into the urethra, vagina, or vaginal vestibule; incontinence is the primary presenting symptom. Most of the aforementioned urinary abnormalities remain asymptomatic unless obstruction or infection supervenes. In that case, anomalous embryologic development must be included in the differential diagnosis.

Genital System

Because the early development of the genital system is similar in both sexes, congenital defects in sexual development, usually arising from a variety of chromosomal abnormalities, tend to present clinically with ambiguous external genitalia. These conditions are known as intersex conditions or hermaphroditism and are classified according to the histologic appearance of the gonads (see Chapter 24).

True Hermaphroditism
Individuals with true hermaphroditism have both ovarian and testicular tissue, most commonly as composite ovotestes but occasionally with an ovary on one side and a testis on the other. In the latter case, a fallopian tube and single uterine horn may develop on the side with the ovary because of the absence of local AMH. True hermaphroditism is an extremely rare condition associated with chromosomal mosaicism, mutation, or abnormal cleavage involving the X and Y chromosomes.

Pseudohermaphroditism
In individuals with pseudohermaphroditism, the genetic sex indicates one gender, and the external genitalia has characteristics of the other gender. Males with pseudohermaphroditism are genetic males with feminized external genitalia, most commonly manifesting as hypospadias (urethral opening on the ventral surface of the penis) or incomplete fusion of the urogenital or labioscrotal folds. Females with pseudohermaphroditism are genetic females with virilized external genitalia, including clitoral hypertrophy and some degree of fusion of the urogenital or labioscrotal folds. Both types of pseudohermaphroditism are caused either by abnormal levels of sex hormones or abnormalities in the sex hormone receptors.

Another major category of genital tract abnormalities involves various types of uterovaginal malformations (Fig. 5.12), which occur in 0.16% of women (12). These malformations are believed to result from one or more of the following situations:

1. Improper fusion of the paramesonephric ducts
2. Incomplete development of one paramesonephric duct
3. Failure of part of the paramesonephric duct on one or both sides to develop
4. Absent or incomplete canalization of the vaginal plate

Genital Structures

Vagina

A sagittal section of the female pelvis is presented in Fig. 5.13.

Figure 5.13 The pelvic viscera. A sagittal section of the female pelvis with the pelvic viscera and their relationships.

The vagina is a hollow fibromuscular tube extending from the vulvar vestibule to the uterus. In the dorsal lithotomy position, the vagina is directed posteriorly toward the sacrum, but its axis is almost horizontal in the upright position. It is attached at its upper end to the uterus just above the cervix. The spaces between the cervix and vagina are known as the anterior, posterior, and lateral vaginal fornices. Because the vagina is attached at a higher point posteriorly than anteriorly, the posterior...
The posterior vaginal fornix is separated from the posterior cul-de-sac and peritoneal cavity by the vaginal wall and peritoneum. This proximity is clinically useful, both diagnostically and therapeutically. Culdocentesis, a technique in which a needle is inserted just posterior to the cervix through the vaginal wall into the peritoneal cavity, has been used to evaluate intraperitoneal hemorrhage (e.g., ruptured ectopic pregnancy, hemorrhagic corpus luteum, other intraabdominal bleeding), pus (e.g., pelvic inflammatory disease, ruptured intraabdominal abscess), or other intraabdominal fluid (e.g., ascites). Incision into the peritoneal cavity from this location in the vagina, known as a posterior colpotomy, can be used as an adjunct to laparoscopic excision of adnexal masses, with removal of the mass intact through the posterior vagina.

The vagina is attached to the lateral pelvic wall with endopelvic fascial connections to the arcus tendineus (white line), which extends from the pubic bone to the ischial spine. This connection converts the vaginal lumen into a transverse slit with the anterior and posterior walls in apposition; the lateral space where the two walls meet is the vaginal sulcus. Lateral detachments of the vagina are recognized in some cytologic formation.

The opening of the vagina may be covered by a membrane or surrounded by a fold of connective tissue called the hymen. This tissue is usually replaced by irregular tissue tags later in life as sexual activity and childbirth occur. The lower vagina is somewhat constricted as it passes through the urogenital hiatus in the pelvic diaphragm; the upper vagina is more spacious. However, the entire vagina is characterized by its distensibility, which is most evident during childbirth.

The vagina is closely applied anteriorly to the urethra, bladder neck and trigonal region, and posterior bladder; posteriorly, the vagina lies in association with the perineal body, anal canal, lower rectum, and posterior cul-de-sac. It is separated from both the lower urinary and gastrointestinal tracts by their investing layers of fibromuscular elements known as the endopelvic fascia.

The vagina is composed of three layers:

1. **Mucosa**—nonkeratinized stratified squamous epithelium, without glands. Vaginal lubrication occurs by transudation primarily, with contributions from cervical and Bartholin gland secretions. The mucosa has a characteristic pattern of transverse ridges and furrows, known as rugae. It is hormonally sensitive, responding to stimulation by estrogen with proliferation and maturation. The mucosa is colonized by mixed bacterial flora with lactobacillus predominant; normal pH is 3.5 to 4.5.
2. **Muscularis**—contains connective tissue and smooth muscle, loosely arranged in inner circular and outer longitudinal layers.
3. **Adventitia**—consists of endopelvic fascia, adherent to the underlying muscularis.

**Blood Supply** The blood supply of the vagina includes the vaginal artery and branches from the uterine, middle rectal, and internal pudendal arteries.

**Innervation** The innervation of the vagina is as follows: the upper vagina—uterovaginal plexus; the distal vagina—pudendal nerve.

**Uterus**

The uterus is a fibromuscular organ usually divided into a lower cervix and an upper corpus or uterine body (Fig. 5.14).

![Figure 5.14 The uterus, fallopian tubes, and ovaries.](image)

**Cervix**

The portion of cervix exposed to the vagina is the excocervix or portio vaginalis, It has a convex round surface with a circular or slitlike opening (the external os) into the endocervical canal. The endocervical canal is about 2 to 3 cm in length and opens proximally into the endometrial cavity at the internal os.

The cervical mucosa generally contains both stratified squamous epithelium, characteristic of the excocervix, and mucus-secreting columnar epithelium, characteristic of the endocervical canal. However, the intersection where these two epithelia meet—the squamocolumnar junction—is geographically variable and dependent on hormonal stimulation. It is this dynamic interface, the transformation zone, that is most vulnerable to the development of squamous neoplasia.

In early childhood, during pregnancy, or with oral contraceptive use, columnar epithelium may extend from the endocervical canal onto the exocervix, a condition described in terms of positioning—anterior, midposition, or posterior; flexion; and version. Flexion is the angle between the long axis of the uterine corpus and the cervix, whereas version is the angle of the junction of the uterus with the upper vagina. Occasionally, abnormal positioning may occur secondary to associated pelvic pathology, such as endometriosis or adhesions.

Cervical mucus production is under hormonal influence. It varies from profuse, clear, and thin mucus around the time of ovulation to scant and thick mucus in the postovulatory phase of the cycle. Deep in the mucosa and submucosa, the cervix is composed of fibrous connective tissue and a small amount of smooth muscle in a circular arrangement.

**Corpus**

The body of the uterus varies in size and shape, depending on hormonal and childbearing status. At birth, the cervix and corpus are about equal in size; in adult women, the corpus has grown to 2 to 3 times the size of the cervix. The position of the uterus in relation to other pelvic structures is also variable and is generally described in terms of positioning—anterior, midposition, or posterior; flexion; and version. Flexion is the angle between the long axis of the uterine corpus and the cervix, whereas version is the angle of the junction of the uterus with the upper vagina. Occasionally, abnormal positioning may occur secondary to associated pelvic pathology, such as endometriosis or adhesions.

The uterine corpus is divided into several different regions. The area where the endocervical canal opens into the endometrial cavity is known as the isthmus or lower uterine segment. On each side of the upper uterine body, a funnel-shaped area receives the insertion of the fallopian tubes and is called the uterine cornu; the uterus above this area is the fundus.

The endometrial cavity is triangular in shape and represents the mucosal surface of the uterine corpus. The epithelium is columnar and gland forming with a specialized stroma. It undergoes cyclic structural and functional change during the reproductive years, with regular shedding of the superficial endometrium and regeneration from the basal layer.

The muscular layer of the uterus, the myometrium, consists of interlacing smooth muscle fibers and ranges in thickness from 1.5 to 2.5 cm. Some outer fibers are continuous with those of the tube and round ligament.
Peritoneum covers most of the corpus of the uterus and the posterior cervix and is known as the serosa. Laterally, the broad ligament, a double layer of peritoneum covering the neurovascular supply to the uterus, inserts into the cervix and corpus. Anteriorly, the bladder lies over the isthmic and cervical region of the uterus.

**Blood Supply** The blood supply to the uterus is the uterine artery, which anastomoses with the ovarian and vaginal arteries.

**Innervation** The nerve supply to the uterus is the uterovaginal plexus.

---

**Falloplian Tubes**

The fallopian tubes and ovaries collectively are referred to as the adnexa. The fallopian tubes are paired hollow structures representing the proximal unfused ends of the müllerian duct. They vary in length from 7 to 12 cm, and their function includes ovum pickup, provision of physical environment for conception, and transport and nourishment of the fertilized ovum.

The tubes are divided into several regions:

1. **Interstitial**—narrowest portion of the tube, lies within the uterine wall and forms the tubal ostia at the endometrial cavity.
2. **Isthmus**—narrow segment closest to the uterine wall.
3. **Ampulla**—larger diameter segment lateral to the isthmus.
4. **Fimbria (infundibulum)**—funnel-shaped abdominal ostia of the tubes, opening into the peritoneal cavity; this opening is fringed with numerous finger-like projections that provide a wide surface for ovum pickup. The fimbria ovarica is a connection between the end of the tube and ovary, bringing the two closer.

The tubal mucosa is ciliated columnar epithelium, which becomes progressively more architecturally complex as the fimbriated end is approached. The muscularis consists of an inner circular and outer longitudinal layer of smooth muscle. The tube is covered by peritoneum and, through its mesentery (mesosalpinx), which is situated dorsal to the round ligament, is connected to the upper margin of the broad ligament.

**Blood Supply** The vascular supply to the fallopian tubes is the uterine and ovarian arteries.

**Innervation** The innervation to the fallopian tubes is the uterovaginal plexus and the ovarian plexus.

---

**Ovaries**

The ovaries are paired gonadal structures that lie suspended between the pelvic wall and the uterus by the infundibulopelvic ligament laterally and the uteroovarian ligament medially. Inferiorly, the hilar surface of each ovary is attached to the broad ligament by its mesentery (mesovarium), which is dorsal to the mesosalpinx and fallopian tube. Primary neurovascular structures reach the ovary through the infundibulopelvic ligament and enter through the mesovarium. The normal ovary varies in size, with measurements up to 5 × 3 × 3 cm. Variation in dimension results from endogenous hormonal production, which varies with age and with each menstrual cycle. Exogenous substances, including oral contraceptives, gonadotropin-releasing hormone agonists, or ovulation-inducing medication, may either stimulate or suppress ovarian activity and, therefore, affect size.

Each ovary consists of a cortex and medulla and is covered by a single layer of flattened cuboidal to low columnar epithelium that is continuous with the peritoneum at the mesovarium. The cortex is composed of a specialized stroma and follicles in various stages of development or attrition. The medulla occupies a small portion of the ovary in its hilar region and is composed primarily of fibromuscular tissue and blood vessels.

**Blood Supply** The blood supply to the ovary is the ovarian artery, which anastomoses with the uterine artery.

**Innervation** The innervation to the ovary is the ovarian plexus and the uterovaginal plexus.

---

**Urinary Tract**

**Ureters**

The ureter is the urinary conduit leading from the kidney to the bladder; it measures about 25 cm in length and is totally retroperitoneal in location.

The lower half of each ureter traverses the pelvis after crossing the common iliac vessels at their bifurcation, just medial to the ovarian vessels. It descends into the pelvis adherent to the peritoneum of the lateral pelvic wall and the medial leaf of the broad ligament and enters the bladder base anterior to the upper vagina, traveling obliquely through the bladder wall to terminate in the bladder trigone.

The ureteral mucosa is a transitional epithelium. The muscularis consists of an inner longitudinal and outer circular layer of smooth muscle. A protective connective tissue sheath, which is adherent to the peritoneum, encloses the ureter.

**Blood Supply** The blood supply is variable, with contributions from the renal, ovarian, common iliac, internal iliac, uterine, and vesical arteries.

**Innervation** The innervation is through the ovarian plexus and the vesical plexus.

---

**Bladder and Urethra**

**Bladder**

The bladder is a hollow organ, spherically shaped when full, that stores urine. Its size varies with urine volume, normally reaching a maximum volume of at least 500 mL. The bladder is often divided into two areas, which are of physiologic significance:

1. The **base of the bladder** consists of the urinary trigone posteriorly and a thickened area of detrusor anteriorly. The three corners of the trigone are formed by the two ureteral orifices and the opening of the urethra into the bladder. The bladder base receives a-adrenergic sympathetic innervation and is the area responsible for maintaining continence.
2. The **dome of the bladder** is the remaining bladder area above the bladder base. It has parasympathetic innervation and is responsible for micturition.

The bladder is positioned posterior to the pubis and lower abdominal wall and anterior to the cervix, upper vagina, and part of the cardinal ligament. Laterally, it is bounded by the pelvic diaphragm and obturator internus muscle.

The bladder mucosa is transitional cell epithelium and the muscle wall (detrusor). Rather than being arranged in layers, it is composed of intermeshing muscle fibers.

**Blood Supply** The blood supply to the bladder is from the superior, middle, and inferior vesical arteries, with contribution from the uterine and vaginal vessels.

**Innervation** The innervation to the bladder is from the vesical plexus, with contribution from the uterovaginal plexus.

**Urethra**

The vesical neck is the region of the bladder that receives and incorporates the urethral lumen. The female urethra is about 3 to 4 cm in length and extends...
from the bladder to the vestibule, traveling just anterior to the vagina.

The urethra is lined by nonkeratinized squamous epithelium that is responsive to estrogen stimulation. Within the submucosa on the dorsal surface of the urethra are the paraurethral or Skene glands, which empty through ducts into the urethral lumen. Distally, these glands empty into the vestibule on either side of the external urethral orifice. Chronic infection of Skene glands, with obstruction of their ducts and cystic dilation, is believed to be an inciting factor in the development of suburethral diverticula.

The urethra contains an inner longitudinal layer of smooth muscle and outer, circularly oriented smooth muscle fibers. The inferior fascia of the urogenital diaphragm or perineal membrane begins at the junction of the middle and distal thirds of the urethra. Proximal to the middle and distal parts of the urethra, voluntary muscle fibers derived from the urogenital diaphragm intermix with the outer layer of smooth muscle, increasing urethral resistance and contributing to continence. At the level of the urogenital diaphragm, the skeletal muscle fibers leave the wall of the urethra to form the sphincter urethrae and deep transverse perineal muscles.

**Blood Supply**
The vascular supply to the urethra is from the vesical and vaginal arteries and the internal pudendal branches.

**Innervation**
The innervation to the urethra is from the vesical plexus and the pudendal nerve.

The lower urinary and genital tracts are intimately connected anatomically and functionally. In the midline, the bladder and proximal urethra can be dissected easily from the underlying lower uterine segment, cervix, and vagina through a loose avascular plane. The distal urethra is essentially inseparable from the vagina. Of surgical significance is the location of the bladder trigone immediately over the middle third of the vagina. Unrecognized injury to the bladder during pelvic surgery may result in development of a vesicovaginal fistula.

Fortunately, dissection to the level of the trigone is rarely required, and damage to this critical area is unusual. If dissection is carried too far laterally away from the midline, attachments between the bladder and cervix or vagina become much more dense and vascularized, resulting in increased blood loss and technical difficulty.

---

**Lower Gastrointestinal Tract**

**Sigmoid Colon**

The sigmoid colon begins its characteristic S-shaped curve as it enters the pelvis at the left pelvic brim (Fig. 5.15). The columnar mucosa and richly vascularized submucosa are surrounded by an inner circular layer of smooth muscle and three overlying longitudinal bands of muscle called tenia coli. A mesentery of varying length attaches the sigmoid to the posterior abdominal wall.

![Figure 5.15 The rectosigmoid colon, its vascular supply, and muscular support. (Coronal view: peritoneum removed on right.)](image)

**Blood Supply**
The blood supply to the sigmoid colon is from the sigmoid arteries.

**Innervation**
The nerves to the sigmoid colon are derived from the inferior mesenteric plexus.

**Rectum**

The sigmoid colon loses its mesentery in the midsacral region and becomes the rectum about 15 to 20 cm above the anal opening. The rectum follows the curve of the lower sacrum and coccyx and becomes entirely retroperitoneal at the level of the rectouterine pouch or posterior cul-de-sac. It continues along the pelvic curve just posterior to the vagina until the level of the anal hiatus of the pelvic diaphragm, at which point it takes a sharp 90-degree turn posteriorly and becomes the anal canal, separated from the vagina by the perineal body.

The rectal mucosa is columnar epithelium characterized by three transverse folds that contain mucosa, submucosa, and the inner circular layer of smooth muscle. The tenia of the sigmoid wall broaden and fuse over the rectum to form a continuous longitudinal external layer of smooth muscle to the level of the anal canal.

**Anal Canal**

The anal canal begins at the level of the sharp turn in the direction of the distal colon and is 2 to 3 cm in length. At the anorectal junction, the mucosa changes to stratified squamous epithelium (the pectinate line), which continues until the termination of the anus at the anal verge, where there is a transition to perianal skin with typical skin appendages. It is surrounded by a thickened ring of circular muscle fibers that is a continuation of the circular muscle of the rectum, the internal anal sphincter. Its lower part is surrounded by bundles of striated muscle fibers, the external anal sphincter (Fig. 5.15).

**Fecal continence is primarily provided by the puborectalis muscle and the internal and external anal sphincters.** The puborectalis surrounds the anal hiatus in the pelvic diaphragm and interdigitates posterior to the rectum to form a rectal sling. The external anal sphincter surrounds the terminal anal canal below the level of the levator ani.

The practicing gynecologist must be familiar with the lower gastrointestinal tract because of its anatomic proximity to the lower genital tract. This is particularly important during surgery of the vulva and vagina. Lack of attention to this proximity during repair of vaginal lacerations or episiotomies can lead to damage of the rectum and resulting fistula formation or injury to the external anal sphincter with development of fecal incontinence. Because of the avascular nature of the rectovaginal space, it is relatively easy to dissect the rectum from the vagina in the midline, which is routinely done in the repair of rectoceles.

**Blood Supply**
The vascular supply to the rectum and anal canal is from the superior, middle, and inferior rectal arteries. The venous drainage is a complex submucosal plexus of vessels that, under conditions of increased intraabdominal pressure (pregnancy, pelvic mass, ascites), may dilate and become symptomatic with rectal bleeding or pain as hemmorhoids.

**Innervation**
The nerve supply to the anal canal is from the middle rectal plexus, the inferior mesenteric plexus, and the pudendal nerve.

---

**The Genital Tract and Its Relations**

The genital tract is situated at the bottom of the intraabdominal cavity and is related to the intraperitoneal cavity and its contents, the retroperitoneal spaces, and the...
pelvic floor. Its access through the abdominal wall or the perineum requires a thorough knowledge of the anatomy of these areas and their relationships.

**The Abdominal Wall**

The anterior abdominal wall is bound superiorly by the xiphoid process and the costal cartilage of the seventh to tenth ribs and inferiorly by the iliac crest, anterosuperior iliac spine, inguinal ligament, and pubic bone. It consists of skin, muscle, fascia, and nerves and vessels.

**Skin**

The lower abdominal skin may exhibit striae, or “stretch marks,” and increased pigmentation in the midline in parous women. The subcutaneous tissue contains a variable amount of fat.

**Muscles**

Five muscles and their aponeuroses contribute to the structure and strength of the anterolateral abdominal wall (Fig. 5.16; Table 5.7).

**Fascia**

**Superficial Fascia**

The superficial fascia consists of two layers:

1. **Camper fascia**—the most superficial layer, which contains a variable amount of fat and is continuous with the superficial fatty layer of the perineum
2. **Scarpa fascia**—a deeper membranous layer continuous in the perineum with Colles fascia (superficial perineal fascia) and with the deep fascia of the thigh (fascia lata).

**Rectus Sheath**

The aponeuroses of the external and internal oblique and the transversus abdominis combine to form a sheath for the rectus abdominis and pyramidalis, fusing medially in the midline at the linea alba and laterally at the semilunar line (Fig. 5.17). Above the arcuate line, the aponeurosis of the internal oblique muscle splits into anterior and posterior lamella (Fig. 5.17A). Below this line, all three layers are anterior to the body of the rectus muscle (Fig. 5.17B). The rectus is then covered posteriorly by the transversalis fascia, providing access to the muscle for the inferior epigastric vessels.

**Transversalis Fascia and Endopelvic Fascia**

The transversalis fascia is a firm membranous sheet on the internal surface of the transversus abdominis muscle that extends beyond the muscle and forms a fascia lining the entire abdominopelvic cavity. Like the peritoneum, it is divided into a parietal and a visceral component. It is continuous from side to side across the linea alba and covers the posterior aspect of the rectus abdominis muscle below the arcuate line. Superiorly, it becomes the inferior fascia of the diaphragm. Inferiorly, it is

![Figure 5.16](image1.png)  
**Figure 5.16** The abdominal wall muscles.

![Figure 5.17](image2.png)  
**Figure 5.17** A transverse section of the rectus abdominis. The aponeurosis of the external and internal oblique and the transversus abdominis from the rectus abdominis. A: Above the arcuate line. B: Below the arcuate line.
attached to the iliac crest, covers the iliac fascia and the obturator internus fascia, and extends downward and medially to form the superior fascia of the pelvic diaphragm.

Characteristically, the transversalis fascia continues along blood vessels and other structures leaving and entering the abdominopelvic cavity and contributes to the formation of the visceral (endopelvic) pelvic fascia (19). The pelvic fascia invests the pelvic organs and attaches them to the pelvic sidewalls, thereby playing a critical role in pelvic support. In the inguinal region, the fascial relationships result in the development of the inguinal canal, through which the round ligament exits into the perineum. The fascia is separated from the peritoneum by a layer of preperitoneal fat. Areas of fascial weaknesses or congenital or posttraumatic and surgical injuries result in herniation of the underlying structures through a defective abdominal wall. The incisions least likely to result in damage to the integrity and innervation of the abdominal wall muscles include a midline incision through the linea alba and a transverse incision through the recti muscle fibers that respects the integrity of its innervation (14).

Nerves and Vessels

The tissues of the abdominal wall are innervated by the continuation of the inferior intercostal nerves T4 to T11 and the subcostal nerve T12. The inferior part of the abdominal wall is supplied by the first lumbar nerve through the iliohypogastric and the ilioinguinal nerves. The primary blood supply to the anterior lateral abdominal wall includes the following:

1. The inferior epigastric and deep circumflex iliac arteries, branches of the external iliac artery
2. The superior epigastric artery, a terminal branch of the internal thoracic artery

The inferior epigastric artery runs superiorly in the transverse fascia to reach the arcuate line, where it enters the rectus sheath. It is vulnerable to damage with abdominal incisions in which the rectus muscle is completely or partially transected or with excessive lateral traction on the rectus. The deep circumflex artery runs on the deep aspect of the anterior abdominal wall parallel to the inguinal ligament and along the iliac crest between the transverse abdominis muscle and the internal oblique muscle. The superior epigastric vessels enter the rectus sheath superiorly just below the seventh costal cartilage.

The venous system drains into the saphenous vein, and the lymphatics drain to the axillary chain above the umbilicus and to the inguinal nodes below it. The subcutaneous tissues drain to the lumbar chain.

Perineum

The perineum is situated at the lower end of the trunk between the buttocks. Its bony boundaries include the lower margin of the pubic symphysis anteriorly, the tip of the coccyx posteriorly, and the ischial tuberosities laterally. These landmarks correspond to the boundaries of the pelvic outlet. The diamond shape of the perineum is customarily divided by an imaginary line joining the ischial tuberosities immediately in front of the anus, at the level of the perineal body, into an anterior urogenital and a posterior anal triangle (Fig. 5.18).

Urogenital Triangle

The urogenital triangle includes the external genital structures and the urethral opening (Fig. 5.18). These external structures cover the superficial and deep perineal compartments (Fig. 5.19 and Fig. 5.20) and are known as the vulva.

Vulva
Mons Pubis
The mons pubis is a triangular eminence in front of the pubic bones that consists of adipose tissue covered by hair-bearing skin up to its junction with the abdominal wall.

Labia Majora
The labia majora are a pair of fibroadipose folds of skin that extend from the mons pubis downward and backward to meet in the midline in front of the anus at the posterior fourchette. They include the terminal extension of the round ligament and occasionally a peritoneal diverticulum, the canal of Nuck. They are covered by skin with scattered hairs laterally and are rich in sebaceous, apocrine, and eccrine glands.

Labia Minora
The labia minora lie between the labia majora, with which they merge posteriorly and are separated into two folds as they approach the clitoris anteriorly. The anterior folds unite to form the prepuce or hood of the clitoris. The posterior folds form the frenulum of the clitoris as they attach to its inferior surface. The labia minora are covered by hairless skin overlying a fibroelastic stroma rich in neural and vascular elements. The area between the posterior labia minora forms the vestibule of the vagina.

Clitoris
The clitoris is an erectile organ that is 2 to 3 cm in length. It consists of two crura and two corpora cavernosa and is covered by a sensitive rounded tubercle (the glans).

Vaginal Orifice
The vaginal orifice is surrounded by the hymen, a variable crescentic mucous membrane that is replaced by rounded caruncles after its rupture. The opening of the duct of the greater vestibular (Bartholin) glands is located on each side of the vestibule. Numerous lesser vestibular glands are also scattered posteriorly and between the urethral and vaginal orifices.

Urethral Orifice
The urethral orifice is immediately anterior to the vaginal orifice about 2 to 3 cm beneath the clitoris. The Skene (paraurethral) gland duct presents an opening on its posterior surface.

Superficial Perineal Compartment
The superficial perineal compartment lies between the superficial perineal fascia and the inferior fascia of the urogenital diaphragm (perineal membrane) (Fig. 5.19). The superficial perineal fascia has a superficial and deep component. The superficial layer is relatively thin and fatty and is continuous superiorly with the superficial fatty layer of the lower abdominal wall (Camper fascia). It continues laterally as the fatty layer of the thighs. The deep layer of the superficial perineal (Colles) fascia is continuous superiorly with the deep layer of the superficial abdominal fascia (Scarpa fascia), which attaches firmly to the ischiopubic rami and ischiatic tuberosities. The superficial perineal compartment is continuous superiorly with the superficial fascial spaces of the anterior abdominal wall, allowing spread of blood or infection along that route. Such spread is limited laterally by the ischiopubic rami, anteriorly by the transverse ligament of the perineum, and posteriorly by the superficial transverse perineal muscle. The superficial perineal compartment includes the following.

Erectile Bodies
The vestibular bulbs are 3-cm, highly vascular structures surrounding the vestibule and located under the bulbocavernosus muscle. The body of the clitoris is attached by two crura to the internal aspect of the ischiopubic rami. They are covered by the ischiocavernous muscle.

Muscles
The muscles of the vulva are the ischiocavernosus, the bulbocavernosus, and superficial transverse perineal.

Ischiocavernosus
- Origin—ischial tuberosity
- Insertion—ischiopubic bone
- Action—compresses the crura and lowers the clitoris

Bulbocavernosus
- Origin—perineal body
- Insertion—posterior aspect of the clitoris; some fibers pass above the dorsal vein of the clitoris in a slinglike fashion
- Action—compresses the vestibular bulb and dorsal vein of the clitoris

Superficial Transverse Perineal
- Origin—ischial tuberosity
- Insertion—central perineal tendon
- Action—fixes the perineal body

Vestibular Glands
The vestibular glands are situated on either side of the vestibule under the posterior end of the vestibular bulb. They drain between the hymen and the labia minora. Their mucus secretion helps maintain adequate lubrication. Infection in these glands can result in an abscess.

Deep Perineal Compartment
The deep perineal compartment is a fascial space bound inferiorly by the perineal membrane and superiorly by a deep fascial layer that separates the urogenital diaphragm from the anterior recess of the ischiorectal fossa (Fig. 5.20). It is stretched across the anterior half of the pelvic outlet between the ischiopubic rami. The deep compartment may be directly continuous with the pelvic cavity superiorly (19). Indeed, the posterior pubourethral ligaments, functioning as winglike elevations of the fascia ascending from the pelvic floor to the posterior aspect of the symphysis pubis, provide a point of fixation to the urethra and support the concept of the continuity of the deep perineal compartment with the pelvic cavity.

The anterior pubourethral ligaments represent a similar elevation of the inferior fascia of the urogenital diaphragm and are joined by the intermediate pubourethral ligament, with the junction between the two fascial structures arcing under the pubic symphysis (19). The urogenital diaphragm includes the sphincter urethrae (urogenital sphincter) and the deep transverse perineal (transversus vaginae) muscle.
The sphincter urethrae is a continuous muscle fanning out as it develops proximally and distally, including the following:

- The external urethral sphincter, which surrounds the middle third of the urethra
- The compressor urethrae, arcing across the ventral side of the urethra
- The urethrovaginal sphincter, which surrounds the ventral aspect of the urethra and terminates in the lateral vaginal wall

The deep transverse perineal muscle originates at the internal aspect of the ischial bone, parallels the muscle compressor urethrae, and attaches to the lateral vaginal wall along the perineal membrane.

There is a common reliance of the urinary and genital tracts on several interdependent structures for support. The cardinal and uterosacral ligaments are condensations of endopelvic fascia that support the cervix and upper vagina over the levator plate. Laterally, endopelvic fascial condensations attach the midvagina to the pelvic walls at the arcus tendineus fascia pelvis anteriorly and the arcus tendineus levator ani posteriorly. The distal anterior vagina and urethra are anchored to the urogenital diaphragm, and the distal posterior vagina to the perineal body.

Anteriorly, the pubourethral ligaments and pubovesical fascia and ligaments provide fixation and stabilization for the urethra and bladder. Posteriorly, they rely on the vagina and lower uterus for support. Partial resection or relaxation of the uterosacral ligaments often leads to relaxation of the genitourinary complex, resulting in the formation of a cystocele. Various types and degrees of genit tract prolapse or relaxation are almost always associated with similar findings in the bladder, urethra, or both.

**Blood Supply**
The blood supply to the vulva is as follows:

1. External pudendal artery (from femoral artery), internal pudendal artery
2. Venous drainage—internal pudendal veins

The blood supply to the superficial and deep perineal compartments is as follows:

1. Internal pudendal artery, dorsal artery of the clitoris
2. Venous drainage—internal pudendal veins, which are richly anastomotic
3. Lymphatic drainage—internal iliac chain

**Innervation**
The innervation to the vulva is from branches of the following nerves:

1. Iliinguinal nerve
2. Genitofemoral nerve (genital branch)
3. Lateral femoral cutaneous nerve of the thigh (perineal branch)
4. Perineal nerve (branch of pudendal)

Superficial and deep perineal compartments are innervated by the perineal nerve.

---

**Perineal Body**
The perineal body or central perineal tendon is critical to the posterior support of the lower aspect of the anterior vaginal wall. It is a triangle-shaped structure separating the distal portion of the anal and vaginal canals that is formed by the convergence of the tendinous attachments of the bulbocavernous, the external anal sphincter, and the superficial transverse perinei muscle. Its superior border represents the point of insertion of the rectovaginal (Denovilliers) fascia, which extends to the underside of the peritoneum covering the cul-de-sac of Douglas, separating the anorectal from the urogenital compartment (Fig. 5.21). The perineal body also plays an important anchoring role in the muscular fasical support of the pelvic floor. It represents the central connection between the two layers of support of the pelvic floor—the pelvic and urogenital diaphragm. It also provides a posterior connection to the anococcygeal raphe. Thus, it is central to the definition of the biletvel support of the floor of the pelvis.

**Anal Triangle**
The anal triangle includes the lower end of the anal canal. The external anal sphincter surrounds the anal triangle, and the ischiorectal fossa is on each side.

Posteriorly, the anococcygeal body lies between the anus and the tip of the coccyx and consists of thick fibromuscular tissue (of levator ani and external anal sphincter origin) giving support to the lower part of the rectum and the anal canal.

The external anal sphincter forms a thick band of muscular fibers arranged in three layers running from the perineal body to the anococcygeal ligament. The subcutaneous fibers are thin and surround the anus and, without bony attachment, decussate in front of it. The superficial fibers sweep forward from the anococcygeal ligament, and the tip of the coccyx around the anus inserts into the perineal body. The deep fibers arise from the perineal body to encircle the lower half of the anal canal to form a true sphincter muscle, which fuses with the puborectalis portion of the levator ani.

The ischiorectal fossa is mainly occupied by fat and separates the ischium laterally from the median structures of the anal triangle. It is a fascia-lined space located between the perineal skin inferiorly and the pelvic diaphragm superiorly; it communicates with the contralateral ischiorectal fossa over the anococcygeal ligament. Superiorly, its apex is at the origin of the levator ani muscle from the obturator fascia. It is bound medially by the levator ani and the external sphincter with their fascial covering, laterally by the obturator internus muscle with its fascia, posteriorly by the sacrotuberous ligament and the lower border of the gluteus maximus muscle, and anteriorly by the base of the urogenital diaphragm. It is widest and deepest posteriorly and weakest medially. Thus, an ischiorectal abscess should be drained without delay, or it will extend into the anal canal. The cavity is filled with fat that cushions the anal canal and is traversed by many fibrous bands, vessels, and nerves, including the pudendal and the inferior rectal nerves. The perforating branch of S2 and S3 and the perineal branch of S4 also run through this space.

The pudendal (Alcock) canal is a tunnel formed by a splitting of the inferior portion of the obturator fascia running anteromedially from the ischial spine to the posterior
edge of the urogenital diaphragm. It contains the pudendal artery, vein, and nerve in their traverse from the pelvic cavity to the perineum.

**Blood Supply** The blood supply to the anal triangle is from the inferior rectal (hemorrhoidal) artery and vein.

**Innervation** The innervation to the anal triangle is from the perineal branch of the fourth sacral nerve and the inferior rectal (hemorrhoidal) nerve.

### Retroperitoneum and Retroperitoneal Spaces

The subperitoneal area of the true pelvis is partitioned into potential spaces by the various organs and their respective fascial coverings and by the selective thickenings of the endopelvic fascia into ligaments and septa (Fig. 5.22). It is imperative that surgeons operating in the pelvis be familiar with these spaces, which include the following:

#### Prevesical Space

The prevesical (Retzius) space is a fat-filled potential space bound anteriorly by the pubic bone, covered by the transversalis fascia, and extending to the umbilicus between the medial umbilical ligaments (obliterated umbilical arteries); posteriorly, the space extends to the anterior wall of the bladder. It is separated from the paravesical space by the ascending bladder septum (bladder pillars).

Upon entering the prevesical space, the pubourethral ligaments may be seen inserting the posterior aspect of the symphysis pubis as a thickened prolongation of the arcus tendineus fascia. With combined abdominal and vaginal bladder neck suspensory procedures, the point of entry is usually the Retzius space between the arcus tendineus and the pubourethral ligaments.

#### Paravesical Space

The paravesical spaces are fat-filled and limited by the fascia of the obturator internus muscle and the pelvic diaphragm laterally, the bladder pillar medially, the endopelvic fascia inferiorly, and the lateral umbilical ligament superiorly.

#### Vesicovaginal Space

The vesicovaginal space is separated from the Retzius space by the endopelvic fascia. This space is limited anteriorly by the bladder wall (from the proximal urethra to the upper vagina), posteriorly by the anterior vaginal wall, and laterally by the bladder septa (selective thickenings of the endopelvic fascia inserting laterally into the arcus tendineus). A tear in these fascial investments and thickenings medially, transversely, or laterally allows herniation and development of a cystocele.

#### Rectovaginal Space

The rectovaginal space extends between the vagina and the rectum from the superior border of the perineal body to the underside of the rectouterine Douglas pouch. It is bound anteriorly by the rectovaginal septum (firmly adherent to the posterior aspect of the vagina), posteriorly by the anterior rectal wall, and laterally by the descending rectal septa separating the rectovaginal space from the pararectal space on each side. The rectovaginal septum represents a firm membranous transverse septum dividing the pelvis into rectal and urogenital compartments, allowing the independent function of the vagina and rectum and providing support for the rectum. It is fixed laterally to the pelvic sidewall by rectovaginal fascia (part of the endopelvic fascia) along a line extending from the posterior fourchette to the arcus tendineus fasciae pelvis, midway between the pubis and the ischial spine (18). An anterior rectocele often results from a defective septum or an avulsion of the septum from the perineal body. Reconstruction of the perineum is critical for the restoration of this important compartmental separation as well as for the support of the anterior vaginal wall (19). Lateral detachment of the rectovaginal fascia from the pelvic sidewall may constitute a “pararectal” defect analogous to anterior paravaginal defects.

#### Pararectal Space

The pararectal space is bound laterally by the levator ani, medially by the rectal pillars, and posteriorly above the ischial spine by the anterolateral aspect of the sacrum. It is separated from the retrorectal space by the posterior extension of the descending rectal septa.

#### Retrorectal Space

The retrorectal space is limited by the rectum anteriorly and the anterior aspect of the sacrum posteriorly. It communicates with the pararectal spaces laterally above the uterosacral ligaments and extends superiorly into the presacral space.

#### Presacral Space

The presacral space is the superior extension of the retrorectal space and is limited by the deep parietal peritoneum anteriorly and the anterior aspect of the sacrum posteriorly. It harbors the middle sacral vessels and the hypogastric plexi between the bifurcation of the aorta invested by loose areolar tissue. Presacral neurectomy requires a good familiarity and working knowledge of this space.

#### Peritoneal Cavity

The female pelvic organs lie at the bottom of the abdominopelvic cavity covered superiorly and posteriorly by the small and large bowel. Anteriorly, the uterine wall is in contact with the posteriuperior aspect of the bladder. The uterus is held in position by the following structures:

1. The round ligaments coursing inferolaterally toward the internal inguinal ring
2. The **uterosacral ligaments**, which provide support to the cervix and upper vagina and interdigitate with fibers from the cardinal ligament near the cervix.
3. The **cardinal ligaments**, which provide support to the cervix and upper vagina and contribute to the support of the bladder.

Anteriorly, the uterus is separated from the bladder by the vesicouterine pouch and from the rectum posteriorly by the rectouterine pouch or Douglas cul-de-sac. Laterally, the bilateral broad ligaments carry the neurovascular pedicles and their respective fascial coverings, attaching the uterus to the lateral pelvic sidewall.

The broad ligament is in contact inferiorly with the paravesical space, the obturator fossa, and the pelvic extension of the iliac fossa, to which it provides a peritoneal covering, and with the uterosacral ligament. Superiorly, it extends into the infundibulopelvic ligament.

## Ureter

In its pelvic path, in the retroperitoneum, several relationships are of significance and identify areas of greatest vulnerability to injury of the ureter (Fig. 5.23):

1. The ovarian vessels cross over the ureter as it approaches the pelvic brim and lie in proximity just lateral to the ureter as it enters the pelvis.
2. As the ureter descends into the pelvis, it runs within the broad ligament just lateral to the uterosacral ligament, separating the uterosacral ligament from the mesosalpinx, mesovarium, and ovarian fossa.
3. At about the level of the ischial spine, the ureter crosses under the uterine artery in its course through the cardinal ligament; the ureter divides this area into the supraureteric parametrium surrounding the uterine vessels and the infraureteric paracervix molded around the vaginal vessels and extending posteriorly into the uterosacral ligament. In this location, the ureter lies 2 to 3 cm lateral to the cervix and in proximity to the insertion of the uterosacral ligament at the cervix. This proximity warrants caution when using the uterosacral ligament for vaginal vault suspension (Fig. 5.24).
4. The ureter then turns medially to cross the anterior upper vagina as it traverses the bladder wall.

About 75% of all iatrogenic injuries to the ureter result from gynecologic procedures, most commonly abdominal hysterectomy (21). Distortions of pelvic anatomy, including adnexal masses, endometriosis, other pelvic adhesive disease, or fibroids, may increase susceptibility to injury by displacement or alteration of usual anatomy. Even with severe intraperitoneal disease, however, the ureter can always be identified using a retroperitoneal approach and noting fundamental landmarks and relationships.

## Pelvic Floor

The pelvic floor includes all of the structures closing the pelvic outlet from the skin inferiorly to the peritoneum superiorly. It is commonly divided by the pelvic diaphragm into a pelvic and a perineal portion (22). The pelvic diaphragm is spread transversely in a hammock-like fashion across the true pelvis, with a central hiatus for the urethra, vagina, and rectum. Anatomically and physiologically, the pelvic diaphragm can be divided into two components—the internal and external components.

The **external component** originates from the arcus tendineus, extending from the pubic bone to the ischial spine. It gives rise to fibers of differing directions, including the pubococcygeus, the iliococcygeus, and the coccygeus.

The **internal component** originates from the pubic bone above and medial to the origins of the pubococcygeus and is smaller but thicker and stronger (22). Its fibers run in a sagittal direction and are divided into the following two portions.

- **Pubovaginalis** The fibers of the pubovaginalis run in a perpendicular direction to the urethra, crossing the lateral vaginal wall at the junction of its lower one third and upper two thirds to insert into the perineal body. The intervening anterior interlevator space is covered by the urogenital diaphragm.
- **Puborectalis** The superior fibers of the puborectalis sling around the rectum to the symphysis pubis; its inferior fibers insert into the lateral rectal wall between the internal and external sphincter.

The pelvic diaphragm is covered superiorly by fascia, which includes a parietal and a visceral component and is a continuation of the transversalis fascia (Fig. 5.24). The parietal fascia has areas of thickening (ligaments, septa) that provide reinforcement and fixation for the pelvic floor. The visceral (endopelvic) fascia extends medially to invest the pelvic viscera, resulting in a fascial covering to the bladder, vagina, uterus, and rectum. It becomes attenuated where the peritoneal covering is well defined and continues laterally with the pelvic cellular tissue and neurovascular pedicles.

Musculofascial elements (the hypogastric sheath) extend along the vessels originating from the internal iliac artery. Following these vessels to their respective organs, the hypogastric sheath extends perivascular investments that contribute to the formation of the endopelvic fascia so critical for the support of the pelvic organs.

Thus, the parietal fascia anchors the visceral fascia, which defines the relationship of the various viscera and provides them with significant fixation (uterosacral and
cardinal ligaments), septation (vesicovaginal and rectovaginal), and definition of pelvic spaces (prevesical, vesicovaginal, rectovaginal, paravesical, pararectal, and retorectal).

For its support, the pelvic floor relies on the complementary role of the pelvic diaphragm and its fascia resting on the perineal fibromuscular complex. It is composed of the perineal membrane (urogenital diaphragm) anteriorly, and the perineal body joined to the anococcygeal raphe by the external anal sphincter posteriorly. This double-layered arrangement, when intact, provides optimal support for the pelvic organs and counterbalances the forces pushing them downward with gravity and with any increase in intraabdominal pressure (Fig. 5.25).

Figure 5.25 The double-layered muscular support of the pelvic diaphragm.

Summary

Continuing review and education in anatomy are important for every pelvic surgeon. New surgical approaches are being developed to solve old problems and often require surgeons to revisit familiar anatomy from an unfamiliar perspective (e.g., through a laparoscope) or with a different understanding of complex anatomic relationships. Anatomic alterations secondary to disease, congenital variation, or intraoperative complications may make even familiar surgical territory suddenly seem foreign. All of these situations require surgeons to be perpetual students of anatomy, regardless of breadth or depth of experience.

Several strategies for continuing education in anatomy are suggested:

1. Review relevant anatomy before each surgical procedure.
2. Study the gynecologic literature on an ongoing basis—numerous publications have documented the evolution of newer concepts regarding anatomic issues such as pelvic support.
3. Operate with more experienced pelvic surgeons, particularly when incorporating new surgical procedures into practice.
4. Periodically dissect fresh or fixed cadaveric specimens; this practice can generally be arranged through local or regional anatomy boards or medical schools or by special arrangement at the time of autopsy.

References

Significant scientific advances in molecular biology and genetics have occurred in the recent past. Completion of the human genome project, the emergence of new areas of investigation such as proteomics, and the development of new technologies for the manipulation of cells ex vivo are just some of the accomplishments that will have an impact on the specialty of obstetrics and gynecology. To place the significance of these advances in perspective, one must understand the basic concepts of molecular and cellular biology.

Normal cells are characterized by discrete metabolic, biochemical, and physiologic functions and responses. The observed functions and responses are influenced by the specific cell type and its genetic complement (Fig. 6.1). To orchestrate a coordinated and appropriate response, an external stimulus must be converted to an intracellular signal that is reliably transduced to the nucleus and then converted to specific genetic messages. Through these steps, extracellular signals prompt changes in cellular function, differentiation, and proliferation. Although specific cell types and tissues by definition exhibit unique functions and characteristics, there are also many aspects of cell biology and genetics that are common to all eukaryotic cells.

**Cell Cycle**

**Normal Cell Cycle**

The cell cycle and the factors that influence it are key to cell biology. Control of the cell cycle is the result of multiple levels of complex molecular regulation, most of which is incompletely understood. Progression through the cell cycle occurs through four distinct phases: G₁, S, G₂, and M (Fig. 6.2). The duration of the cell cycle (e.g., the generation time) may be quite variable, although most human cells complete the cell cycle within approximately 24 hours. Variations in cell-cycle time reflect different durations of the G₁ phase. With respect to the cell cycle, there are three subpopulations of cells.
1. **Terminally differentiated cells** cannot reenter the cell cycle.  
2. **Quiescent (G₀) cells** can enter the cell cycle if appropriately stimulated.  
3. **Dividing cells** are currently in the cell cycle.

Red blood cells, striated muscle cells, uterine smooth muscle cells, and nerve cells are terminally differentiated. Other cells, such as fibroblasts, exist in the G₁ phase and are considered to be out of the cell cycle. These cells are stimulated to enter the cell cycle following exposure to specific stimuli, such as growth factors and steroid hormones. Dividing cells are found in the gastrointestinal tract, the skin, and the cervix.

### G₀ Phase

In response to specific external stimuli, cells enter the cell cycle by moving from the G₀ phase into the G₁ phase. The G₁ phase of the cell cycle is characterized by diverse biosynthetic activities. The synthesis of enzymes and regulatory proteins necessary for DNA synthesis occurs during this phase. **Variation in the duration of the G₁ phase of the cell cycle, ranging from less than 8 hours to longer than 100 hours, accounts for the different generation times exhibited by different types of cells.**

### S Phase

The nuclear DNA content of the cell is copied during the S phase of the cell cycle. It is not known what actually triggers the initiation of DNA synthesis, but once it begins, it proceeds as an “all-or-none” phenomenon. Upon completion of this phase, the DNA content of the cell is doubled.

### G₂ Phase

**RNA and protein synthesis** occurs during the G₂ phase of the cell cycle. The burst of biosynthetic activity provides the metabolic substrates and enzymes to meet the metabolic requirements of the two daughter cells. Another important event that occurs during the G₂ phase of the cell cycle is repair of errors of DNA replication that may have occurred during the S phase. Failure to detect and correct these genetic errors can result in a broad spectrum of adverse consequences for the organism as well as the individual cell (1). Defects in the DNA repair mechanism have been associated with an increased incidence of cancer (2).

### M Phase

**During mitosis, or the M phase of the cell cycle, nuclear division occurs.** During this phase, cellular DNA is equally distributed to each of the daughter cells. Mitosis provides a diploid (2n) DNA complement to each somatic daughter cell. Following mitosis, eukaryotic mammalian cells normally contain diploid DNA reflecting a karyotype that includes 44 somatic chromosomes and an XX or XY sex chromosome complement. Exceptions to the diploid cellular content include hepatocytes (4n) and the functional syncytiotrophoblast of the placenta.

### Ploidy

Germ cells contain a haploid (1n) genetic complement after meiosis. After fertilization, a 46,XX or 46,XY diploid DNA complement is restored. Restoration of the normal cellular DNA content is crucial to normal function. Abnormalities of cellular DNA content cause distinct phenotypic abnormalities as exemplified by hydatidiform molar pregnancy (see Chapter 34). With complete hydatidiform mole, an oocyte without any nuclear genetic material (e.g., an empty ovum) is fertilized by one sperm. The haploid genetic content of the fertilized ovum is then duplicated and the diploid cellular DNA content is restored, resulting in a homozygous 46,XX gamete. Less often, a complete hydatidiform mole results from the fertilization of an empty ovum by two sperm, resulting in a heterozygous 46,XX or 46,XY gamete. In complete molar pregnancies, the nuclear DNA is paternally derived, embryonic structures do not develop, and trophoblast hyperplasia occurs. A partial hydatidiform mole follows the fertilization of a haploid ovum by two sperm, resulting in a 69,XXX, 69,XXY, or 69,XYY karyotype. A partial mole contains paternal and maternal DNA, and both embryonic and placental development occur.

Both the 69,YYY karyotype and the 46,YY karyotype are incompatible with embryonic and placental development. These observations indicate the importance of the maternal genetic contribution, in general, and the X chromosome, in particular, to normal embryonic and placental development.

In addition to total cellular DNA content, the chromosome number is an important determinant of cellular function. Abnormalities of chromosome number, which are often the result of nondisjunction during meiosis, result in well-characterized clinical syndromes such as trisomy 21 (Down’s syndrome), trisomy 18, and trisomy 13.

Nuclear division and the allocation of replicated DNA to the daughter cells is closely followed by cytoplasmic division (e.g., cytokinesis). Exceptions are hepatocytes and syncytiotrophoblasts, in which several nuclei exist in a common cytoplasm. After mitosis and completion of cellular division, the daughter cells continue in G₀ phase, or undergo programmed cell death. The option that is pursued by the daughter cell has important implications for the integrity of the tissue and the organ.

### Genetic Control of the Cell Cycle

Cellular proliferation must occur to balance normal cellular loss and maintain tissue and organ integrity. This process requires the coordinated expression of many genes at discrete times during the cell cycle (3). To successfully complete the cell cycle, a number of cell division cycle (cdc) genes are activated. In addition, the cell must traverse two checkpoints, one at the G₁/S boundary and one at the G₂/M boundary (4,5). The G₁/S boundary marks the point at which a cell commits to proliferation and the G₂/M boundary marks the point at which repair of any DNA damage must be completed (6,7).

#### Cell Division Cycle Genes

Among the factors that regulate the cell cycle checkpoints, proteins encoded by the cdc2 family of genes and the cyclin proteins appear to play particularly important roles (8,9). The accumulation and degradation of cyclins regulate the checkpoint at the G₁/S boundary. It has been hypothesized that these proteins bind to specific chromosomal sites. When the chromosomal sites are fully occupied, a critical threshold is exceeded, the free intracellular concentration of cyclins increases, and the cell enters the S phase of the cycle. By an unknown mechanism, cyclins can also inhibit progression through the cell cycle in the presence of DNA damage.

The p53 tumor suppressor gene also appears to participate in delay of the cell cycle in order for DNA repair to be completed. As an example, cells exposed to radiation therapy exhibit an S-phase arrest that is accompanied by increased expression of p53. This delay permits the repair of radiation-induced DNA damage. When the p53 gene is mutated, the S-phase arrest that normally follows radiation therapy does not occur (10,11). A normal p53 gene that is not mutated can be inactivated when human papillomavirus 16 E6 protein is present, and the S-phase arrest in response to ultraviolet-induced DNA damage does not occur (12).

**Mitosis is initiated by activation of the cdc gene at the G₂/M checkpoint** (13,14). The p34cdc2 protein and specific cyclins form a complex heterodimer referred to as mitosis-promoting factor (MPF), which catalyzes protein phosphorylation and drives the cell into mitosis. Once the G₂/M checkpoint has been passed, the cell undergoes mitosis. In the presence of abnormally replicated chromosomes, progression past the G₂/M checkpoint does not occur.

Following cytoplasmic division, the daughter cells exit the cell cycle (e.g., enter the G₀ phase), continue in the G₁ phase of the cell cycle, or undergo programmed cell death. Failure of the progeny cells to respond to the signals that regulate cellular proliferation at this point in the cell cycle is a fundamental characteristic of the neoplastic phenotype.
Apoptosis

The regulation and maintenance of normal tissue mass requires a balance between cell proliferation and programmed cell death, or apoptosis. When proliferation exceeds programmed cell death, the result is hyperplasia. When programmed cell death exceeds proliferation, the result is atrophy. Programmed cell death is a crucial concomitant of normal embryologic development. This mechanism accounts for deletion of the interdigital webs (15), palatal fusion (16), and development of the intestinal mucosa (17). Programmed cell death is also an important phenomenon in normal physiology (18). The reduction in the number of endometrial cells following alterations in steroid hormone levels during the menstrual cycle is, in part, a consequence of programmed cell death (19,20). In response to androgens, granulosa cells undergo programmed cell death (e.g., follicular atresia (21)).

Programmed cell death, or apoptosis, is an energy-dependent, active process that is initiated by the expression of specific genes. It is a process distinct from cell necrosis, although both mechanisms result in a reduction in total cell number. In programmed cell death, cells shrink and undergo phagocytosis. Apoptosis is an energy-dependent process that results from the expression of specific genes. Conversely, in cell necrosis, groups of cells expand and lyse, and it is an energy-independent process that results from noxious stimuli. Programmed cell death is triggered by a variety of factors, including intracellular signals and exogenous stimuli such as radiation exposure, chemotherapy, and hormones. Cells undergoing programmed cell death may be identified on the basis of histologic, biochemical, and molecular biologic changes. Histologically, apoptotic cells exhibit cellular condensation and fragmentation of the nucleus. Biochemical correlates of impending programmed cell death include an increase in transglutaminase expression and fluxes in intracellular calcium concentration. The molecular mechanisms of programmed cell death are the subject of intense investigation (22,23).

Programmed cell death has recently emerged as an important factor in the growth of neoplasia. Historically, neoplastic growth has been characterized by uncontrolled cellular proliferation that resulted in a progressive increase in tumor burden. It is now recognized that the increase in tumor burden associated with progressive disease reflects an imbalance between cell proliferation and cell death. Cancer cells not only fail to respond to the normal signals to stop proliferating, but they may also fail to recognize the physiologic signals that trigger programmed cell death.

Modulation of Cell Growth and Function

The normal cell exhibits an orchestrated response to the changing extracellular environment. The three groups of substances that signal these extracellular changes are steroid hormones, growth factors, and cytokines. The capability to respond to these stimuli requires a cell surface recognition system, an intracellular signal transduction system, and a means to elicit the expression of specific genes in a coordinated fashion to affect changes in cell structure and function.

Oncogenes and Tumor Suppressor Genes

Among the genes that participate in cell growth and function, protooncogenes and tumor suppressor genes are particularly important (24,25, and 26). Protooncogenes encode growth factors, membrane and cytoplasmic receptors, proteins that play key roles in the intracellular signal transduction cascade, and nuclear DNA binding proteins (Table 6.1). More than 50 protooncogene products that contribute to growth regulation have been identified. As a group, protooncogenes exert positive effects upon cellular proliferation. In contradistinction, tumor suppressor genes exert inhibitory regulatory effects on cellular proliferation (Table 6.2).

Steroid Hormones

Steroid hormones play crucial roles in reproductive biology as well as in general physiology. To mention only a few of their roles, steroid hormones influence pregnancy, phenotype, cardiovascular function, bone metabolism, and an individual’s sense of general well-being. Steroid hormone action reflects the intracellular and genetic mechanisms that are necessary for the transduction of an extracellular signal to the nucleus to affect a physiologic response. Estrogen diffuses through the cell membrane and binds to estrogen receptors that are located in the nucleus. The receptor-estrogen complex then binds to the DNA at specific sequences designated as estrogen-response elements (EREs). These steroid-responsive elements are located near the promoter regions of genes that are regulated by estrogen (27). In the uterus, these interactions result in discrete changes in gene expression, protein synthesis, and cellular and tissue function (28). In any estrogen-responsive tissue, the estrogen receptor plays a pivotal role.

The estrogen receptor has been characterized in terms of its molecular biology, structure, function, and tissue distribution. As is the case for all hormone receptors, specificity of action is conferred by the ligand-binding and the DNA-binding domains (EREs). The role of hormone receptors in normal tissue and organ function, as well as their role in the cause and progression of clinically defined estrogen responsive neoplasms, is much more complicated than originally appreciated.

The estrogen receptor actually represents two distinct receptors, E R-a and E R-b that are encoded by different genes on different chromosomes. Both E R-a and E R-b bind estrogen and regulate transcription through interactions with EREs. These receptors exhibit different affinities and responsiveness not only to estrogen but also to selective estrogen receptor modulators (SERMs). Compared with E R-a, the E R-b receptor requires 5- to 10-fold higher concentrations of estradiol for maximal transcriptional activity. Tamoxifen is a mixed agonist/antagonist for E R-a but it is a pure antagonist for E R-b. The E R-b receptor is ubiquitously expressed in hormone-responsive tissues, whereas the expression of E R-a fluctuates in response to the hormonal milieu. The cellular and tissue effects
of an estrogenic compound appear to reflect a dynamic interplay between the actions of these estrogen receptor isoforms. These observations underscore the complexity of estrogen actions with both normal and neoplastic tissue.

Mutations of hormone receptors and their functional consequences illustrate their important contributions to normal physiology. For example, absence of E2Rα in a male human has been reported (29). The clinical sequelae attributed to this mutation include incomplete epiphyseal closure, increased bone turnover, tall stature, and impaired glucose tolerance. The androgen insensitivity syndrome is caused by mutations of the androgen receptor (30). Mutations of the receptors for growth hormone and thyroid-stimulating hormone that result in a spectrum of phenotypic alterations have also been identified. It is speculated that mutations of hormone receptors may contribute to the progression of neoplastic disease and resistance to hormone therapy (31,32).

**Growth Factors**

Growth factors are polypeptides that are produced by a wide range of cell types and exhibit a wide range of overlapping biochemical actions (23). Growth factors bind to high-affinity cell membrane receptors and trigger complex positive and negative signaling pathways that regulate cell proliferation and differentiation (33). In general, growth factors exert positive or negative effects upon the cell cycle by influencing gene expression related to events that occur at the G1/S cell cycle boundary (34).

Because of their short half-life in the extracellular space, growth factors generally act over limited distances through autocrine or paracrine mechanisms. The autocrine and paracrine mechanisms of growth control involves the elaboration of a growth factor that acts on the cell that produced it. The paracrine mechanism of growth control involves the elaboration of a growth factor that acts on another cell in proximity.

More than 40 growth factors have been described. Those that appear to play important roles in female reproductive physiology are listed in Table 6.3. The biologic response of a cell to a specific growth factor depends on the cell type and the other stimuli that are concomitantly acting on the cell. Two growth factors acting in concert may produce a very different effect from either factor independently.

**Table 6.3. Growth Factors that Play Important Roles in Female Reproductive Physiology**

The regulation of ovarian function occurs through autocrine, paracrine, and endocrine mechanisms (35,36,37,38,39,40, and 41). The growth and differentiation of ovarian cells are particularly influenced by the insulin-like growth factors (IGF) (3). The IGF amplify the actions of gonadotropin hormones on autocrine and paracrine mechanisms of growth control involves the elaboration of a growth factor that acts on the cell that produced it. The paracrine mechanism of growth control involves the elaboration of a growth factor that acts on another cell in proximity. Epidermal growth factor acts on granulosa cells to stimulate mitogenesis. Insulin-like growth factor 2 is the principal growth factor found in follicular fluid although other factors, including IGF-1, TNF-α, TNF-β, and EGF, also play important roles. Disruption of these autocrine and paracrine intraovarian pathways may be the basis of polycystic ovarian disease and disorders of ovulation.

**Figure 6.3 The regulation of ovarian function occurs through autocrine, paracrine, and endocrine mechanisms.**

Transforming growth factor (TGF)-β activates intracytoplasmic serine threonine kinases and inhibits cells in the late G1 phase of the cell cycle (41). It appears to play an important role in embryonic remodeling. Müllerian inhibiting substance (MIS), which is responsible for regression of the müllerian duct, is structurally and functionally related to TGF-β (42).

Transforming growth factor α is an EGF homologue that binds to the EGF receptor and acts as an autocrine factor in normal cells. Like EGF, TGF-α promotes entry of G0 cells into the G1 phase of the cell cycle. The role of growth factors in endometrial growth and function has been the subject of several reviews (36,37,38,39,40, and 41). Similar to the ovary, autocrine, paracrine, and endocrine mechanisms of control also occur in endometrial tissue.

**Intracellular Signal Transduction**

Growth factors trigger intracellular biochemical signals by binding to cell membrane receptors. In general, these membrane-bound receptors are protein kinases that convert an extracellular signal into an intracellular signal. The interaction between growth factor ligand and its receptor results in receptor dimerization, autophosphorylation, and tyrosine kinase activation. Activated receptors in turn phosphorylate substrates in the cytoplasm and trigger the intracellular signal transduction system (Fig. 6.4). The intracellular signal transduction system relies on serine threonine kinases, src-related kinases, and G proteins. Intracellular signals in turn activate nuclear effectors that regulate gene expression. Many of the proteins that participate in the intracellular signal transduction system are encoded by protooncogenes that are conveniently divided into subgroups based on their cellular location or enzymatic function (33,49).
The RAF and MOS protooncogenes encode proteins with serine threonine kinase activity. These kinases integrate signals originating at the cell membrane with those that are forwarded to the nucleus (45,46). Protein kinase C (PKC) is an important component of the second messenger system that exhibits serine threonine kinase activity. This enzyme plays a central role in phosphorylation, which is a general mechanism for activating and deactivating proteins. It also plays an important role in cell metabolism and division (47).

The Src family of tyrosine kinases is related to PKC and includes protein products encoded by the 
scr, yes, fgr, hck, lyn, fyn, lck, alt, and fps/fes protooncogenes. These proteins bind to the inner cell membrane surface.

The G proteins are guanyl nucleotide-binding proteins. The heterotrimeric or large G proteins link receptor activation with effector proteins such as adenyly cyclase, which activates the cAMP-dependent, kinase-signaling cascade (48,49). The monomeric or small G proteins, encoded by the ras protooncogene family, are designated p21 and are particularly important regulators of mitogenic signals (50). The p21 Ras protein exhibits guanyl triphosphate (GTP) binding and GTPase activity. Hydrolysis of GTP to guanyl diphosphate (GDP) terminates p21 Ras activity. The p21 Ras protein influences the production of deoxyguanosine (dG) and inositol phosphate (IP) 3, arachidonic acid production, and IP turnover.

Gene Expression

Regulation of genetic transcription and replication is crucial to the normal function of the daughter cells as well as the tissues and ultimately the organism. Transmission of external signals to the nucleus by way of the intracellular signal transduction cascade culminates in the transcription and translation of specific genes that ultimately affect the structure, function, and proliferation of the cell.

The human genome project has resulted in the determination of the sequence of DNA of the entire human genome. With the completion of this project, it appears that the human genetic complement consists of approximately 30,000 genes. Sequencing the human genome is a major scientific achievement that opens the door for more detailed studies of structural and functional genomics. Structural genomics involves the study of three-dimensional structures of proteins based on their amino acid sequences. Functional genomics provides a way to correlate structure and function. Proteomics involves the identification and cataloging of all proteins used by a cell, and cytomics involves the study of cellular dynamics, including intracellular system regulation and response to external stimuli. Each of these areas of investigation requires an understanding of basic genetic alterations.

Gene replication, transcription, and translation are imperfect processes and the fidelity is less than 100% (51). Genetic errors may result in abnormal structure and function. Genomic alterations have been identified in premalignant, malignant, and benign neoplasms of the female genital tract (52,53 and 54).

In view of the critical roles that oncogenes and tumor suppressor genes play in the regulation of normal cell growth, it is understandable that mutations of these genes may causally contribute to the neoplastic phenotype. By convention, mutated protooncogenes are referred to as c-oncogenes. Mutations may occur by one of several mechanisms (Fig. 6.6).

Genetic abnormalities, such as amplification, point mutations, and deletions or rearrangements, are progressive in successive generations. One error tends to permit additional aberrations. A variety of genetic abnormalities have been associated with the neoplastic phenotype. The end result of the genetic abnormalities found in transformed cells is defective control of the cell cycle. Proliferation may be abnormally increased with inoperative normal constraints on cell growth, programmed cell death may fail to occur, or some combination of the two processes may exist.

A single genetic mutation that causes cancer has not been identified. In fact, specific genetic mutations may not be as important as the accumulation of some critical number of mutations in a cell. Available data suggest that cancer results from the accumulation of mutations over time in several genes (55). From this perspective,
Amplification

Amplification refers to an increase in the copy number of a gene. Amplification results in enhanced gene expression by increasing the amount of template DNA that is available for transcription. Protooncogene amplification is a relatively common event in malignancies of the female genital tract.

Point Mutations

Point mutations of a gene, in which the codon sequence is altered, may result in altered gene action by qualitatively altering the gene product. The ras gene family is perhaps the best example of oncogene-encoded proteins that disrupt the intracellular signal transduction system following mutation. Transforming Ras proteins contain point mutations in critical codons (e.g., 11, 12, 59, 61) that reduce GTase activity so that Ras is constitutively active in the GTP-bound form. Point mutations of the p53 gene are the most common genetic mutation described in solid tumors. These mutations occur at preferential “hot spots” that coincide with the most highly conserved regions of the gene. Loss of normal p53 gene activity removes one of the inhibitors of cell proliferation and also increases the likelihood that DNA damage may be successfully passed to daughter cells. Mutations of the p53 gene occur in approximately 50% of ovarian cancers and 30% to 40% of endometrial cancers. In contrast, point mutations of p53 are uncommon in cervical cancer. However, in cervical cancer, p53 activity is often abnormal as a consequence of interactions between the p53 protein and the E6 protein encoded by the human papillomavirus.

As with p53, the BRCA1 and BRCA2 genes also play a role in DNA repair, and the activity of these genes may be altered by point mutations. Unlike the situation with p53, mutations of BRCA1 and BRCA2 do not occur at preferential positions. The “random” location of mutations coupled with the large size of these genes make genetic screening a complicated task. Mutations of the BRCA1 and BRCA2 genes may be associated with an increased risk of ovarian and breast cancer.

Deletions and Rearrangements

Deletions and rearrangements reflect gross changes in the DNA template that may result in the synthesis of a markedly altered protein product. As an example, deletion mutations of the EGF receptor affect tyrosine kinase activity. The mutated receptor is activated constitutively and transmits a signal to the cytoplasm for cellular proliferation in the absence of a bound ligand.

Immunology

The immune system plays an essential part in host defense and can respond to host cells that have undergone transformation to become neoplastic cells. These responses, whether natural or induced, can in some cases lead to tumor regression. As more is learned about the regulation of immune responses, new opportunities for novel immunotherapeutic approaches develop. Immunodiagnostic procedures using antitumor marker antibodies also show great promise as diagnostic and prognostic tools.

Immunologic Mechanisms

The human immune system has the potential to respond to abnormal or tumor cells in various ways. Some of these immune responses occur in an innate or antigen-nonspecific manner, whereas others are adaptive or antigen specific. Adaptive responses are specific to a given antigen and also establish a memory, allowing a more rapid and vigorous response to the same antigen in future encounters (55). Various innate and adaptive immune mechanisms are involved in responses to tumors, including cytokotoxicity directed to tumor cells mediated by cytotoxic T cells, natural killer (NK) cells, macrophages, and antibody-dependent cytotoxicity mediated by complement activation (56).

Adaptive or specific immune responses are made up of humoral and cellular responses. Humoral immune responses refer to the production of antibodies that are antigen reactive, soluble, bifunctional molecules composed of specific antigen-binding sites that react with foreign antigens. They are associated with a constant region that directs the biologic activities of the antibody, such as the binding of antibody molecules to cells, including phagocytic cells, or the activation of complement. Cellular immune responses are antigen-specific immune responses mediated directly by activated immune cells rather than by the production of antibodies. The distinction between humoral and cellular responses is historical and originates from the experimental observation that humoral immune function can be transferred by serum, whereas cellular immune function requires the transfer of cells. Most immune responses include both humoral and cellular components.

Several types of cells, including cells from both the myeloid and lymphoid lineages, make up the immune system. Specific humoral and cellular immune responses to foreign antigens involve the coordinated action of populations of lymphocytes operating in concert with each other and with phagocytic cells (macrophages). These cellular interactions include both direct cognate interactions involving cell-to-cell contact and cellular interactions involving the secretion of and response to cytokines or lymphokines. Lymphoid cells are found in lymphoid tissues, such as lymph nodes or spleen, or in the peripheral circulation. The cells that make up the immune system originate from stem cells in the bone marrow.

B Cells, Hormonal Immunity, and Monoclonal Antibodies

The cells that synthesize and secrete antibodies are B lymphocytes (55). Mature, antigen-responsive B cells develop from pre-B cells (committed B-cell progenitors) and differentiate to become plasma cells, which produce large quantities of antibodies. Pre-B cells originate from bone marrow stem cells in adults, after the rearrangement of immunoglobulin genes from their germ-cell configuration to that seen in B cells. Mature B cells express cell surface immunoglobulin molecules, which these cells use as their receptors for antigen.

Following interaction with antigen, and in the presence of appropriate cell—cell stimulatory signals and cytokines, mature B cells respond to become antibody-producing cells. Although the generation of antibodies directed to tumor cells is generally not thought to have a central role in antitumor immune responses, the production of monoclonal antibodies to tumor cell antigens has shown great potential for immunotherapy and tumor detection.

Kohler and Milstein developed monoclonal antibody technology more than 20 years ago, and there has been considerable interest in the use of monoclonal antibodies for detection and monitoring of tumors and for treatment (57). Monoclonal antibodies that react with tumor-associated antigens may provide new therapeutic agents for cancer. Immunotoxin-conjugated monoclonal antibodies directed to human ovarian adenocarcinoma antigens can induce tumor cell killing and can prolong survival in mice implanted with a human ovarian cancer cell line (58). However, many obstacles limit the clinical use of monoclonal antibodies, including tumor antigenic heterogeneity, modulation of tumor-associated antigens, and cross-reactivity of normal host and tumor-associated antigens. No unique tumor-specific antigens have been identified; all tumor antigens that have been identified to date are tumor-related antigens, which are expressed to a lesser extent by nonmalignant tissues. Because most monoclonal antibodies are murine, the host’s immune system can also recognize and respond to these foreign mouse proteins. The use of the genetically engineered monoclonal antibodies regions with specific antigen-reactive murine variable regions should result in reduced antigenicity to the host (58). This may help eliminate many of the problems associated with the use of murine monoclonal antibodies.

T Lymphocytes and Cellular Immunity

T lymphocytes have a central role in the generation of immune responses by acting as helper cells in both humoral and cellular immune responses and by acting as effector cells in cellular responses (59). T-cell precursors originate in bone marrow and move to the thymus, where they mature into functional T cells. During the process of maturation, T cells learn to recognize antigen in the context of the major histocompatibility complex (MHC) type of the individual person. It also seems that self-responding T cells are removed during development in the thymus (54, 55 and 56).

T cells can be distinguished from other types of lymphocytes by their cell surface phenotype based upon the pattern of expression of various molecules as well as by differences in their biologic functions. All mature T cells express certain cell surface molecules such as the cluster determinant 3 (CD3) molecular complex and the T-cell antigen receptor, which is found in close association with the CD3 complex. The availability of monoclonal antibody reagents specific for cell surface markers has led to great progress in understanding the organization of the immune system in recent years. Certainly, such monoclonal antibodies are of great
value in monitoring the effects on the human immune system of experimental treatment with biologic response modifiers or cytokines.

**T cells recognize antigen through the cell surface T-cell antigen receptor (TCR).** The structure and molecular organization of this molecule are similar to those of antibody molecules, which are the B-cell receptors for antigen. During T-cell development, the T-cell receptor gene undergoes gene arrangements similar to those seen in B cells, but there are important differences between the antigen receptors on B cells and T cells. The T-cell receptor is not secreted, and its structure is somewhat different from that of antibody molecules. The way in which the B-cell and T-cell receptors interact with antigens is also quite different. T cells can respond to antigens only when these antigens are presented in association with MHC molecules on antigen-presenting cells. Effective antigen presentation involves the processing of antigen into small fragments of peptide within the antigen-presenting cell and the subsequent presentation of these fragments of antigen in association with MHC molecules expressed on the surface of the antigen-presenting cell. T cells can respond to antigen only when presented in this manner, unlike B cells, which can bind antigen directly, without processing and presentation by antigen-presenting cells (56).

There are two major subsets of mature T cells that are phenotypically and functionally distinct: T helper/inducer cells, which express the CD4 cell surface marker, and the T suppressor/cytotoxic cells, which express the CD8 marker. The expression of these markers is acquired during the passage of T cells through the thymus. CD4 T cells can provide help to B cells, resulting in the production of antibodies by B cells, and interact with antigen presented by antigen-presenting cells in association with MHC class II molecules. CD4 T cells can also act as helper cells for other T cells. CD8 T cells include cells that are cytotoxic (cells that can kill target cells bearing appropriate antigens), and they interact with antigen presented on target cells in association with MHC class I molecules. The CD8 T-cell subset also contains suppressor T cells. These T cells can inhibit the biologic functions of B cells or other T cells (56). Although the primary biologic role of cytotoxic T cells (CTLs) seems to be lysis of virus-infected autologous cells, cytotoxic immune T cells can mediate the lysis of tumor cells directly. Presumably, CTLs recognize antigens associated with MHC class I molecules on tumor cells through their antigen-specific T-cell receptor, setting off a series of events that ultimately results in the lysis of the target cell.

**Monocytes and Macrophages**

Monocytes and macrophages, which are myeloid cells, have important roles in both innate and adaptive immune responses; macrophages play a key part in the generation of immune receptors. T cells do not respond to foreign antigens unless those antigens are processed and presented by antigen-presenting cells. **Macrophages** (and B cells) express MHC class II molecules and are effective antigen-presenting cells for CD4 T cells (55). Helper-inducer (CD4) T cells that bear a T-cell receptor of appropriate antigen and self-specificity are activated by this antigen-presenting cell to provide help (various factors—lymophokines—that induce the activation of other lymphocytes). In addition to their role as antigen-presenting cells, macrophages play an important part in innate responses by ingesting and killing microorganisms. Activated macrophages, in addition to their many other functional capabilities, can act as cytotoxic, antitumor killer cells.

**Natural Killer Cells**

A third major population of lymphocytes includes NK cells (55). These cells do not consistently bear cell surface markers that are characteristic of T or B cells, although they can share certain cell surface molecules with other types of lymphocytes. Characteristically, NK cells have a large granular lymphocyte morphology (59).

Natural killer cells are effector cells in an innate type of immune response: the nonspecific killing of tumor cells and virus-infected cells. Therefore, NK activity represents an innate form of immunity that does not require an adaptive, memory response for optimal biologic function, but the antitumor activity can be increased by exposure to several agents, particularly cytokines such as interleukin-2 (IL-2).

Although NK cells can express certain cell surface receptors, particularly a receptor for the crystallizable fragment (Fc) portion of antibodies and other NK-associated markers, it seems that cells with NK function are phenotypically heterogeneous, at least when compared with T or B cells. The cells that can carry out antibody-dependent cellular cytotoxicity, or antibody-targeted cytotoxicity, seem to be NK-like cells. Antibody-dependent cellular cytotoxicity by NK-like cells has been shown to result in the lysis of tumor cells in vitro. The mechanisms of this tumor cell killing are not clearly understood, although close cellular contact between the effector cell and the target cell seems to be required.

**Biologic Response Modifiers**

Most immunotherapeutic agents used in the treatment of cancer have been nonspecific agents that, when introduced into the human system, elicit a generalized inflammatory reaction and immune response, probably mediated by the secretion of a range of cytokines by many different types of cells. These agents have diverse and broad biologic effects and are often referred to as immunomodulators or biologic response modifiers.

The response of a given patient to treatment with biologic response modifiers depends on the ability to react to treatment with a generalized immune response. It is possible that some elements of the immune response elicited by immunotherapeutic agents or biologic response modifiers may be counterproductive, possibly causing immune suppression, inducing the production of cytokines that enhance tumor growth, or inducing an unfavorable or inappropriate immune response.

**Bacille Calmette-Guerin (BCG)** vaccine has been widely used in many tumor systems, either systemically, by injection into the lesion, or by scarification (60). Occasionally, it has been mixed with whole irradiated tumor cells and injected into the patient as a vaccine. In a large series, intracutaneous injection of melanoma lesions with BCG resulted in some tumor regression in patients with cutaneous recurrence (61), but visceral or parenchymal metastatic disease is resistant to this treatment. Although there have been some recent observations about the use of BCG as an adjuvant in children with acute lymphocytic leukemia and with stage II melanoma, randomized studies have not shown any appreciable responses.

**Cytokines, Lymphokines, and Immune Modulators**

Many events in the generation of immune responses (as well as during the effector phase of immune responses) require or are enhanced by cytokines, which are soluble mediator molecules (Table 6.4) (62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81 and 82). Cytokines are pleiotropic, in that they have multiple biologic functions that depend on the type of target cell or its maturational state. Cytokines are also heterogeneous in that the most cytokines share little structural or amino acid homology. Cytokines (also called monokines if they are derived from monocytes, lymphokines if they are derived from lymphocytes, interleukins if they exert their actions on leukocytes, or interferons [IFNs] if they have antiviral effects) are produced by a wide variety of cell types and seem to have important roles in many biologic responses outside the immune response, such as hematopoiesis. They may also be involved in the pathophysiology of a wide range of diseases and show great potential as therapeutic agents in immunotherapy for cancer.

**Table 6.4. Sources, Target Cells, and Biological Activities of Cytokines Involved**

Although cytokines are a heterogeneous group of proteins, they share some characteristics. For instance, most cytokines are low- to intermediate-molecular-weight
Cytokines have growth-increasing effects on tumor cells in addition to inducing antitumor effects. They can act as autocrine or paracrine growth factors for human is possible that a single cytokine could increase tumor growth directly by acting as a growth factor, while at the same time increasing immune responses directed The precise roles of cytokines in antitumor responses have not been elucidated. Cytokines can exert antitumor effects by many different direct or indirect activities. It Cytokines are extraordinarily pleiotropic with a bewildering array of biologic activities, including some outside the immune system ( ). Cytokines in Cancer Therapy immune system as well as direct antitumor effects. For instance, IFN-α, a cytokine produced by T lymphocytes, can affect immune function by increasing the induction of T cells do not produce IL-10, so high concentrations of IL-10 could certainly result in a peritoneal environment characterized by immune unresponsiveness and ovarian cancer including IL-6, IL-10, TNF-α, ovarian cancer from patients with ovarian cancer contained increased concentrations of IL-10 ( ). Because epithelial cancers of the ovary usually remain confined to the peritoneal cavity, even in the advanced stages of the disease, it has been suggested that the growth of ovarian cancer intraperitoneally could be related to a local deficiency of antitumor immune effector mechanisms ( ). Studies have shown that ascitic fluid from patients with ovarian cancer contained increased concentrations of IL-10 ( ). Various other cytokines are also seen in ascitic fluid obtained from women with ovarian cancer including IL-6, IL-10, TNF-α, granulocyte colony-stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF) ( ). A similar pattern was seen in serum samples from women with ovarian cancer with elevations of IL-6 and IL-10. Preliminary results have revealed that ovarian cancer cells do not produce IL-10, so high concentrations of IL-10 could certainly result in a peritoneal environment characterized by immune unresponsiveness and promotion of tumor growth.

Interferons

There are three types of interferons: IFN-α, IFN-β, and IFN-γ ( ). They can interfere with viral production in infected cells and have various effects on the immune system as well as direct antitumor effects. For instance, IFN-α, a cytokine produced by T lymphocytes, can affect immune function by increasing the induction of MHC molecule expression, increasing the activity of antigen-presenting cells, and thereby increasing T-lymphocyte activation.

Cytokines in Cancer Therapy

Cytokines are extraordinarily pleiotropic with a bewildering array of biologic activities, including some outside the immune system ( ). The precise roles of cytokines in antitumor responses have not been elucidated. Cytokines can exert antitumor effects by many different direct or indirect effects. It is possible that a single cytokine could increase tumor growth directly by acting as a growth factor, while at the same time increasing immune responses directed toward the tumor. The potential of cytokines to potentiate antitumor immune responses has been tested in experimental adoptive immunotherapy by exposing the patient's peripheral blood cells or tumor-infiltrating lymphocytes to cytokines such as IL-2 in vitro, thus generating activated cells with antitumor effects that can be given back to the patient ( ). Some cytokines can also exert direct antitumor effects. Tumor necrosis factor can induce cell death in sensitive tumor cells.

The effects of cytokines on patients with cancer might be modulated by soluble receptors or blocking factors. For instance, blocking factors for TNF and for lymphotoxin were found in ascitic fluid from patients with ovarian ancer ( ). Such factors could inhibit the cytolytic effects of TNF or lymphotoxin and should be taken into account in the design of clinical trials of intraperitoneal infusion of these cytokines.

Cytokines have growth-increasing effects on tumor cells in addition to inducing antitumor effects. They can act as autocrine or paracrine growth factors for human tumor cells, including those of nonlymphoid origin. For instance, IL-6 (which is produced by various types of human tumor cells) can act as a growth factor for human myeloma, Kaposi's sarcoma, renal carcinoma, and epithelial ovarian cancer cells ( ). Clearly, cytokines are of great potential value in the treatment of cancer, but because of their multiple, even conflicting biologic effects, a thorough understanding of
Adoptive Immunotherapy

Recently, the ex vivo enhancement of antitumor immune cell responses, including the generation of lymphokine-activated killer (LAK) cells or the activation of tumor-infiltrating lymphocytes (TIL), has provided new immune system—based approaches for antitumor responses. The simultaneous treatment of patients with ex vivo activated autologous cells, along with IL-2, is the basis of adoptive immunotherapy, a form of experimental antitumor immunotherapy. In particular, adoptive immunotherapy with IL-2 can produce regression of tumor in various animals and human tumors, such as melanoma and renal cell carcinoma, when used in conjunction with the adoptive transfer of autologous LAK cells (84,85).

Exposure of peripheral blood mononuclear cells to cytokines in vitro (particularly IL-2) leads to the generation of cytotoxic effect cells called LAK cells (85). These cells are cytotoxic for various tumor cells, including those that are resistant to NK-cell—or T-cell—mediated lysis.

Experimental treatment of human subjects with autologous ex vivo-generated LAK cells and IL-2 has yielded tumor regression in some cases (84,85,86,87,88,89,90,91,92,93,94,95,96,97). This treatment has resulted in some complete responses (86); the combined response rate was 27% in 146 patients with cancer who were treated in two separate studies (88,89 and 90). The overall response rate to LAK treatment is low, however, and this type of adoptive immunotherapy causes high morbidity (90). It is also costly and impractical in most medical settings.

Much current experimental work is aimed at developing more efficient and practical applications of adoptive immunotherapy (91,92,93,94,95,96 and 97). One approach involves the ex vivo generation of immune effector cells from TILs, which are lymphocytes that are isolated from tumors and activated and expanded in vitro to generate enough effector cells for treatment. Recently, attention has been directed toward the development of new methods for the generation of LAK cells or TILs, including methods that use cytokines other than IL-2 to stimulate these cells.

Another promising approach that has been explored in animal studies involves the targeting of activated T lymphocytes with a bifunctional monoclonal antibody that binds to the CD3—T-cell receptor complex (on the target tumor cell) (93). This approach has the potential advantage of allowing a large number of the activated lymphocytes to target their effects directly on tumor cells, thereby reducing the need to amplify a large number of effector cells from TILs. It also has the potential to avoid some of the side effects associated with LAK treatment, which is a more nonspecific form of adoptive immunotherapy.

Factors that Trigger Neoplasia

Cell biology is characterized by considerable redundancy and functional overlap, so that a defect in one mechanism does not invariably jeopardize the function of the cell. However, with a sufficient number of abnormalities in structure and function, normal cell function is jeopardized and uncontrolled cell growth or cell death results. Either end point may result from accumulated genetic mutations over time. Factors have been identified that enhance the likelihood of genetic mutations, jeopardize normal cell biology, and may increase the risk of cancer.

Increased Age

Increasing age is considered the single most important risk factor for the development of cancer (98). Cancer is diagnosed in as much as 50% of the population by 75 years of age (99). It has been suggested that the increasing risk of cancer with age reflects the accumulation of critical genetic mutations over time that ultimately culminate in neoplastic transformation. The basic premise of the multistep somatic mutation theory of carcinogenesis is that genetic or epigenetic alterations of numerous independent genes result in cancer. Factors that have been associated with an increased likelihood of cancer include exposure to exogenous mutagens, altered host immune function, and certain inherited genetic syndromes and disorders.

Environmental Factors

A mutagen is a compound that results in a genetic mutation. A number of environmental pollutants act as mutagens when tested in vitro. Environmental mutagens usually produce specific types of mutations that can be differentiated from spontaneous mutations. As an example, activated hydrocarbons tend to produce G—T transversions (100). A carcinogen is a compound that can produce cancer. It is important to recognize that all carcinogens are not mutagens and that all mutagens are not necessarily carcinogens.

Smoking

Cigarette smoking is perhaps the best known example of animal exposure that is associated with the development of lung cancer when the exposure is of sufficient duration and quantity in a susceptible individual. An association between cigarette smoking and cervical cancer has been recognized for decades. More recently, it has been determined that the mutagens in cigarette smoke are selectively concentrated in cervical mucus (52). It has been hypothesized that exposure of the proliferating epithelial cells of the transformation zone to cigarette smoke mutagens may increase the likelihood of DNA damage and subsequent cellular transformation.

Radiation

Radiation exposure can also be considered an environmental mutagen that increases the risk of cancer. This statement does not apply to exposure secondary to diagnostic radiology studies, which is not associated with an increased risk of cancer. Interestingly, the overall risk of radiation-induced cancer is approximately 10% greater in women than in men (101). This difference has been attributed to gender-specific cancers, including breast cancer. With respect to gynecology, radiation therapy for cervical cancer is associated with a small increase in the risk of colon cancer and thyroid cancer.

Radiation-induced cancer may be the result of sublethal DNA damage that is not repaired (101). Normally, radiation damage prompts an S-phase arrest so that DNA damage is repaired. This requires normal p53 gene function. If DNA repair does not occur for some reason, the damaged DNA is propagated to daughter cells following mitosis. If a sufficient number of critical genes are mutated, cellular transformation may result.

Immune Function

Systemic immune dysfunction has been recognized as a risk factor for cancer for decades. The immunosuppressed renal transplant patient may have a 40-fold increased risk of cervical cancer (52). Patients infected with human immunodeficiency virus (HIV) who have a depressed CD4 cell count have been reported to be at increased risk of cervical dysplasia and invasive disease (96). Individuals who have undergone high-dose chemotherapy with stem cell support may be at increased risk of developing a variety of solid neoplasms. These examples illustrate the importance of immune function in host surveillance for transformed cells.

Another interesting example of altered immune function that may be related to the development of cervical dysplasia is the alteration in mucosal immune function that occurs in women who smoke cigarettes (52). The Langerhans cell population of the cervix is decreased in women who smoke. Langerhans cells are responsible for antigen processing. It is postulated that a reduction in these cells increases the likelihood of successful human papillomavirus infection of the cervix.

Diet

The role of diet in disease prevention and predisposition is widely recognized but poorly understood (96,99). Dietary fat intake has been correlated with the risk of colon and breast cancer. Fiber is considered protective against colon cancer. With respect to the female reproductive system, epidemiologic studies provide conflicting results. Deficiencies of folic acid and vitamins A and C have been associated with the development of cervical dysplasia and cervical cancer. Considerable
Neuroendocrinology

Neuroendocrinology represents facets of two traditional fields of medicine: endocrinology, which is the study of hormones (i.e., substances secreted into the bloodstream that have diverse actions at sites remote from the point of secretion), and neuroscience, which is the study of the action of neurons. The discovery of neurons that transmit impulses and secrete their products into the vascular system to function as hormones themselves, a process known as neurosecretion, demonstrates that the two systems are intimately linked. For instance, the menstrual cycle is regulated through the feedback of hormones on the neural tissue of the central nervous system (CNS).

Anatomy

Hypothalamus

The hypothalamus is a small neural structure situated at the base of the brain above the optic chiasm and below the third ventricle (Fig. 7.1). It is connected directly to the pituitary gland and is the part of the brain that is the source of many pituitary secretions. Anatomically, the hypothalamus is divided into three zones: periventricular (adjacent to the third ventricle), medial (primarily cell bodies), and lateral (primarily axonal). Each zone is further subdivided into structures known as nuclei, which represent locations of concentrations of similar types of neuronal cell bodies (Fig. 7.2).
Several levels of feedback to the hypothalamus exist and are known as the long, short, and ultrashort feedback loops. The long feedback loop is composed of endocrine input from circulating hormones, just as feedback of androgens and estrogens onto steroid receptors is present in the hypothalamus (2, 3). Similarly, pituitary hormones may feed back to the hypothalamus and serve important regulatory functions in short-loop feedback. Finally, hypothalamic secretions may directly feed back to the hypothalamus, itself, in an ultrashort feedback loop.

The major secretory products of the hypothalamus are the pituitary-releasing factors (Fig. 7.3).

**Figure 7-3 The hypothalamic secretory products function as pituitary releasing factors that control the endocrine function of the ovaries, the thyroid, and the adrenal glands.**

1. **Gonadotropin-releasing hormone (GnRH),** which controls the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH)
2. **Corticotropin-releasing hormone (CRH),** which controls the release of adrenocorticotropic hormone (ACTH)
3. **Growth hormone–releasing hormone (GHRH),** which regulates the release of growth hormone (GH)
4. **Thyrotropin-releasing hormone (TRH),** which regulates the secretion of thyroid-stimulating hormone (TSH).

The hypothalamus is the source of all neurohypophyseal hormone production. The neural posterior pituitary can be viewed as a direct extension of the hypothalamus connected by the finger-like infundibular stalk. The discovery that the capillaries in the median eminence differ from those in other regions of the brain was a major one. Unlike the usual tight junctions that exist between adjacent capillary endothelial lining cells, the capillaries in this region are fenestrated in the same manner as capillaries outside the CNS. As a result, there is no blood-brain barrier in the median eminence.

**Pituitary**

The pituitary is divided into three regions or lobes: anterior, intermediate, and posterior. The anterior pituitary (adenohypophysis) is quite different structurally from the posterior neural pituitary (neurohypophysis), which is a direct physical extension of the hypothalamus. The adenohypophysis is derived embryologically from epidermal ectoderm from an infolding of Rathke's pouch. Therefore, it is not composed of neural tissue, as is the posterior pituitary, and does not have direct neural connections to the hypothalamus. Instead, a unique anatomic relationship exists that combines elements of neural production and endocrine secretion. The adenohypophysis itself has no direct arterial blood supply. Its major source of blood flow is also its source of hypothalamic input—the portal vessels. Blood flow in these portal vessels is primarily from the hypothalamus to the pituitary. Blood is supplied to the posterior pituitary via the superior, middle, and inferior hypophyseal arteries. In contrast, the anterior pituitary has no direct arterial blood supply. Instead, it receives blood via a rich capillary plexus of the portal vessels that originate in the median eminence of the hypothalamus and descend along the pituitary stalk. This pattern is not absolute, however, and retrograde blood flow has been demonstrated (5). This blood flow, combined with the location of the median eminence outside the blood-brain barrier, permits bidirectional feedback control between the two structures.

The specific secretory cells of the anterior pituitary have been classified based on their hematoxylin- and eosin-staining patterns. Acidophilic-staining cells primarily secrete GH and prolactin and, to a variable degree, ACTH (6). The gonadotropins are secreted by basophilic cells, and TSH is secreted by the neutral-staining chromophobes.

**Reproductive Hormone**

**Hypothalamus**

**Gonadotropin-releasing Hormone**

Gonadotropin-releasing hormone (GnRH) (also called luteinizing hormone–releasing hormone, or LHRH) is the controlling factor for gonadotropin secretion (6). It is a decapeptide produced by neurons with cell bodies primarily in the arcuate nucleus of the hypothalamus (7, 8) (Fig. 7.4). Embryologically, these neurons originate in the olfactory pit and then migrate to their adult locations (10). These GnRH-secreting neurons project axons that terminate on the portal vessels at the median eminence where GnRH is secreted for delivery to the anterior pituitary. Less clear in function are multiple other secondary projections of GnRH neurons to locations within the CNS.

**Figure 7-4 Gonadotropin-releasing hormone (GnRH) is a decapeptide.**

**Pulsatile Secretion**

GnRH is unique among releasing hormones in that it simultaneously regulates the secretion of two hormones—FSH and LH. It also is unique among the body's hormones because it must be secreted in a pulsatile fashion to be effective, and the pulsatile release of GnRH influences the release of the two gonadotropins (11, 12, and 13). Using animals that had undergone electrical destruction of the arcuate nucleus and have no detectable levels of gonadotropins, a series of experiments were performed with varying dosages and intervals of GnRH infusion (13, 14). Continuous infusions did not result in gonadotropin secretion, whereas a pulsatile pattern led to physiologic secretion patterns and follicular growth. Continuous exposure of the pituitary gonadotroph to GnRH results in a phenomenon called downregulation, through which the number of gonadotroph cell surface GnRH receptors is decreased (15). Similarly, intermittent exposure to...
The endogenous opioids are three related families of naturally occurring substances produced in the CNS that are named for their endogenous morphine-like activity. These substances are produced in the hypothalamus from the precursor proopiomelanocortin (POMC) and have diverse activities, including regulation of temperature, appetite, mood, and behavior (27). Enkephalins function primarily in regulation of the autonomic nervous system. Proenkephalin A is the precursor for the two enkephalins of primary importance: met-enkephalin and leu-enkephalin. Dynorphins are endogenous opioids produced from the precursor proenkephalin B that serve a function similar to that of the endorphins. The endogenous opioids play a significant role in the regulation of hypothalamic-pituitary function. Endorphins appear to inhibit GnRH release within the hypothalamus, resulting in inhibition of gonadotropin secretion (28). Ovarian sex steroids can increase the secretion of central endorphins, further depressing gonadotropin levels (29).

Endorphin levels vary significantly throughout the menstrual cycle, with peak levels in the luteal phase and a nadir during menses (29). This inherent variability, although helping to regulate gonadotropin levels, may contribute to cycle-specific symptoms experienced by ovulatory women. For example, the dysphoria experienced by some women in the premenstrual phase of the cycle may be related to a withdrawal of endogenous opiates (31).

### Pituitary Hormone Secretion

#### Anterior Pituitary

The anterior pituitary is responsible for the secretion of the major hormone-releasing factors: FSH, LH, TSH, and ACTH, as well as GH and prolactin. Each hormone is released by a specific pituitary cell type.

#### Gonadotropins

The gonadotropins FSH and LH are produced by the anterior pituitary gonadotroph cells and are responsible for ovarian follicular stimulation. Structurally, there is great similarity between FSH and LH (Fig. 7.5). They are both glycoproteins that share identical a subunits and differ only in the structure of their b subunits, which confer receptor specificity (32-33). The synthesis of the b subunits is the rate-regulating step in gonadotropin biosynthesis (34). TSH and placental chorionic gonadotropin also share identical a subunits with the gonadotropins. There are several forms of each gonadotropin, which differ in carbohydrate content as a result of posttranslational modification. The degree of modification varies with steroid levels and is an important regulator of gonadotropin bioactivity.
Figure 7-6 The structural similarity between FSH, LH, and TSH. The α subunits are identical and the β subunits differ.

Prolactin

Prolactin, a 198–amino acid polypeptide secreted by the anterior pituitary lactotroph, is the primary trophic factor responsible for the synthesis of milk by the breast (35). Several forms of this hormone, which are named according to their size and bioactivity, are normally secreted (36). Prolactin production is under tonic inhibitory control by the hypothalamic secretion of dopamine (37). Therefore, disease states characterized by decreased dopamine secretion or any condition that interrupts transport of dopamine down the infundibular stalk to the pituitary gland will result in increased synthesis of prolactin. In this respect, prolactin is unique in comparison to all other pituitary hormones; it is predominantly under tonic inhibition, and release of control produces an increase in secretion. Clinically, increased prolactin levels are associated with amenorrhea and galactorrhea, and hyperprolactinemia should be suspected in any individual with symptoms of either of these conditions.

Although prolactin appears to be primarily under inhibitory control, many stimuli can elicit its release, including breast manipulation, drugs, stress, exercise, and certain foods. The existence of a releasing factor or factors for prolactin has been long hypothesized. Whereas such a factor has been identified in a variety of animal species, no physiologically significant releasing factor has been definitively identified in humans, although TRH appears to play this role to a large extent (38). Other hormones that may stimulate prolactin release include vasopressin, γ-aminobutyric acid (GABA), dopamine, β-endorphin, vasoactive intestinal peptide (VIP), epidermal growth factor, and angiotensin II (39,40). The relative contributions of these substances under normal conditions remain to be determined.

Thyroid-stimulating Hormone, Adrenocorticotropic Hormone, and Growth Hormone

The other hormones produced by the anterior pituitary are TSH, ACTH, and GH. Thyroid-stimulating hormone is secreted by the pituitary thyrotrophs in response to TRH. As with GnRH, TRH is synthesized primarily in the arcuate nucleus of the hypothalamus and is then secreted into the portal circulation for transport to the pituitary. In addition to stimulating TSH release, TRH is also a major stimulus for the release of prolactin. Thyroid-stimulating hormone stimulates release of T₃ and T₄ from the thyroid gland, which in turn has a negative feedback effect on pituitary TSH secretion. Abnormalities of thyroid secretion (both hyper- and hypothyroidism) are frequently associated with ovulatory dysfunction as a result of diverse actions on the hypothalamic-pituitary-ovarian axis (41).

ACTH is secreted by the anterior pituitary in response to another hypothalamic-releasing factor, CRH, and stimulates the release of adrenal glucocorticoids. Unlike the other anterior pituitary products, ACTH secretion has a diurnal variation with an early morning peak and a late evening nadir. As with the other pituitary hormones, ACTH secretion is negatively regulated by feedback from its primary end product, which in this case is cortisol.

The anterior pituitary hormone that is secreted in the greatest absolute amount is GH. It is secreted in response to the hypothalamic releasing factor, GHRH, as well as by thyroid hormone and glucocorticoids. This hormone is also secreted in a pulsatile fashion but with peak release occurring during sleep. In addition to its vital role in the stimulation of linear growth, GH plays a diverse role in physiologic hemostasis. The hormone has been shown to play a role in bone mitogenesis, CNS function (improved memory, cognition, and mood), body composition, breast development, and cardiovascular function. It also affects insulin regulation and acts anabolically. Growth hormone appears to have a role in the regulation of ovarian function, although the degree to which it serves this role in normal physiology is unclear (42).

Posterior Pituitary

Structure and Function

The posterior pituitary (neurohypophysis) is composed exclusively of neural tissue and is a direct extension of the hypothalamus. It lies directly adjacent to the adenohypophysis but is embryologically distinct, derived from an invagination of neuroectodermal tissue in the third ventricle. Axons in the posterior pituitary originate from neurons with cell bodies in two distinct regions of the hypothalamus, the supraoptic and paraventricular nuclei, named for their anatomic relationship to the optic chiasm and the third ventricle. Together these two nuclei comprise the hypothalamic magnocellular system. These neurons can secrete their synthetic products directly from axonal boutons into the general circulation to act as hormones. This is the mechanism of secretion of the hormones of the posterior pituitary, oxytocin and arginine vasopressin (AVP). Although this is the primary mode of release of these hormones, numerous other secondary pathways have been identified, including secretion into the portal circulation, intrahypothalamic secretion, and secretion into other regions of the CNS (43).

In addition to the established functions of oxytocin and vasopressin, several other diverse roles have been suggested in animal models. These include modulation of sexual activity and appetite, learning and memory consolidation, temperature regulation, and regulation of maternal behaviors (44). It remains to be seen which, if any, of these functions also exist in humans.

Oxytocin

Oxytocin is a nine–amino acid peptide primarily produced by the paraventricular nucleus of the hypothalamus (Fig. 7.7). The primary function of this hormone in humans is the stimulation of two specific types of muscular contractions (Fig. 7.8). The first type, uterine muscular contraction, occurs during parturition. The second type of muscular contraction regulated by oxytocin is breast lactiferous duct myoepithelial contractions that occur during the milk letdown reflex. Oxytocin release may be stimulated by suckling, triggered by a signal from nipple stimulation transmitted via thoracic nerves to the spinal cord and then to the hypothalamus, where oxytocin is released in an episodic fashion (45). Oxytocin release also may be triggered by olfactory, auditory, and visual clues, and it may play a role in the conditioned reflex in nursing animals. Stimulation of the cervix and vagina can cause significant release of oxytocin, which may trigger reflex ovulation (the Ferguson reflex) in some species, although it is unclear to what extent this effect exists in humans.

Figure 7-7 Oxytocin and arginine-vasopressin (AVP) are nine–amino acid peptides produced by the hypothalamus. They differ in only two amino acids.
Arginine-vasopressin (AVP) (also known as antidiuretic hormone, or ADH) is the second major secretory product of the posterior pituitary (Fig. 7.7). It is synthesized primarily by neurons with cell bodies in the supraoptic nuclei (Fig. 7.8). Its major function is the regulation of circulating blood volume, pressure, and osmolality (45). Specific receptors throughout the body can trigger the release of AVP. Osmoreceptors located in the hypothalamus sense changes in blood osmolality from a mean of 285 mOsm/kg. Baroreceptors sense changes in blood pressure caused by alterations in blood volume and are peripherally located in the walls of the left atrium, carotid sinus, and aortic arch (46). These receptors can respond to changes in blood volume of more than 10%. In response to decreases in blood pressure or volume, AVP is released and causes arteriolar vasoconstriction and renal free-water conservation. This in turn leads to a decrease in blood osmolarity and an increase in blood pressure. Activation of the renal renin–angiotensin system can also activate AVP release.

Figure 7-8 Oxytocin stimulates muscular contractions of the uterus during parturition and the breast lactiferous duct during the milk letdown reflex. Arginine-vasopressin (AVP) regulates circulating blood volume, pressure, and osmolality.

Menstrual Cycle Physiology

In the normal menstrual cycle, there is an orderly cyclic hormone production and parallel proliferation of the uterine lining in preparation for implantation of the embryo. Disorders of the menstrual cycle and, likewise, disorders of menstrual physiology may lead to various pathologic states, including infertility, recurrent miscarriage, and malignancy.

Disorder of menstruation is one of the most frequent reasons women seek medical care (Table 7.1). Although helpful in formulating a diagnostic or therapeutic plan, specific abnormalities of menstrual flow are not directly related to specific defects.

Table 7.1. Definitions of Menstrual Cycle Irregularities

<table>

<tbody>
<tr>
<td>The normal human menstrual cycle can be divided into two segments: the ovarian cycle and the uterine cycle, based on the organ under examination. The ovarian cycle may be further divided into follicular and luteal phases, whereas the uterine cycle is divided into corresponding proliferative and secretory phases (Fig. 7.9). The phases of the ovarian cycle are characterized as follows:</td>
</tr>
</tbody>
</table>

1. **Follicular phase**—hormonal feedback promotes the orderly development of a single dominant follicle, which should be mature at midcycle and prepared for ovulation. The average length of the human follicular phase ranges from 10 to 14 days, and variability in this length is responsible for most variations in total cycle length.

2. **Luteal phase**—the time from ovulation to the onset of menses, with an average length of 14 days.

A normal menstrual cycle lasts from 21 to 35 days, with 2 to 6 days of flow and an average blood loss of 20 to 60 ml. However, studies of large numbers of women with normal menstrual cycles have shown that only approximately two-thirds of adult women have cycles lasting 21 to 35 days (47). The extremes of reproductive life (after menarche and perimenopause) are characterized by a higher percentage of anovulatory or irregularly timed cycles (48,49).
The relative pattern of ovarian, uterine, and hormonal variation along the normal menstrual cycle is shown in Fig. 7.9.

1. At the beginning of each monthly menstrual cycle, levels of gonadal steroids are low and have been decreasing since the end of the luteal phase of the previous cycle.
2. With the demise of the corpus luteum, FSH levels begin to rise and a cohort of growing follicles is recruited. These follicles each secrete increasing levels of estrogen as they grow in the follicular phase. This, in turn, is the stimulus for uterine endometrial proliferation.
3. Rising estrogen levels provide negative feedback on pituitary FSH secretion, which begins to wane by the midpoint of the follicular phase. Conversely, LH normally decreases in response to rising estradiol levels, but late in the follicular phase the LH level is increased dramatically (biphasic response).
4. At the end of the follicular phase (just prior to ovulation), FSH-induced LH receptors are present on granulosa cells and, with LH stimulation, modulate the secretion of progesterone.
5. After a sufficient degree of estrogenic stimulation, the pituitary LH surge is triggered, which is the proximate cause of ovulation that occurs 24 to 36 hours later. Ovulation heralds the transition to the luteal-secretory phase.
6. The estrogen level decreases through the early luteal phase from just before ovulation until the midluteal phase, when it begins to rise again as a result of corpus luteum secretion.
7. Progesterone levels rise precipitously after ovulation and can be used as a presumptive sign that ovulation has occurred.
8. Both estrogen and progesterone levels remain elevated through the lifespan of the corpus luteum and then wane with its demise, thereby setting the stage for the next cycle.

### Uterus

#### Cyclic Changes of the Endometrium

The cyclic histologic changes in the adult human endometrium were described by Noyes, Hertig, and Rock in 1950 (Fig. 7.10). These changes proceed in an orderly fashion in response to cyclic hormonal production by the ovaries (Fig. 7.9). Histologic cycling of the endometrium can best be viewed in two parts: the endometrial glands and the surrounding stroma. The superficial two-thirds of the endometrium is the zone that proliferates and is ultimately shed with each cycle if pregnancy does not occur. This cyclic portion of the endometrium is known as the decidua functionalis and is composed of a deeply situated intermediate zone (stratum spongiosum) and a superficial compact zone (stratum compactum). The decidua basalis is the deepest region of the endometrium. It does not undergo significant monthly proliferation but, instead, is the source of endometrial regeneration after each menopause (51).

**Figure 7-10** The histologic changes of the menstrual cycle. Endometrial biopsy can be used to determine the state of the endometrium corresponding to the day of the cycle.

#### Proliferative Phase

By convention, the first day of vaginal bleeding is called day 1 of the menstrual cycle. After menses, the decidua basalis is composed of primordial glands and dense scant stroma in its location adjacent to the myometrium. The proliferative phase is characterized by progressive mitotic growth of the decidua functionalis in preparation for implantation of the embryo in response to rising circulating levels of estrogen (52). At the beginning of the proliferative phase, the endometrium is relatively thin (1 to 2 mm). The predominant change seen during this time is evolution of the initially straight, narrow, and short endometrial glands into longer, tortuous structures (53). Histologically, these proliferating glands have multiple mitotic cells, and their organization changes from a low columnar pattern in the early proliferative period to a pseud stratified pattern before ovulation. The stroma is a dense compact layer throughout this time. Vascular structures are infrequently seen.

#### Secretory Phase

In the typical 28-day cycle, ovulation occurs on cycle day 14. Within 48 to 72 hours following ovulation, the onset of progesterone secretion produces a shift in histologic appearance of the endometrium to the secretory phase, so named for the clear presence of eosinophilic protein-rich secretory products in the glandular lumen. In contrast to the proliferative phase, the secretory phase of the menstrual cycle is characterized by the cellular effects of progesterone in addition to estrogen. In general, progesterone's effects are antagonistic to those of estrogen and there is a progressive decrease in the endometrial cells’ estrogen receptor concentration. As a result, during the latter half of the cycle, there is an antagonism of estrogen-induced DNA synthesis and cellular mitosis (52).

During the secretory phase, the endometrial glands form characteristic periodic acid–Schiff positive-staining, glycogen-containing vacuoles. These vacuoles initially appear subnuclearly (by cycle day 16) and then progress toward the glandular lumen (50). The nuclei can be seen in the midportion of the cells by cycle day 17 and ultimately undergo apocrine secretion into the glandular lumen by cycle day 19 to 20. At postovulatory day 6 to 7, secretory activity of the glands is maximal and the endometrium is optimally prepared for implantation of the blastocyst.

The stroma of the secretory phase remains unchanged histologically until the seventh post-ovulatory day, when there is a progressive increase in edema. Coincident with maximal stromal edema in the late secretory phase, the spiral arteries become clearly visible and then progressively lengthen and coil during the remainder of the secretory phase. By day 24, an eosinophilic staining pattern, known as cufing, is visible in the perivascular stroma. Eosinophilia then progresses to form islands in the stroma followed by areas of confluence. This staining pattern of the edematous stroma is termed pseudodecidual because of its similarity to the pattern that occurs in pregnancy. Approximately 2 days prior to menses, there is a dramatic increase in the number of polymorphonuclear lymphocytes that migrate from the vascular system. This leukocytic infiltration heralds the collapse of the endometrial stroma and the onset of the menstrual flow.

#### Menses

In the absence of implantation, glandular secretion ceases and an irregular breakdown of the decidua functionalis occurs. The result is a shedding of this layer of the endometrium, a process termed menses. It is the destruction of the corpus luteum and its production of estrogen and progesterone that is the proximate cause of the shedding. With withdrawal of sex steroids, there is a profound spiral artery vascular spasm that ultimately leads to endometrial ischemia. Simultaneously, there is a breakdown of lysosomes and a release of proteolytic enzymes, which further promote local tissue destruction. This layer of endometrium is then shed, leaving the decidua basalis as the source of subsequent endometrial growth. Prostaglandins are produced throughout the menstrual cycle and are at their highest concentration during menses (53). Prostaglandin $\text{E}_2$ is a potent vasoconstrictor, causing further arteriolar vasoconstriction and endometrial ischemia. Prostaglandin $\text{E}_2$ also produces myometrial contractions that decrease local uterine wall blood flow and may serve to physically expel sloughing endometrial tissue from the uterus.

#### Dating the Endometrium

The precise nature of the histologic changes that occur in secretory endometrium relative to the LH surge allows the assessment of the “normalcy” of endometrial
development (Fig. 7.9). By knowing when a patient is chronologically postovulatory, it is possible to obtain a sample of the endometrium by endometrial biopsy and determine whether the state of the endometrium corresponds to the phase of the cycle (Fig. 7.10). Any large discrepancy (more than 2-day lag time) is termed a luteal phase defect and has been linked to both failure of implantation and early pregnancy loss (54). To perform this diagnostic test, it is first critical to determine when ovulation occurs. Once the timing of ovulation has been established, investigators have traditionally chosen 10 to 12 days postovulation as the time for biopsy. However, endometrial sampling at the time of implantation (6 to 8 days postovulation) may be more accurate (55).

Simple hematoxylin and eosin (H&E) stain evaluation is a crude, insensitive, and frequently inaccurate method of assessing endometrial receptivity. Normal implantation requires a complex set of events, many being expressed as changes within the endometrium (56). These changes include expression of specific growth factors, cytokines, and adhesion molecules, production of prostaglandins, and change in tissue enzyme levels (57). As the importance of each of these factors in implantation becomes clear, it will likely become possible to subject one or more endometrial biopsy samples to a complex variety of stains, thereby assessing the development of individual markers. Such complex screening, already used in other tissue systems, will allow a more precise diagnosis of endometrial dysfunction than the current general diagnosis of luteal phase defect.

### Ovarian Follicular Development

The number of oocytes peaks in the fetus at 6 to 7 million by 20 weeks of gestation (58) (Fig. 7.11). Simultaneously (and peaking at the fifth month of gestation), atresia of the oogonia occurs, rapidly followed by follicular atresia. At birth, only 1 to 2 million oocytes remain in the ovaries, and at puberty, only 300,000 of the original 6 to 7 million oocytes are available for ovulation (58,59). Of these, only 400 to 500 will ultimately be released during ovulation. By the time of menopause, the ovary will be composed primarily of dense stromal tissue with only rare interspersed oocytes remaining.

![Figure 7-11 The number of oocytes in the ovary before and after birth and through menopause.](image)

In humans, oogonial formation or mitosis does not occur postnatally. Because oocytes enter the diplotene resting stage of meiosis in the fetus and persist in this stage until ovulation, much of the deoxyribonucleic acid (DNA), proteins, and messenger ribonucleic acid (mRNA) necessary for development of the preimplantation embryo will have been synthesized by this stage. At the diplotene stage, a single layer of 8 to 10 granulosa cells surround the oogonia to form the primordial follicle. The oogonia that fail to become properly surrounded by granulosa cells undergo atresia (60).

### Meiotic Arrest of Oocyte and Resumption

Meiosis (the germ cell process of reduction division) is commonly divided into four phases: prophase, metaphase, anaphase, and telophase. The prophase of meiosis I is further divided into five stages: leptotene, zygotene, pachytene, diplotene, and diakinesis.

Oogonia differ from spermatogonia in that only one final daughter cell (oocyte) forms from each precursor cell, with the excess genetic material discarded in three polar bodies. When the developing oogonia begin to enter meiotic prophase I, they are known as primary oocytes (61). This process begins at roughly 8 weeks of gestation. Only those oogonia that enter meiosis will survive the wave of atresia that sweeps the fetal ovary before birth. The oocytes arrested in prophase (in the late diplotene or "dictyate" stage) will remain so until the time of ovulation, when the process of meiosis resumes. The mechanism for this mitotic stasis is believed to be an oocyte maturation inhibitor (OMI) produced by granulosa cells (62). This inhibitor gains access to the oocyte via gap junctions connecting the oocyte and its surrounding cumulus of granulosa. With the midcycle LH surge, the gap junctions are disrupted, granulosa cells are no longer connected to the oocyte, and meiosis I is allowed to resume.

### Follicular Development

Follicular development is a dynamic process that continues from menarche until menopause. The process is designed to allow the monthly recruitment of a cohort of follicles and, ultimately, to release a single mature dominant follicle during ovulation each month.

### Primordial Follicles

The initial recruitment and growth of the primordial follicles is gonadotropin independent and affects a cohort over several months (63). However, the stimuli responsible for the recruitment of a specific cohort of follicles in each cycle are unknown. At the primordial follicle stage, shortly after initial recruitment, FSH assumes control of follicular differentiation and growth and allows a cohort of follicles to continue differentiation. This process signals the shift from gonadotropin-independent to gonadotropin-dependent growth. The first changes seen are growth of the oocyte and expansion of the single layer of follicular granulosa cells into a multilayer of cuboidal cells. The decline in luteal phase progesterone and inhibin production by the normal corpus luteum from the previous cycle decreases the amount of FSH that stimulates this follicular growth (64).

### Preantral Follicle

During the several days following the breakdown of the corpus luteum, growth of the cohort of follicles continues, driven by the stimulus of FSH. The enlarging oocyte then secretes a glycoprotein-rich substance, the zona pellucida, which separates it from the surrounding granulosa cells (except for the aforementioned gap junction). With transformation from a primordial to a preantral follicle, there is continued mitotic proliferation of the encompassing granulosa cells. Simultaneously, theca cells in the stroma bordering the granulosa cells proliferate. Both cell types function synergistically to produce estrogens that are secreted into the systemic circulation. At this stage of development, each of the seemingly identical cohort members must either be selected for dominance or undergo atresia. It is likely that the follicle destined to ovulate has been selected prior to this point, although the mechanism for selection remains obscure.

### Two-cell Two-gonadotropin Theory

The fundamental tenet of follicular development is the two-cell two-gonadotropin theory (65,66 and 67) (Fig. 7.12). This theory states that there is a subdivision and compartmentalization of steroid hormone synthesis activity in the developing follicle. In general, most aromatase activity (for estrogen production) is in the granulosa cells (68). Aromatase activity is enhanced by FSH stimulation of specific receptors on these cells (69,70). However, granulosa cells lack several enzymes that occur earlier in the steroidogenic pathway and require androgens as a substrate for aromatization. Androgens, in turn, are synthesized primarily in response to stimulation by LH, and the theca cells possess most of the LH receptors at this stage (69,70). Therefore, a synergistic relationship must exist: LH stimulates the theca cells to produce androgens (primarily androstenedione) which, in turn, are transferred to the granulosa cells for FSH-stimulated aromatization into estrogens. These locally produced estrogens create a microenvironment within the follicle that is favorable for continued growth and nutrition (71). Both FSH and local estrogens serve to further stimulate estrogen production, FSH receptor synthesis and expression, and granulosa cell proliferation and differentiation.
Following is a summary of the regulation of the menstrual cycle:

1. GnRH is produced in the arcuate nucleus of the hypothalamus and secreted in a pulsatile fashion into the portal circulation, where it travels to the anterior pituitary.
2. Ovarian follicular development moves from a period of gonadotropin independence to a phase of FSH dependence.

3. As the corpus luteum of the previous cycle fades, luteal production of progesterone and inhibin A decreases, allowing FSH levels to rise.

4. In response to FSH stimuli, the follicle grows and differentiates and secretes increasing amounts of estrogen.

5. Estrogens stimulate growth and differentiation of the functional layer of the endometrium, which prepares for implantation. Estrogens work in FSH to stimulate folliculogenesis and follicular development.

6. The two-cell-two-gonadotropin theory dictates that with LH stimulation the ovarian theca cells will produce androgens that are converted by the granulosa cells into estrogens under the stimulus of FSH.

7. If the rising estrogen levels negatively affect the pituitary gland and hypothalamus and decrease the secretion of FSH.

8. The one follicle destined to ovulate each cycle is called the dominant follicle. It has relatively more FSH receptors and produces a larger concentration of estradiol.

9. As the corpus luteum of the previous cycle fades, luteal production of progesterone and inhibin A decreases, allowing FSH levels to rise.

10. Rising estrogen levels negatively feed back on the pituitary gland and hypothalamus and decrease the secretion of FSH.

11. The two-cell-two-gonadotropin theory dictates that with LH stimulation the ovarian theca cells will produce androgens that are converted by the granulosa cells into estrogens under the stimulus of FSH.

12. The dominant follicle secretes FSH, which causes the ovulation to occur.

13. Sustained high estrogen levels cause a surge in pituitary LH secretion that triggers ovulation, progesterone production, and the shift to the secretory, or luteal, phase.

14. Luteal function is dependent on the presence of LH. Without continued LH secretion, the corpus luteum will degenerate after 12 to 16 days.

15. If pregnancy occurs, the embryo secretes hCG, which mimics the action of LH by sustaining the corpus luteum. The corpus luteum continues to secrete progesterone and supports the secretory endometrium, allowing the pregnancy to continue to develop.

References

Although obstetrician-gynecologists traditionally focus on the management of illnesses and abnormal conditions, many provide care that is oriented toward health maintenance and prevention or early detection of disease. The value of preventive services is apparent in trends such as the reduced mortality rate from cervical cancer, in part resulting from the increased use of cervical cytology testing. Neonatal screening for phenylketonuria (PKU) and hypothyroidism are examples of effective mechanisms for prevention of mental retardation. Women often regard their gynecologist as their primary care provider; indeed, many women of reproductive age have had no other physician since childhood. In this role, some gynecologists include as a routine part of their practices screening for certain medical conditions, such as hypertension, diabetes mellitus, and thyroid disease, as well as management of those conditions in the absence of complications.

Some traditional aspects of gynecologic practice, such as family planning, can be considered preventive health care. Although hormone replacement therapy can be prescribed to relieve the relatively time-limited symptoms of menopause, it also offers long-term benefits in the prevention of osteoporosis. As primary care physicians, obstetrician-gynecologists provide ongoing care for women through all stages of their lives—from reproductive age to postmenopause. Preventive medical services encompass screening and counseling for a broad range of health behaviors and risks, including family planning, sexual practices, sexually transmitted diseases (STDs), smoking, alcohol and other drug use, diet, and exercise.

In recent years there has been increasing emphasis on women's health and gender-specific medicine. This has enabled obstetrician-gynecologists to become more knowledgeable about the pathophysiologic aspects of diseases in women and thus better equipped to manage them.

Gynecologist as Primary Care Provider

Primary preventive health care in obstetrics and gynecology has been defined as including the following elements (1):

1. The entry point to the health care system
2. Direct involvement in the patient's health care
3. Continuity in relationship between the physician and patient
4. Care managed with an awareness of the relationship of disease to the family structure
5. Dedication to long-term prevention and early detection of serious illness
6. Provision of general health care (i.e., concerned with diseases other than those of the reproductive tract)
7. Application of skill and judgment regarding consultation and referral, when required, for assurance of complete care by multiple health care providers
8. Availability on a 24-hour basis

In addition, the American College of Obstetricians and Gynecologists (ACOG) has outlined the components of primary preventive care as including the ability to (2):

1. Establish a physician-patient relationship that creates a health-promoting alliance, including helping patients to control their own health choices, to recognize the benefits of avoiding high-risk behavior, and to acquire the necessary attitudes and skills to change behaviors that place their health at risk.
2. Be familiar with the leading causes of death and morbidity within different age groups in order to incorporate a holistic approach to assessing patients' risks.
3. Apply the knowledge and skills needed to identify underlying problems, counsel patients, and educate patients, adapting to their individual needs, communication skills, age, race, sex, and socioeconomic status.
4. Encourage patient follow-up.
5. Incorporate a team approach to patient care, using the expertise of nurses, health educators, other allied health professionals, and relevant social services.

According to ACOG, primary care emphasizes health maintenance, preventive services, early detection of disease, availability of services, and continuity of care. The obstetrician-gynecologist often serves as a primary medical resource and counselor to the patient and her family for a wide range of medical conditions. However, all clinicians, regardless of the extent of their training, have limitations to their knowledge and skills and should seek consultation at appropriate times for the benefit of their patients in providing both reproductive and nonreproductive care (3).

Guidelines for primary and preventive services have been issued by a number of medical bodies (4,5): the American Academy of Family Physicians (6), the U.S. Preventive Services Task Force (7), and the American Medical Association (8). The guidelines from various organizations differ somewhat in their specifics, and a national guideline clearinghouse for evidence-based clinical practice guidelines, sponsored by the Agency for Healthcare Policy and Research, is available to provide comparisons between guidelines for a given medical condition or intervention (9). Books specific to the provision of primary health care by obstetrician-gynecologists are now available (10,11,12,13,14,15 and 16).

In 1998 in the United States, there were approximately 500 million visits by women to ambulatory medical care providers. Eighteen percent of the visits (76 million) were made to gynecologists (17). Forty-six percent of ambulatory visits were made by individuals between the ages of 15 and 44 years (17). The most frequently cited reason for an office visit to an obstetrician-gynecologist by women older than 15 years of age was routine prenatal examination. The second most frequently cited reason was general medical examination. For women in this age group, obstetrician-gynecologists provided more general medical examinations than general family practitioners and internists combined. For women of reproductive age (15 to 44 years), gynecologists provided nearly 4 times as many general medical examinations than did general and family practitioners, and almost 12 times as many examinations as internists (18).

In a survey of practicing physicians who were asked to categorize themselves as a primary care physician, a specialist, or a consultant, nearly one-half of
obstetricians and gynecologists (48%) considered themselves to be primary care providers (19). Gynecologists younger than 35 years of age, those in the South Atlantic census region, and those who were paid by hospitals and medical centers were more likely to consider themselves primary care providers. In a 1995 survey of those completing their residencies, 87% of the respondents believed that obstetrics and gynecology was primary care and 85% planned to practice accordingly after residency (19). However, only one-half of residency training directors support the inclusion of 6 months of primary care in the residency education program (20).

Obstetricians and gynecologists are less likely than other primary care physicians to refer their patients. Data compiled by the National Center for Health Statistics (NCHS) indicate that gynecologists had a referral rate of 4%, general internists 7.3%, and family and general practitioners 7.3% (21).

In 1993, ACOG commissioned a Gallup poll to assess how women viewed the care provided by their obstetrician-gynecologists (22). When compared with other physicians, obstetrician-gynecologists were more likely to perform cervical cytology testing, pelvic examination, and breast examination than were other physicians. Obstetrician-gynecologists were as likely as other physicians to have checked blood pressure and referred patients for mammography. When compared with other physicians, they were slightly less likely to have checked cholesterol levels. Obstetrician-gynecologists are somewhat more likely than other physicians to have discussed family planning, preconception issues, and STDs, including human immunodeficiency virus. Other physicians were more likely to discuss medication use than were obstetrician-gynecologists. Other physicians were as likely as obstetrician-gynecologists to have discussed diet and exercise, smoking, alcohol use, hormone replacement therapy, osteoporosis, emotional problems, illegal drug use, and physical abuse (22). More than one-half of all women who reported seeing an obstetrician-gynecologist considered him or her to be their primary physician. As expected, the percentage was highest among women aged 18 to 29 years (69%) and lowest among women older than 40 years (45%) (22).

Approaches to Preventive Care

Currently in health care, there is a shift from a focus on disease to a focus on prevention. Efforts are underway to promote effective screening measures that can have a beneficial effect on public and individual health. Following is a brief description of programs developed by ACOG, the U.S. Preventive Services Task Force, and the American Medical Association to provide guidelines for preventive care.

Guidelines for Primary and Preventive Care

The initial evaluation involves a complete history, physical examination, routine and indicated laboratory studies, evaluation and counseling, appropriate immunizations, and relevant interventions. Risk factors should be identified and arrangements should be made for continuing care or referral, as needed. The leading causes of death and morbidity within different age groups are listed in Table 8.1 and Table 8.2 (4). Subsequent care should follow a specific schedule, yearly or as appropriate based on the patient's needs and age. The ACOG recommendations for periodic evaluation, screening, and counseling by age groups are shown in Table 8.3, Table 8.4, and Table 8.5. These tables also include recommendations for patients who have high-risk factors that require targeted screening or treatment (7). High-risk factors are listed in Table 8.7. Recommendations for immunizations are included in Table 8.8.

Guide to Clinical Preventive Services

The U.S. Preventive Services Task Force, commissioned in 1984, was a 20-member nongovernmental panel of experts in primary care medicine, epidemiology, and public health. Initial and subsequent reviews and recommendations are being revised and released (23). In 1976, a similar panel was convened in Canada—the Canadian Task Force on the Periodic Health Examination—which issued its report in 1979 (24). The charge of both panels was to develop recommendations for the appropriate use of preventive interventions based on a systematic review of evidence of clinical effectiveness.

The task force used several criteria for selecting conditions to evaluate, including the burden of suffering posed by a given condition, its prevalence (proportion of the population affected), and its incidence (number of new cases per year) (23). The task force reviewed only those preventive services that would be provided for asymptomatic individuals. Primary preventive measures are those that involve intervention before the disease develops, for example, quitting smoking, increasing physical activity, eating a healthy diet, quitting alcohol and other drug use, using seat belts, and receiving immunizations. Secondary preventive measures are those used to identify and treat asymptomatic persons who have risk factors or preclinical disease but in whom the disease itself has not become clinically apparent.
Examples of secondary preventive measures are well known in gynecology: screening mammography and cervical cytology testing.

The Preventive Services Task Force analyzed the effectiveness of various screening measures and tests. For screening tests, they assessed the accuracy of the test, including its sensitivity, specificity, and positive and negative predictive values. The task force also reviewed the methodologic quality of the studies. Because the design of a study influences the interpretation of the data and the weight given to the results, the U.S. Preventive Services Task Force established a hierarchy of the types of studies available to assess the effectiveness of various interventions. This hierarchy is listed in Table 8.9. The strength of the task force’s recommendations regarding the value of a screening or preventive intervention is based on the quality of the evidence available. In some circumstances, there is good evidence to recommend for or against an intervention, whereas in others, there is only fair or poor evidence regarding the effectiveness of an intervention. The strength of the task force’s recommendations were graded according to a system used by the Canadian Task Force on the Periodic Health Examination (24) (Table 8.10).

Table 8.9. Quality of Evidence—U.S. Preventive Services Task Force

| Informed estimate of the true value of the intervention in the general population is accurate and precise. | Likely to be beneficial |
| Informed estimate of the true value of the intervention in the general population is uncertain. | Likely to be ineffective or harmful |
| Informed estimate of the true value of the intervention in the general population is very uncertain. | Likely to be ineffective or harmful |
| Informed estimate of the true value of the intervention in the general population is very uncertain. | Likely to be ineffective or harmful |

Table 8.10. The Task Force Graded the Strength of Recommendations for or Against Preventive Interventions as Follows

1. Interventions that address patients’ personal health practices are vitally important.
2. The clinician and patient should share decision making.
3. Clinicians should be selective in ordering tests and providing preventive services.
4. Clinicians must take every opportunity to deliver preventive services, especially to persons with limited access to care.
5. For some health problems, community-level interventions may be more effective than clinical preventive services.

The quality of clinical evidence also has been rated and published internationally by other medical groups using a rating system similar to that used by the U.S. Preventive Services Task Force (25). In one source, which is updated every 6 months and has a lag time of 5 to 9 months from search to publication, treatment effects are categorized as follows (25):

1. Beneficial
2. Likely to be beneficial
3. Trade-off between benefits and harms
4. Unknown effectiveness
5. Unlikely to be beneficial
6. Likely to be ineffective or harmful

Other international efforts to categorize the effectiveness of treatments include the Cochrane Library, which produces and publishes high-quality systematic reviews of controlled trials (26). The Cochrane Library provides searchable databases available online and through institutional purchase of licenses. Evidence-based guidelines are published in journals available in print and online, by discipline (i.e., medicine, mental health, and nursing).

Guidelines For Adolescent Preventive Service:

Around the same time that clinicians were evaluating the primary health care needs of adults, clinicians who practice adolescent medicine (with backgrounds in pediatrics, internal medicine, family medicine, gynecology, nursing, psychology, nutrition, and other professions) recognized that the guidelines for adult and pediatric health services did not always fit the needs and health risks of adolescence. Neither the ACOG Guidelines for Primary Preventive Care (4) nor the U.S. Preventive Services Task Force recommendations (7) are sufficiently comprehensive or focused on this age group, although both documents include many important aspects of adolescent health care. The American Medical Association, with the assistance of a national scientific advisory board, developed the Guidelines for Adolescent Preventive Services (GAPS) in response to this perceived need for recommendations for delivering comprehensive adolescent preventive services (8,27).

Obstetrician-gynecologists typically see adolescents in crisis, to provide care for unintended pregnancies or STDs, including pelvic inflammatory disease. The need for preventing these crises is evident. The GAPS report extends the framework of services provided to adolescents. The impetus for developing GAPS was the belief that a fundamental change in the delivery of adolescent health services was necessary. Gynecologists could easily provide most, if not all, of the recommended services; annual preventive visits to a gynecologist might well lead to the prevention of gynecologic health problems. There are numerous opportunities for primary preventive care of adolescents in a gynecologist’s office.

The GAPS report includes 24 recommendations (Table 8.11). These recommendations address the delivery of health care, focus on the use of health guidance to promote the health and well-being of adolescents and their families, promote the use of screening to identify conditions that occur relatively frequently in adolescents and cause significant suffering either during adolescence or later in life, and provide guidelines for immunizations for the primary prevention of specific infectious diseases (8).
Total fat intake should be 30% of calories or less.

Every day, five or more servings of a combination of vegetables and fruits, especially green and yellow vegetables and citrus fruit, should be eaten.

Figure 8.1 The Food Guide Pyramid. A Guide to Daily Food Choices. This is a guide to help men and nonpregnant women choose foods that will give them the nutrients they need. Because a pregnant woman needs extra calories, she should get at least the number of servings shown in parentheses after the standard servings.

Table 8.11. Guidelines for Adolescent Preventive Services

The GAPS recommendations stem from the conclusion that the current health threats to adolescents are predominantly behavioral rather than biomedical, that more of today's adolescents are involved in health behaviors with the potential for serious consequences, that today's adolescents are involved in health-risk behaviors at younger ages than previous generations, that many adolescents engage in multiple health-risk behaviors, and that most adolescents engage in at least some type of behavior that threatens their health and well-being (3). Gynecologists are in a good position to detect high-risk behaviors and to determine whether multiple risk-taking behaviors exist; for example, the early initiation of sexual activity and unsafe sexual practices are associated with substance use (28). Adolescents who are sexually active are much more likely to have used alcohol (6.3 times greater risk), 4 times more likely to have used drugs other than marijuana, and nearly 10 times more likely to have been a passenger in a motor vehicle with a driver who was using drugs than are adolescents who are not sexually active (29). Thus, by being aware of comorbidities, gynecologists can screen for these behaviors and potentially intervene before there are serious harmful health consequences.

ACOG has issued guidelines that build on the GAPS recommendations in recognition of the role that obstetrician-gynecologists potentially could play in providing preventive services for adolescents (5). These guidelines suggest an initial visit (not necessarily examination) to the obstetrician-gynecologist for health guidance, screening, and the provision of preventive health care service between the ages of 13 and 15 years (30) and subsequent annual preventive health care visits (5).

Counseling for Health Maintenance

During periodic assessments, patients should be counseled about preventive care depending on their age and risk factors. Obesity, smoking, and alcohol abuse are associated with preventable problems that can have major long-term impacts on health. Thus, patients should be counseled about smoking cessation and moderation in alcohol use and directed to appropriate community resources as necessary. Positive health behaviors, such as eating a healthy diet and engaging in regular exercise, should be reinforced.

Adjustments may be necessary based on the presence of risk factors and the woman's current lifestyle and condition. Efforts should focus on weight control, cardiovascular fitness, and reduction of risk factors associated with cardiovascular disease and diabetes (30,31,32 and 33).

Nutrition

Patients should be given general nutritional information and referred to other professionals if they have special needs (34). Assessment of the patient's body mass index (weight [in kilograms] divided by height [in meters] squared [kilograms per square meter]) will give valuable information about the patient's nutritional status. Patients who are 20% above or below the normal range require evaluation and counseling and should be assessed for systemic disease or an eating disorder.

Central obesity—measured as waist-to-hip ratio—is a risk factor for coronary heart disease and some forms of cancer. When the waist-to-hip ratio exceeds 0.76, there is a greater relative risk of death from cancer or cardiovascular disease in women aged 55 to 69 years.

The Food Guide Pyramid developed by the U.S. Department of Agriculture helps women choose food from five groups to provide needed nutrients (Fig. 8.1) (35). The pyramid is based on the need to eat a variety of foods to get adequate energy, protein, vitamins, minerals, and fiber. The diet portrayed is high in vegetables, fruits, and grain products.

Fiber content of the diet is being studied for its potential role in the prevention of several disorders, particularly colon cancer. Currently, it is recommended that the average diet contain 20 to 30 g of fiber per day. Foods high in dietary fiber include whole-grain breads and cereals, green and yellow vegetables, citrus fruits, and some legumes.

Adequate calcium intake is important in the prevention of osteoporosis. A postmenopausal woman should ingest 1,500 mg/day. Adolescents require 1,300 mg/day. There is no evidence that moderate caffeine intake causes osteoporosis when calcium intake is inadequate. Because it is difficult to ingest an adequate amount of calcium daily in an average diet, supplements may be required.

The Centers for Disease Control and Prevention has recommended that women of reproductive age who are capable of becoming pregnant take supplemental folic acid (0.4 mg daily) to help prevent neural tube defects in their infants (36). Women who are contemplating pregnancy should be counseled about the risk of fetal neural tube defects and the role of folic acid in their prevention.

Following are some general nutritional guidelines for all women issued by the Committee on Diet and Health of the National Research Council (37):

1. Total fat intake should be 30% of calories or less. Saturated fatty acid intake should be less than 10% of calories, and the intake of cholesterol should be less than 300 mg daily.
2. Every day, five or more servings of a combination of vegetables and fruits, especially green and yellow vegetables and citrus fruit, should be eaten. The daily intake of starches and other complex carbohydrates should be increased by eating six or more servings of a combination of breads, cereals, and legumes.
3. Protein should be maintained at moderate levels (<1.6 g/kg of body weight).
4. Total daily intake of salt should be limited to 6 g or less.
5. Vitamin-mineral supplement intake should not exceed the recommended dietary intake per day.

Alcohol

Alcoholic beverages should be limited to less than 1 oz of absolute alcohol per day (equivalent to two cans of beer, two glasses of wine, or two average cocktails).

A simple device called the T-ACE questionnaire can be used to elicit information about alcohol use and identify problem drinkers (Table 8.12). Women should be questioned in a nonjudgmental fashion about their alcohol use and directed to counseling services as required.

Exercise

Exercise can help control or prevent hypertension, diabetes mellitus, hypercholesterolemia, and cardiovascular disease. Moderate exercise along with calcium supplementation and hormone replacement therapy can help retard bone loss in postmenopausal women (38). Exercise helps promote weight loss, strength and fitness, and stress reduction.

Before beginning an exercise program, patients should be examined to ensure that exercise will not pose a risk to their health. Women should be counseled about safety guidelines for exercise. Factors that should be considered in establishing an exercise program include medical limitations and selection of activities that promote health and exercise compliance. A variety of physical activities (e.g., gardening, raking leaves, walking to work, taking the stairs) can be incorporated easily into an individual's daily routine. Emphasis should be placed on regular physical activity (e.g., 30 min/day) rather than episodic vigorous exercise, especially in sedentary individuals (38). High-impact exercise is not necessary to achieve benefits, and it may be harmful. Regular low-impact or moderate aerobic exercise has been associated with improved long-term compliance and adequate health maintenance benefits.

Cardiovascular fitness can be evaluated by measurement of heart rate during exercise. As conditioning improves, the heart rate stabilizes at a fixed level. The heart rate at which conditioning will develop is called the target heart rate (38). The formula for calculating the target heart rate is 220 minus the patient's age times 0.75. For example, a 50-year-old woman would target her heart rate at 119 (220 – 50 × 0.75 = 119).

Smoking Cessation

Smoking is a major cause of preventable illness, and every opportunity should be taken to encourage patients who smoke to quit. The effectiveness of smoking cessation programs varies, however, and numerous approaches have been used. The American Cancer Society suggests the following five-step approach:

1. Begin by obtaining a patient history of smoking habits and assessing the patient's motivation to stop smoking.
2. Give clear advice to stop smoking, emphasizing the benefits of cessation.
3. Set a specific goal (e.g., a realistic date to stop smoking).
4. Suggest cessation strategies.
5. Arrange a visit or phone call to monitor progress.

Patient education about the benefits of smoking cessation, clear advice to quit smoking, and physician support improve smoking cessation rates, although 95% of smokers who successfully quit do so on their own. Self-help materials are available from the National Cancer Institute as well as community-based support groups and local chapters of the American Cancer Society and the American Lung Association. To aid in cessation, nicotine replacement therapy may be offered in the form of chewing gum or a transdermal patch. This should be prescribed only in conjunction with, not as a replacement for, ongoing visits for counseling and support.

Gynecologists have become responsible for care that extends beyond diseases of the reproductive organs to include much of the general medical care of women. Broadening the spectrum of care places emphasis on the caring nature of the physician rather than the surgical or procedural aspects of the specialty. Early diagnosis and treatment of medical illnesses can have a major impact on a woman's health and is a key component of primary care. Although timely referral is important for complex and advanced disorders, the gynecologist initially may treat many conditions.

The gynecologist should provide screening and early intervention for certain conditions that commonly arise in the office setting or have a significant impact on women's health. Respiratory problems are the most common reasons patients seek care from a physician, so gynecologists should be aware of their pathophysiology. Cardiovascular disease has a significant impact on overall morbidity and is the main cause of death in women. Cardiovascular illness is associated with cigarette smoking, hypertension, hypercholesterolemia, and diabetes mellitus. These conditions are responsive to screening, behavioral modification, and control to lower risk factors. A major cause of morbidity for women is thyroid disease; because of the interaction of hormones and the overall effect on the endocrine system, thyroid disease can be of special significance in women.

Respiratory Infections

Infections of the respiratory system can range from the common cold to life-threatening illness. Those who have risk factors should be counseled about preventive measures. Vaccines against flu and pneumonia should be offered as indicated (see Chapter 8, Table 8.7).

Sinusitis

A problem frequently encountered in women is self-diagnosed “sinus problems” (1). Many medical problems—headaches, dental pain, postnasal drainage, halitosis, and dyspepsia—may be related to sinus conditions. The sinuses are not an isolated organ, and diseases of the sinuses are often related to conditions that affect other portions of the respiratory system (i.e., the nose, bronchial tree, and lung) (2). The entire respiratory system may be infected by one particular virus or pathogen (the sinobronchial or sinopulmonary syndrome); however, the most prominent symptoms are usually produced in one anatomic area. Therefore, during the evaluation of complaints attributable to sinusitis, the presence of other infections should be investigated.

Exposure to multiple infectious and chemical agents or reaction to nervous, physical, emotional, or hormonal stimuli may cause an inflammatory response in the respiratory system (3). Systemic diseases such as connective tissue syndromes and malnutrition may contribute to chronic sinusitis. Environmental factors in the workplace and geographic conditions (e.g., cold and damp weather) may aggravate or accelerate the development of sinusitis. Factors contributing to the development of sinus disease include atmospheric pollutants, allergy, tobacco smoke, skeletal deformities, dental conditions, barotrauma from scuba diving or airline travel, and neoplasms.

Most infections begin with a viral agent in the nose or nasopharynx that causes inflammation that blocks the draining ostia. The location of the symptoms varies by anatomic site: maxillary sinus over the cheeks, ethmoid sinus across the nose, frontal sinus in the supraorbital area and sphenoid sinus to the vertex of the head. Viral agents impede the sweeping motion of cilia in the sinus and, in combination with edema from inflammation, lead to superinfection with bacteria. Common bacterial agents infecting sinuses are Streptococcus pyogenes, Streptococcus pneumoniae, Haemophilus influenzae, Staphylococcus aureus, and a-hemolytic streptococcus species. Gram-negative organisms are usually limited to compromised hosts in intensive care units. Chronic sinusitis develops from either inadequate drainage or compromised local defense mechanisms. The flora in chronic disease is usually polymicrobial, with mixed infections consisting of aerobic and anaerobic organisms.

Sinus ailments frequently occur in middle-aged individuals. Acute infection is usually located in the maxillary and frontal sinuses. Classically, infection in the maxillary sinus is due to obstruction of the ostia found in the medial wall of the nose. Fever, malaise, a vague headache, and pain in the maxillary teeth are early symptoms. Complaints of “fullness” in the face or exploding pressure behind the ears are elicited. Pressure and percussion over the malar areas results in complaints of severe pain. Pulsatile exudates in the middle meatus of the nose or in the nasopharynx are commonly observed. The five clinical findings of maxillary toothache, poor response to nasal decongestants, abnormal transillumination, a colored nasal discharge established by history or a colored nasal discharge on examination are the most useful clinical findings. When four or more features are present the likelihood of sinusitis is high, and when none is present sinusitis is highly unlikely (4). Initial episodes of sinusitis do not require imaging studies, but when persistent infections occur, studies and referral are indicated. Therapy is usually empiric. Unless samples are obtained by direct needle drainage, cultures are of no value because it is impossible to avoid contamination by oropharyngeal flora.

Broad antibiotic therapy is necessary to cover common aerobes and anaerobes but should be limited to patients with acute pain and purulent discharge. For acute, uncomplicated sinus infections amoxicillin (500 mg 3 times a day) or trimethoprim-sulfamethoxazole (one tablet twice daily) remain the treatments of choice. Amoxicillin is inexpensive, penetrates the sinuses well, and can be discontinued and another antibiotic substituted if symptoms have not improved in 48 to 72 hours. If b-lactam resistance is likely, amoxicillin-clavulanic acid (875 mg twice daily), or azithromycin (5-day course once a day) may be used. Other second-line drugs include cefuroxime (250 mg twice daily), ciprofloxacin (500 mg twice daily), clarithromycin (500 mg twice daily), levofloxacin (500 mg once a day), and loracarbef (400
mg twice daily). The usual treatment course is 14 days, and patients should be informed that a relapse may occur if the full course of treatment is not completed. Systemic decongestants containing pseudoephedrine are useful in shrinking the obstructive ostia and promoting sinus drainage and ventilation. Topical decongestants should be used for no longer than 13 days, because prolonged use may lead to rebound vasodilation and worsening of symptoms. Mucolytic agents such as guaifenesin may help thin sinus secretions and promote drainage. Antihistamines should be avoided in acute sinusitis because their drying effects may lead to impaired secretions and poor drainage of the sinuses. Symptomatic therapies should include facial hot packs and analgesics. Improvement in symptoms should be apparent within 48 hours, but 10 days of therapy may be necessary for complete resolution. If symptoms do not respond, other classes of antibiotics should be used based on presumed microbial resistance. In difficult cases, referral to an otolaryngologist for sinus irrigation may be necessary.

Chronic sinusitis may result from repeated infections with inadequate drainage. The interval between infections becomes progressively shorter until there are no remissions. Symptoms are recurrent in the malar area or chronic postnasal drip. Chronic sinusitis is associated with chronic cough and laryngitis with intermittent acute infections. In the preantibiotic era, chronic sinusitis was the result of repeated acute sinusitis with incomplete resolution, whereas allergy currently is receiving greater attention as a possible cause. Surface ciliated epithelia are injured, resulting in impaired mucus removal. A vicious cycle of incomplete resolution of infection followed by reinfection and ending with the emergence of opportunistic organisms occurs. Swelling and edema of the mucosa, in conjunction with hyposecretion of mucus, lead to ductal obstruction and infection. Treatment is directed at the underlying etiology, either allergy control or agressive management of infections. Resistant cases will require computed tomography (CT) and endoscopic surgery with polyp removal. Nasoantral window formation is radical surgery usually reserved for advanced conditions that do not respond to other forms of therapy.

Untreated, sinus infections may have serious consequences such as orbital cellulitis leading to orbital abscess, subperiosteal abscess formation of the facial bones, cavernous sinus thrombosis, and acute meningitis. Brain and dural abscesses are rare and usually are caused by direct spread of pathogens from a sinus. At present, CT scanning is the most accurate diagnostic tool. Aggressive surgical approaches used with broad-spectrum antibiotics are necessary for adequate drainage.

**Otitis Media**

Otitis media remains primarily a disease of children but may affect adults. Serous otitis media is usually secondary to a concurrent viral infection of the upper respiratory tract. In most cases, diagnosis reveals fluid behind the tympanic membrane. Therapy involves treatment of symptoms with antihistamines, decongestants, and glucocorticoids, but little data exist supporting use of these medications. Acute otitis media is usually caused by a bacterial infection; *Streptococcus pneumoniae* and *Haemophilus influenzae* are the pathogens most often involved. Symptoms include acute purulent otorrhea, fever, hearing loss, and leukocytosis (5). Physical examination of the ear will reveal a red, bulging, or perforated membrane. Indicated treatment is broad-spectrum antibiotics such as amoxicillin-clavulanic acid, *cefuroxime*, and *trimethoprim-sulfamethoxazole*. The role of antihistamines in treatment of otitis media is unclear.

**Bronchitis**

Acute bronchitis is an inflammatory condition of the tracheobronchial tree, most often caused by a viral infection and occurring in winter. Common cold viruses (rhinovirus and coronavirus), adenovirus, influenza virus and *Mycoplasma pneumoniae* (a nonvirual pathogen) are the most common pathogens. Bacterial infections are less common but may occur as secondary pathogens. Cough, hoarseness, and fever are the usual initial symptoms. During the first 3 to 4 days, the symptoms of rhinitis and sore throat are prominent; however, coughing may last as long as 3 weeks. Unfortunately, the prolonged nature of these infections results in use of antibiotics to “clear up the infection.” Sputum production is short, requiring only 1 to 3 days. A chest x-ray is helpful for patients who have chest radiographic findings consistent with pneumonia. Cough is usually the most aggravating symptom and may be treated with antitussive preparations containing either dextromethorphan or codeine. The efficacy of expectorants has not been proven.

Chronic bronchitis is defined as the presence of a productive cough with excessive secretions for at least 3 months in a year for 2 consecutive years. Prevalence has been estimated to be between 10% to 25% of the adult population. In the past, incidence has been lower in women than men, but as the prevalence of cigarette smoking in women has increased, so has the incidence of bronchitis in women. Chronic bronchitis is usually classified as a form of chronic obstructive pulmonary disease (COPD). Other causes include chronic infections and environmental pathogens found in dust. The cardinal manifestation of disease is an incessant cough, usually in the morning, with expectation of sputum. Because of frequent exacerbations and hospitalizations required, and the complexity of medical management, these patients should be referred to an internist for treatment.

**Pneumonia**

Pneumonia is defined as inflammation of the distal lung that includes terminal airways, alveolar spaces, and the interstitium. Pneumonia may have multiple causes, including viral and bacterial infections or aspiration. Aspiration pneumonia is usually the result of depressed awareness commonly associated with use of drugs, alcohol, or anesthesia. Viral pneumonias are caused by multiple infectious agents including influenza A or B, parainfluenza virus, or respiratory syncytial virus. Moderate hypoxia with fever and low-grade leukocytosis is common and may be provoked in cigarette smokers. Most serious bacterial infections occur in cigarette smokers because of damage to the lining of the upper respiratory tree and changes in the host flora.

Physical examination will demonstrate a variety of upper airway sounds, usually coarse rhonchi. Rates are usually not auscultated, and signs of consolidation and alveolar involvement are absent. During auscultation of the chest, signs of pneumonia such as fine rales, decreased breath sounds, and euphonia (“E to A changes”) should be sought. If the findings of the physical examination are uncertain or if the patient's condition appears toxic, chest radiography should be performed to detect the presence of parenchymal disease. Paradoxically, as the initial acute syndrome subsides, sputum production may become more purulent. Sputum cultures are of limited value because of the polymicrobial nature of infections. In uncomplicated cases, the goal of treatment is symptom control. When pneumonia is severe, medical management should include a broad spectrum antibiotic. Most cases will require computed tomography (CT) and endoscopic surgery with polyp removal. Nasoantral window formation is radical surgery usually reserved for advanced conditions that do not respond to other forms of therapy.

**Bacterial pneumonia** is classified as either nosocomial or community acquired. The classification determines the prognosis and choice of antibiotic therapy in many cases. Risk factors that contribute to mortality are chronic cardiopulmonary diseases, alcoholism, diabetes mellitus, renal failure, malignancy, and malnutrition. Prognostic features associated with poor outcome include greater than two-lobe involvement, respiratory rate greater than 30 breaths/minute on arrival in the health care center, severe hypoxemia (<60 mm Hg breathing room air), hypoalbuminemia, and septicemia (7). Pneumonia is a common cause of adult respiratory distress syndrome (ARDS), which has a mortality rate of between 50% to 70% (8).

Signs and symptoms of pneumonia vary depending on the infecting organism and the patient's immune status (9). In typical pneumonias, the patient appears toxic with high fever, rigors, productive cough, chills, or pleuritic chest pain. Chest radiographs will often disclose infiltrates. The following agents, listed in decreasing order, cause two-thirds of all bacterial pneumonias: *Streptococcus pneumoniae*, *Haemophilus influenzae*, Klebsiella pneumoniae, gram-negative organisms, and anaerobic bacteria. Atypical pneumonias are more insidious in onset; moderate fever is present without the characteristic rigors and chills. Additional symptoms include a nonproductive cough, headache, myalgias, and mild leukocytosis. Chest radiographic examination reveals a bronchopneumonia with a diffuse interstitial pattern (‘bat wing distribution’); characteristically, the patient does not appear to be as ill as the radiographic findings suggest. Common causes of atypical pneumonia include viruses, *Mycoplasma pneumoniae*, Legionella pneumophila, Chlamydia pneumoniae (also called the TWAR agent), and other rare agents.

A strong index of suspicion is required to establish a diagnosis, especially in elderly and immunocompromised individuals, because of altered response mechanisms. This is even true with so-called typical agents. Subtle clues in the elderly include changes in mentation, confusion, and exacerbation of other illnesses. The febrile response may be entirely absent. Even in high-risk groups, an increased respiratory rate of greater than 25 breaths per minute remains the most reliable sign. In high-risk patients mortality is strongly correlated with the inability to mount normal defenses to the symptoms of fever, chills, and tachycardia.

Laboratory studies helpful in identifying community-acquired pneumonia are sputnum Gram stain, sputnum culture, and blood culture. An adequate sputnum collection (defined as more than 5 neutrophils with less than 10 epithelial cells per low-powered field on microscopic examination) may be difficult to obtain. The assistance of respiratory therapists should be sought to obtain induced sputnum. *Legionella pneumoniae* requires different laboratory techniques such as direct fluorescent antibody
staining of organisms in the sputum or indirect serologic tests using enzyme-linked immunosorbent assay (ELISA) technology. *Mycoplasma pneumoniae* infection should be suspected in the presence of positive cold agglutinin findings and the appropriate clinical symptoms.

Therapy should be directed toward the responsible or most likely pathogen but, in many cases of pneumonia, the exact cause cannot be determined and empiric therapy should be initiated. Pneumonia that occurs without coexisting conditions such as heart disease, lung disease, renal insufficiency, liver disease, or other comorbid medical illnesses in patients who are >60 years of age should be treated on an outpatient basis with a macrolide such as erythromycin (500 mg four times a day), clarithromycin (500 mg twice daily) or azithromycin (500 mg on day 1, followed by 250 mg once a day for 4 weeks) is preferred for smokers or those who are intolerant to erythromycin. Doxycycline (100 mg twice daily) may be used for patients who are allergic or intolerant to macrolides. Patients who have coexisting conditions, are >60 years of age, or both should be treated on an outpatient basis with a second-generation cephalosporin or b-lactam–b-lactamase inhibitor, like amoxicillin-clavulanic acid, with or without a macrolide if legionellosis is a concern.

The same protocol for outpatient therapy may be used for hospitalized patients except that a third-generation cephalosporin may be used (10). Hospitalization is usually necessary in patients who are very ill, elderly, or immunocompromised. Oxygen therapy and hydration, in addition to antibiotic therapy, should be initiated. The use of chest physiotherapy should be reserved for patients who have copious sputum or who have an ineffective cough. Patients may be switched to oral antibiotics when they are able to eat and drink, have negative blood cultures, a temperature <38°C, a respiratory rate of ≤24 breaths per minute and a pulse rate of ≤100 beats per minute. Patients may be discharged when they fulfill the aforementioned criteria and their white blood cell count is 12 × 10^9 per liter, comorbid illnesses are stable, oxygen saturation is >90% on room air, or the patient has COPD with P O₂ >60 mm Hg and P CO₂ <45 mm Hg (1).

The pneumococcal vaccine should be given to women at high risk for pneumonia. All adults 65 years or older and people with special health problems such as heart or lung disease, alcoholism, kidney failure, diabetes mellitus, human immunodeficiency virus (HIV) infection, or certain types of cancer should be immunized (see Chapter 8, Table 8.7). Repeat vaccination is recommended 5 years after the first dose in high-risk groups. The vaccine is active against 23 types of pneumococcal strains and most people develop protection within 2 to 3 weeks of receiving the immunization.

The influenza vaccine should be given every fall to the following high-risk groups: individuals 50 years of age or older, individuals with serious long-term health problems like heart disease, lung disease, kidney disease, diabetes mellitus, immunosuppression secondary to long-term steroid or cancer therapy (see Chapter 8, Table 8.7), women who will be in their third trimester of pregnancy during the flu season (November through April), and anyone coming into close contact with people at risk of serious influenza, such as physicians, nurses, and family members. The best time for vaccination is October to mid-November. Antiviral agents should not be used as a substitute for vaccination but can be a useful adjunct. The four agents approved for use in the United States are amantadine, rimantadine, zanamivir, and oseltamivir. These medications should be given within 2 days of the onset of symptoms to shorten the duration of uncomplicated illness caused by influenza (12).

### Cardiovascular Disease

The risk factors for coronary artery disease are presented in Table 9.1. Central to treating cardiovascular disease is the control of contributing diseases and risk factors (Table 9.2). Aerobic exercise protects against cardiovascular disease (13). Additional aspects of prevention of myocardial disease, renal disease, and stroke include control of hypertension, identification and control of diabetes mellitus and obesity, and control of dietary fats, especially cholesterol, in susceptible individuals (Fig. 9.1). The presence or absence of target-organ damage shown in Table 9.3 also determines the risk for coronary artery disease in hypertensive patients.

#### Figure 9.1 Disease and risk factors contributing to cardiovascular disease.
Hypertension

The relationship between hypertension and cardiovascular events such as stroke, coronary artery disease, congestive heart disease, and renal disease is well known. More than 50 million people in the United States have hypertension and it is found in 15% of the population between the ages of 18 and 74 years. The incidence increases with age and varies with race. After age 50, women have a higher incidence of hypertension than males; however, this may be a confounding variable related to the overall mortality of men at an earlier age (14). Over 60% of those 60 years and older can be classified as hypertensive (15). The contribution of hypertension to overall cardiovascular morbidity and mortality in women has been thought to be less important than in males, but this may reflect the relative absence of research done with women. Recognition and treatment of hypertension may decrease the development of renal and cardiac disease.

Epidemiology

The incidence of hypertension is twice as high in African Americans than in whites. Geographic variations are present: there is a higher prevalence of hypertension and stroke in the southeastern United States, regardless of race (16). One multicenter study confirmed that there is an increased incidence of hypertension, not only in African Americans, but also in those with lower levels of education (17). Preventive measures can be most effective in those at highest risk, such as African American women and individuals from the lowest socioeconomic levels (17). The influence of genetic predisposition is poorly understood. Studies of women have been limited to those that determine side effects of medication and the impact of certain medications on long-term lipid status (14).

Classically, hypertension is defined as blood pressure levels higher than 140/90 when measured on two separate occasions. However, therapy may be indicated only for individuals at high risk. Individuals at low risk, such as white women with no other risk factors, may benefit from lifestyle modification only (17). Elevation of systolic blood pressure in middle-aged and elderly patients was once considered innocuous; however, recent studies suggest that control of systolic blood pressure is more important than control of diastolic blood pressure (18). Life insurance risk tables indicate that when blood pressure is controlled to lower than 140/90, normal survival occurs over a 10- to 20-year follow-up period, regardless of gender. Recommendations for treatment of hypertension are based on sustained blood pressure levels higher than 140/90.

Most individuals (>95%) with hypertension have primary or essential hypertension (cause unknown), whereas less than 5% have secondary hypertension resulting from another disorder. Key factors should be determined in the history and physical examination. The presence of prior elevated readings, previous use of antihypertensive agents, a family history of death from cardiovascular disease prior to age 55, and excessive alcohol and sodium use constitute important historical information. Lifestyle modification is increasingly important in the therapy of hypertension; thus, a detailed history of diet and physical activity should be obtained (19). Baseline laboratory evaluations to rule out reversible causes of hypertension (secondary hypertension) are listed in Table 9.4. Diagnosis and management are based on the classification of blood pressure readings in Table 9.5. In addition, patients are stratified into three different risk groups for therapeutic decision making (Table 9.6).

Table 9.3. Target-organ Damage and Clinical Cardiovascular Disease

| Hypertension | The relationship between hypertension and cardiovascular events such as stroke, coronary artery disease, congestive heart disease, and renal disease is well known. More than 50 million people in the United States have hypertension and it is found in 15% of the population between the ages of 18 and 74 years. The incidence increases with age and varies with race. After age 50, women have a higher incidence of hypertension than males; however, this may be a confounding variable related to the overall mortality of men at an earlier age (14). Over 60% of those 60 years and older can be classified as hypertensive (15). The contribution of hypertension to overall cardiovascular morbidity and mortality in women has been thought to be less important than in males, but this may reflect the relative absence of research done with women. Recognition and treatment of hypertension may decrease the development of renal and cardiac disease. | Epidemiology | The incidence of hypertension is twice as high in African Americans than in whites. Geographic variations are present: there is a higher prevalence of hypertension and stroke in the southeastern United States, regardless of race (16). One multicenter study confirmed that there is an increased incidence of hypertension, not only in African Americans, but also in those with lower levels of education (17). Preventive measures can be most effective in those at highest risk, such as African American women and individuals from the lowest socioeconomic levels (17). The influence of genetic predisposition is poorly understood. Studies of women have been limited to those that determine side effects of medication and the impact of certain medications on long-term lipid status (14). Life insurance risk tables indicate that when blood pressure is controlled to lower than 140/90, normal survival occurs over a 10- to 20-year follow-up period, regardless of gender. Recommendations for treatment of hypertension are based on sustained blood pressure levels higher than 140/90. Most individuals (>95%) with hypertension have primary or essential hypertension (cause unknown), whereas less than 5% have secondary hypertension resulting from another disorder. Key factors should be determined in the history and physical examination. The presence of prior elevated readings, previous use of antihypertensive agents, a family history of death from cardiovascular disease prior to age 55, and excessive alcohol and sodium use constitute important historical information. Lifestyle modification is increasingly important in the therapy of hypertension; thus, a detailed history of diet and physical activity should be obtained (19). Baseline laboratory evaluations to rule out reversible causes of hypertension (secondary hypertension) are listed in Table 9.4. Diagnosis and management are based on the classification of blood pressure readings in Table 9.5. In addition, patients are stratified into three different risk groups for therapeutic decision making (Table 9.6). | Table 9.4. Laboratory Tests and Procedures Recommended in the Evaluation of Uncomplicated Hypertension | Table 9.5. Blood Pressure Classification (Adults 18 years and Older) |
Patients with high normal readings (systolic blood pressure 130 to 139 mm Hg or diastolic blood pressures 85 to 89 mm Hg) are at high risk for developing hypertension. They should be monitored yearly, and consideration should be given to nonpharmacologic interventions (20). A scheme for the treatment of uncomplicated hypertension is found in Fig. 9.2.

1. Patients with high normal readings (systolic blood pressure 130 to 139 mm Hg or diastolic blood pressures 85 to 89 mm Hg) are at high risk for developing hypertension. They should be monitored yearly, and consideration should be given to nonpharmacologic interventions (20). A scheme for the treatment of uncomplicated hypertension is found in Fig. 9.2.

2. A single elevated diastolic blood pressure reading of less than 100 mm Hg should be rechecked within 2 months before initiating therapy. In 33% of patients, elevated readings will spontaneously resolve during the observation period because of so-called white-coat hypertension.

3. If blood pressure control is not easily achieved, systolic blood pressure is higher than 180 mm Hg, or the diastolic reading is higher than 110 mm Hg, referral to an internist is recommended. Referral also is indicated if secondary hypertension is suspected or evidence of end-organ damage (renal insufficiency or congestive heart failure) is detected.

Measurement of Blood Pressure

An often overlooked but essential variable in the evaluation of hypertension is the method used to obtain measurements and the need to standardize measurements (22). Ambulatory or home monitoring devices, which are becoming less expensive and more reliable, may be appropriate for use by patients who have repeated normal measures outside of the office. In most patients, readings done in the office are all that is necessary to adequately diagnose and monitor hypertension and eliminate problems arising from unreliable commercial devices and patient interpretation skills.

Protocols for measurement of blood pressure should be standardized. The patient should be allowed to rest for 5 minutes in a seated position and the right arm used for measurements (for unknown reasons, the right arm has higher readings). The cuff should be applied 20 mm above the bend of the elbow and the arm positioned parallel to the floor. The cuff should be inflated to 30 mm Hg above the disappearance of the brachial pulse, or 220 mm Hg. The cuff should be deflated slowly at a rate no more than 2 mm Hg per second.

The cuff size is important. Most cuffs are marked with “normal limits” for the relative size they can accommodate. The most common clinical problem encountered is small cuffs used for obese patients, resulting in so-called cuff hypertension. Phase IV Korotkoff's sounds are described as the point when pulsations are muffled, while phase V is complete disappearance. Most experts in hypertension advocate the use of phase IV Korotkoff sounds, but phase IV sounds may be used in special circumstances, with the reason documented.

The use of automated devices may help eliminate discrepancies in measurements. Regardless of the method or device used, two measurements should be obtained with less than a 10 mm Hg disparity to be judged adequate. When repeated measures are performed, there should be a 2-minute rest period between readings. Blood pressure has a diurnal pattern, so determinations preferably should be done at the same time of day. Ambulatory monitoring is not cost effective in all patients but should be used in some situations, mainly to evaluate resistance to therapy, to detect white-coat hypertension, and to assess whether syncopal episodes are related to hypertension or episodic hypertension (23).

Therapy

The definition of what constitutes systolic hypertension requiring treatment has been contested for years. Patients with systolic blood pressure higher than 160 mm Hg benefit from antihypertensive therapy regardless of their diastolic pressures (21). Middle-aged to elderly patients treated for systolic hypertension have a significant decrease in cerebral vascular accidents and coronary artery disease.

Lifestyle modification should be initiated for patients with systolic blood pressures greater than 130 mm Hg but less than 160 mm Hg and belonging to risk groups A or B (Fig. 9.2).

Nonpharmacologic interventions or lifestyle modification should be attempted prior to initiation of medication unless the systolic blood pressure exceeds 159 mm Hg, the diastolic blood pressure exceeds 99 mm Hg, or the systolic blood pressure exceeds 139 mm Hg or diastolic blood pressure exceeds 89 mm Hg and the patient has any target-organ damage or diabetes mellitus with or without any other risk factors. Drug therapy should also be initiated for systolic blood pressure higher than 130 mm Hg or diastolic blood pressure higher than 85 mm Hg in those with heart failure, diabetes mellitus, or renal failure (Fig. 9.2). An important element in lifestyle modifications is to modify all contributors to cardiovascular disease. Weight loss in obese patients, especially in individuals with truncal and abdominal obesity, can prevent the development of atherosclerosis (24). A loss of just 10 pounds has been reported to lower blood pressure (25). Patients should be advised to eliminate excess salt in their diets, specifically certain food groups that are high in sodium such as canned goods, snack food, pork products, and soy sauce. Reducing salt intake to 3 grams per day would decrease annual mortality by 70,000 deaths (26). Intake of cholesterol and fat should be limited. Following an exercise program, losing weight, and limiting alcohol intake to no more than 2 drinks per day contributes to overall cardiovascular health. Aerobic exercise alone may prevent hypertension in 20% to 50% of normotensive individuals (27).

The goal of therapy is to lower blood pressure into the normal range, a systolic reading less than 130 mm Hg and a diastolic reading less than 85 mm Hg. If lifestyle modifications are not sufficient to control blood pressure, pharmacologic intervention is indicated. The number of antihypertensive medications has exploded over the past decade. Currently, only diuretics and b-blocking agents have been proved to reduce mortality and morbidity (28).

Diuretics

The most commonly used medication for initial blood pressure reduction is hydrochlorothiazide. The mechanism of action is to reduce plasma and extracellular fluid volume. This lowering of volume is thought to decrease peripheral resistance. Cardiac output initially decreases and then normalizes. The important long-term effect is a slight decrease in extracellular fluid volume. The maximal therapeutic dose of thiazide should be 25 mg rather than the commonly used 50 mg. The benefit of higher doses is eliminated by the corresponding increase in side effects. Potassium-sparing diuretics (spironolactone, triamterene, or amiloride) are usually available in fixed doses and should be prescribed to prevent hypokalemia. Potassium supplementation is less effective than the use of potassium-sparing agents. Thiazide diuretics are best used in patients with creatinine levels less than 2.5 g/L. Loop diuretics (furosemide) work better than thiazide diuretics at lower glomerular filtration.
rates and higher serum creatinine levels. Control of hypertension with concurrent renal insufficiency is difficult and is probably best handled by an internist or nephrologist. Thiazides and loop diuretics should not be used concurrently because they cause profound diuresis, which may lead to renal impairment. Concurrent use of nonsteroidal antiinflammatory drugs (NSAIDs) limits the effectiveness of thiazides. Other side effects, which further limit the usefulness of thiazide diuretics, include hyperuricemia, which may contribute to acute gout attacks, glucose intolerance, and hyperlipidemias (29). The metabolic side effects of these drugs have limited their popularity recently.

Adrenergic Inhibitors

b-Blockers have been used extensively for years as antihypertensive agents. The mechanism of action is decreasing cardiac output and plasma renin activity with some increase in total peripheral resistance. As a class, they are an excellent source of first-line therapy, especially for migraine sufferers. The original formulation, propranolol, was highly lipid soluble, which contributed to bothersome side effects such as depression, sleep disturbances (nightmares in the elderly), and constipation in higher doses. Formulations such as atenolol are water soluble, are β₂ selective, and have fewer side effects. At higher doses, however, β₂ effects emerge. Despite speculation that b₂-selective agents may be safe in asthmatics, they should never be used in these patients. Additional advantages of water-soluble agents are longer half-lives and reduced dosing schedules, which improve compliance. Metabolic changes, similar to those of thiazide diuretics, have reduced the popularity of these drugs. These side effects include an increase in triglyceride levels, a decrease in high-density lipoprotein (HDL) cholesterol levels, and blunting of adrenergic release in response to hypoglycemia. These metabolic problems far outweigh the benefits in patients with diabetes mellitus (30). NSAIDs may also decrease the effectiveness of b-blockers. Additional contraindications are COPD, sick sinus syndrome, or any bradyarrhythmia. A popular use of b-blockers is for treatment of angina and myocardial infarctions. If these drugs are acutely withdrawn, however, a rebound phenomenon of ischemia may occur, leading to acute myocardial infarction. b-Blockers continue to be useful, despite these potential problems, especially to counteract reflex tachycardia common with smooth muscle–relaxing drugs.

Angiotensin-converting Enzyme Inhibitors

Angiotensin-converting enzyme inhibitors (ACE inhibitors) have rapidly become a first-line drug in the treatment of hypertension. Their rapid rise in popularity is due to the introduction of new formulations that allow for once- or twice-daily dosing with a good therapeutic response. There are relatively few side effects; chronic cough is the most worrisome and is the most common cause of discontinuing therapy for this group of drugs. Other side effects are occasional first-dose hypertension and blood dyscrasias. Occasionally patients will suffer from rashes, loss of taste, fatigue, or headaches. Because use is strictly contraindicated during pregnancy, other agents should be considered for women who could become pregnant. ACE inhibitors can be used in combination with other agents, including diuretics, calcium-channel antagonists, and b-blockers. In contrast to b-blockers, these medications can be used in patients with asthma, COPD, depression, and diabetes or peripheral vascular disease. For unknown reasons, they are less effective in African Americans unless a diuretic is used concomitantly. Combined with diuretics, the effectiveness of both drugs increases, but hypotension may result. If renal failure is present, hyperkalemia may result from potassium supplementation and altered tubular metabolism. Any NSAID, including aspirin, may decrease the antihypertensive effectiveness.

Angiotensin Receptor Antagonists

Angiotensin receptor antagonists such as losartan and valsartan are drugs that interfere with the binding of angiotensin-II to AT-1 receptors. They are as effective as ACE inhibitors in lowering blood pressure without causing the side effect of coughing. Their efficacy in protecting the heart and kidney, similar to ACE inhibitors, remains to be established.

Calcium-channel Blockers

Calcium-channel blockers have been a major therapeutic breakthrough for patients with coronary artery disease and have been found to be effective in patients with hypertension and peripheral vascular disease. The mechanism of action is to block calcium movement across smooth muscle, therefore promoting vessel wall relaxation. Calcium-channel blockers are especially useful in treating concurrent hypertension and coronary artery disease. Additionally, these drugs have been shown to be particularly effective in the elderly and African Americans. Side effects noted include headache, dizziness, constipation, and peripheral edema. The introduction of long-acting calcium-channel blockers has made these preparations more amenable for use in hypertension. Heart failure or conduction disturbances are relative contraindications for use of these drugs.

Direct Vasodilators

Hydralazine is a potent vasodilator used for years in obstetrics for severe hypertension associated with preeclampsia and eclampsia. The mechanism of action is direct relaxation of vascular smooth muscle, primarily arterial. Major side effects include headaches, tachycardia, and fluid (sodium) retention that may result in paradoxical hypertension. Several combinations have been used to counter the side effects and enhance antihypertensive effects. Diuretics may be added to reverse fluid retention caused by sodium retention. When used in combination with b-blockers, tachycardia and headaches may be controlled without compromising the objective of lowering blood pressure. Drug-induced lupus erythematosus has been widely noted as a potential side effect but is rare in normal therapeutic doses of 25 to 50 mg three times per day. Minoxidil is another extremely potent drug in this class, but it is limited use to the gynecologist due to its side effects in women (beard growth). Because of minoxidil's potency, only experienced practitioners should use it.

Central-acting Agents

Central-acting agents (methyldopa and clonidine) have long been used in obstetrics. The mechanism of action is to inhibit the sympathetic nervous system, resulting in peripheral vascular relaxation. The popularity of this group of drugs has been limited by side effects such as taste disorders and dry mouth, as well as the need for frequent dosing (except for the transdermal form of clonidine). Sudden withdrawal of clonidine may precipitate a hypertensive crisis and induce angina. The clonidine withdrawal syndrome is more likely with concomitant use of b-blockers. Compliance is always a major issue in patient care, and side effects can have a major impact. With the introduction of new classes of drugs with improved efficacy and reduced side effects, the use of medications in this class is expected to decline.

Monitoring Therapy

For patients with slightly elevated blood pressure who are being managed with lifestyle modification, blood pressure readings should be monitored frequently by a professional nurse, the patient, or medical office staff at 1- to 2-week intervals. If the patient has other diseases (i.e., cardiovascular or renal), therapy should be initiated earlier and should be directed to the target organ. If lifestyle modification alone is successful, close monitoring is necessary at 3- to 6-month intervals. When lifestyle modification is unsuccessful, blood pressure medication should be administered to decrease target organ disease.
Once antihypertensive medications are initiated, monitoring should be frequent. Selected agents and dosages for therapy are found in Table 9.7 and are not meant to be all-inclusive. Patients capable of home blood pressure monitoring should be encouraged to measure blood pressure at the same time twice weekly (32) and maintain a log for physician review of effectiveness of therapy. Once medications are begun, a return appointment should be scheduled in 2 to 4 weeks to monitor effectiveness and side effects. Where possible, single agents (monotherapy) should be used to improve compliance. Monotherapy should control 50% to 60% of patients with mild-to-moderate hypertension. If initial doses are ineffective, then a higher dose should be used prior to changing agents. If resistance to therapy continues, then a different class may be started or a second drug should be added.

</tbody>
</table>

If intolerable side effects develop, a different class of medications should be started and monitored. In the past, step therapy was used, starting with thiazides, followed by the addition of β-blockers, and finally followed by vasodilator drugs. The newer drugs (ACE inhibitors, postadrenergic ganglionic blockers, and calcium-channel blockers) are more potent, have longer half-lives, and may be used as single agents. Patients whose blood pressure is difficult to control with monotherapy should be considered for referral. Causes of resistance to therapy include diseases and secondary causes of hypertension missed during the initial evaluation, unrecognized early end-stage disease, and poor compliance. Patients with evidence of target-organ disease should also be considered for transfer or referral to the appropriate specialist for more intensive diagnostic workup and therapy.

Cholesterol

It has been stated that cholesterol is the most highly decorated small molecule in biology (33). The dietary influence of cholesterol on atherosclerosis and its relationship to hypertension and cardiovascular events (myocardial infarction and stroke) has been widely debated in both the scientific and lay communities (34). The controversy centers on the influence of dietary cholesterol in risk assessment and prevention of cardiovascular disease (35). Many assume that all cholesterol and fat in the diet have negative health consequences. Furthermore, cholesterol metabolism is complex and our understanding in some cases is extrapolated from animal models. The role of cholesterol testing (who, when, and at what age) is hotly debated among health care professionals. Cholesterol testing is fraught with multiple variables that affect results. The purpose of the following discussion is to identify patients at risk for complications of hypercholesterolemia and better understand overall metabolism and therapy.

Terms and Definitions

Exclusively LDL and HDL cholesterol do not determine cholesterol metabolism, despite popular discussion. Cholesterol is usually found in an esterized form with various proteins and glycerides that characterize the stage of metabolism. The following components are important lipid particles in cholesterol metabolism.

Chylomicrons These are large lipoprotein particles that consist of dietary triglycerides and cholesterol. Chylomicrons are secreted in the intestinal lumen, absorbed in the lymph, and then passed into general circulation. In adipose tissue and skeletal muscle, they adhere to binding sites on the capillary wall and are metabolized for energy production.

Lipoprotein Particle A lipoprotein particle is made from three major components. The core consists of nonpolar lipids (triglycerides and cholesterol esters) that are present in varying amounts, depending on which stage of the metabolic pathway they are found. Surrounding the nonpolar core is a surface coat of phospholipids that is made of apoproteins and structural proteins.

Apoprotein Attached to all lipoprotein particles is an apoprotein. This is a specific recognition protein exposed at the surface of a lipoprotein particle. Apoproteins have specific receptors and demarcate the stage of cholesterol metabolism. Certain apoproteins are associated with specific types of cholesterol. For example, apoprotein A-I and apoprotein A-II are associated with HDL cholesterol, the so-called scavenger cholesterol. Apoprotein C-II has additional activity as a cofactor for lipoprotein lipase.

Lipoprotein Class Lipoprotein particles are separated into five classes that are dependent on physical characteristics. Lipoprotein classes are determined by the separation of lipids in an electrophoretic field; however, in vivo they are in a continuum. The various cholesterol metabolites are separated by density. As lipoprotein particles are metabolized and lipids are removed for energy production, they become denser. Additionally, attached apoproteins are modified as cholesterol moves from the so-called exogenous pathway (dietary) to the endogenous pathway (postabsorption and metabolized by the liver).

Subdivisions of the lipoprotein classes are described below and summarized in Fig. 9.3.

Figure 9.3 Metabolic pathways for lipid metabolism.

Prehepatic Metabolites

Chylomicrons and Remnants These metabolites are composed of major lipids and apoproteins of the A, B-48, C, and E classes. Their density is 1.006 g/ml. As expected, these are large particles made up of dietary cholesterol molecules that are absorbed with triglycerides.
Posthepatic Metabolites

**Very-low-density Lipoprotein** These metabolites are transitory remnants found after initial liver metabolism and comprise only 10% to 15% of cholesterol particles. Very-low-density lipoproteins (VLDLs) consist of endogenously synthesized triglycerides with a density of 1.006 g/ml. The diameter is considerably smaller than that of the chylomicrons, ranging from 300 to 800 nm.

**Intermediate-density Lipoprotein (IDL)** The major lipids in this group consist of cholesterol esters that are posthepatic remnants but are derived from dietary sources. Associated apoproteins are B-100, C-III, and E. Apoprotein B-48 is lost after the initial hepatic metabolism and B-100 is substituted. Apoprotein E, which is a liver recognition apoprotein, is found only in VLDLs and intermediate-density lipoproteins (IDL). IDL metabolites are transient lipoproteins and are measured only in certain pathologic conditions. The density is 1.019 g/ml with a diameter of 250 nm—a very significant drop in diameter from 800 nm found in the VLDL.

**LDL Cholesterol** The major lipid in this group is the cholesterol ester and is associated with B-100 apoprotein. LDL cholesterol accounts for approximately 60% to 70% of total cholesterol. Elevated levels of LDL cholesterol have been associated with increased rates of myocardial infarction in women over 65 years of age. There is a structural class called LDL(a) that is associated with myocardial infarction. Several families have been described with structurally abnormal B-100 apoprotein and are at high risk for myocardial infarction due to lipid buildup and premature atherosclerosis (36). Density ranges from 1.019 to 1.063, with a diameter of 180 to 280 nm.

**HDL Cholesterol** This is composed of cholesterol esters with apoproteins A-I and A-II. These particles account for 20% to 30% of total cholesterol and are the densest, with a weight of 1.063 to 1.120 g/ml. The diameter of this group of proteins is 50 to 120 nm.

**Metabolism**

Cholesterol metabolism is divided into two pathways. The first pathway is the exogenous pathway derived from dietary sources. The second pathway is called the endogenous pathway or the lipid transport pathway. Individual variations exist in the ability to metabolize cholesterol, with patients classified as normals, hyporesponders, and hyperresponders (37). Hyporesponders may be given cholesterol-loaded diets with no effect on serum cholesterol measurements. The hyperresponder, in contrast, has high serum cholesterol levels, regardless of dietary intake. Explanations of differences are well described in animal models but not in humans.

Once a meal is eaten, cholesterol is transported as dietary fat. The average American diet contains approximately 100 grams of triglyceride and approximately 1 gram of cholesterol daily. Dietary fats are saponified in the intestinal lumen by pancreatic lipases and synthesized into chylomicrons that are first absorbed by active transport into intestinal lymph and then into the general circulation. Capillaries in the adipose tissue and skeletal muscle are able to incorporate triglycerides and fats by the action of lipoprotein lipase. As schematically depicted in Fig. 9.3, metabolic utilization may occur during either phase of metabolism (e.g., dietary or endogenous). During absorption and synthesis of chylomicrons, apoproteins are incorporated. Apoprotein C-II is important as a cofactor to activate lipoprotein lipase, which enzymatically liberates fatty acids (for energy) and monoglycerides. These fatty acids may enter endothelial, adipose, or muscle cells, where they are either oxidized into active metabolic products or reesterified to triglycerides.

Triglycerides are found in the core lipoprotein particles and are removed through the capillary endothelium and the chylomycin. Predominant apoproteins are B-48 or B-100 and E apoproteins. When chylomycin synthesis occurs in the intestine, the primary B apoprotein is B-48; upon leaving adipose cells, muscle cells, or the liver the second B apoprotein, or B-100, is substituted. Abnormal forms of B-100 are associated with premature cardiovascular disease and are currently used as genetic markers in research laboratories (38). Another apoprotein added during cellular metabolism is apoprotein E. Apoprotein E plays an important role in liver recognition of chylomycin remnants. Theories suggest that hypore- and hyperresponders to dietary cholesterol may be secondary to the liver's ability to recognize and metabolize apoprotein E (39). In the animal model, populations with large numbers of liver receptors for apoprotein E easily metabolize cholesterol and are labeled hyporesponders. Individuals with a reduced number of apoprotein E receptors are unable to metabolize cholesterol as readily, which increases the number of lipid particles in their blood. These individuals are labeled hyperresponders. Despite dietary cholesterol modification, these individuals continue to have high serum cholesterol levels.

After metabolic degradation of dietary chylomycins, apoprotein substitution occurs and liver metabolism of cholesterol esters begins. Lipid transport is now in the endogenous pathway. Carbohydrates are synthesized to fatty acids and esterified with glycerol to form triglycerides. These newly formed triglycerides are not of dietary origin and are placed in the core of VLDLs. VLDL particles are relatively large and carry 5 to 10 times more triglyceride than cholesterol esters with apoprotein B-100. Hypertriglyceridemia is an independent risk factor for cardiovascular disease (40). The relationship between hypertriglyceridemia and cardiovascular disease is well known but poorly defined.

VLDL particles are transported to tissue capillaries, where they are broken down to usable fuels, monoglycerides, and fatty acids. Apoproteins C and E are still present within this lipoprotein particle. After metabolic enzymatic degradation in the peripheral tissues, the IDLs remain. IDLs are either catabolized in the liver by binding to LDL receptors or are modified in the peripheral tissues. As noted above, they are associated with apoprotein E receptors, the liver recognition receptors. During the transformation from IDL to LDL cholesterol, all apoproteins are removed, except apoprotein B-100. The LDL cholesterol, or the so-called high-risk cholesterol, is found in high circulating levels.

Despite the negative connotation of LDL cholesterol in cardiovascular research, it is a very important cellular metabolite that is a precursor for adrenocortical cells, lymphocytes, and renal cells. LDL receptors on cell surfaces allow for LDL cholesterol incorporation into cellular metabolism. In target cells, these lipid particles are hydrolyzed to form cholesterol for use in membrane synthesis and as precursors for steroid hormones (such as estrogen and progesterone). Once the cell has incorporated the necessary cholesterol, the cell surface receptor reforms limiting further absorption. The liver uses the LDL cholesterol for bile acids synthesis and free cholesterol, which is secreted into the bile. In the normal human, 70% to 80% of LDL is removed from the plasma each day and secreted in the bile by utilization of the LDL receptor pathway.

The final metabolic pathway is the transformation of HDL cholesterol in extrapathic tissue. HDL cholesterol carries the plasma enzyme lecithin cholesterol acyltransferase (LCAT). LCAT allows HDL cholesterol to resynthesize lipids to VLDL cholesterol and recycle the lipid cascade. The fate of newly synthesized VLDL cholesterol is the same as absorbed VLDL and it eventually becomes LDL cholesterol. HDL cholesterol acts as a scavenger and therefore reverses the deposit of cholesterol into tissues. There is good evidence that HDL cholesterol is responsible for the reversal of atherosclerotic changes in vessels, hence the term the good cholesterol.

**Hyperlipoproteinemia**

When cholesterol is measured, various fractions are reported. Plasma cholesterol or total cholesterol consists of cholesterol and unesterified cholesterol fractions. If triglycerides are analyzed in conjunction with cholesterol, then assumptions can be made concerning which metabolic pathway may be abnormal. The elevation of both total cholesterol and triglyceride levels signifies a problem with chylomicrons and VLDL synthesis. If the triglyceride-to-cholesterol ratio is greater than 5:1, then the predominant apoprotein is chylomicron; if the ratio is less than 5:1, then the predominant apoprotein is in the VLDL and LDL fractions. Establishing a "normal population" and then setting various limits at the 10th and 90th percentiles define hyperlipoproteinemias. A recent standard for women sets the 90th percentile for cholesterol at 240 mg/dl and the 50th percentile at 200 mg/dl (Table 9.3). Researchers continue to argue that populations vary and may have different cutoff limits depending on the amount of fat versus vegetable and fiber consumption within the diet (43).

The consensus of most researchers is that office laboratory analyses of total cholesterol are virtually worthless as an accurate measure of cholesterol. The eausement techniques are extremely variable. In well-controlled studies, it has been shown that the variation in readings is large (44). Therefore, despite their popularity, they are totally inadequate for either screening or monitoring treatment of patients with hypercholesterolemia.

There are multiple environmental causes of variation in cholesterol measurements (45). Major sources of variation within individuals include diet, obesity, smoking, ethanol intake, and the effects of exercise. Other clinical conditions that affect cholesterol measurements include hypothyroidism, diabetes mellitus, acute or recent myocardial infarction, and recent weight changes. Other variables include the fasting state, position while the sample is drawn, and the use and duration of venous occlusion. Anticoagulants and storage and shipping conditions also can alter lipoprotein measurements (46).

Intraperson variation has been well described. If a single individual has total cholesterol measured 4 times during the day, the variation is 2.5%. If repeated within 1 month, on a twice-weekly basis, the coefficient of variation increases to 4.8%. Monthly measurements over 1 year may result in a variation as high as 6.1%. Therefore, for accurate standardization, at least two and preferably four specimens taken 1 month apart should be collected in the same dietary state in order for a lipid value to be considered accurate.

Age and sex contribute to variations in total cholesterol measurements. Before age 50, women have lower lipid values than men; after age 50, lipid values increase. Exogenous oral conjugated estrogens are thought to contribute to this effect. The genetic basis for interperson variability is thought to be mediated by apolipoprotein receptors.

Seasonal variation also occurs. In December or January, lipid samples taken were found to be approximately 2.5% higher than those measured in June or July. LDL cholesterol and total cholesterol were higher, with no significant variation found for HDL cholesterol. The index population was found to weigh approximately 6% more in December and January than in June or July, which may account for the differences.

The effect of diet and obesity has been well studied. Some researchers felt this effect may be related to hypo- and hyperresponder status. However, weight reduction in an obese individual generally affects the triglyceride level, which may decrease as much as 40%. Total cholesterol and LDL cholesterol levels decrease less than 10% with diet changes; however, HDL cholesterol levels increase approximately 10%. Weight gain negates any benefit from prior weight loss. Therefore, accuracy of lipid measurements depends on the stability of the patient's weight.

Alcohol and cigarette smoking are well-known modifiers of cholesterol levels. Moderate sustained alcohol intake is noted to increase LDL cholesterol and decrease HDL cholesterol levels; however, there is a complementary increase in triglyceride levels. Alcohol has a protective effect when taken in moderation (defined as approximately 2 ounces of absolute alcohol per day), but this effect is negated with higher quantities. The increase in HDL cholesterol levels is in the HDL2 fraction, important in the scavenger mechanism of removing LDL cholesterol. Smoking has the opposite effect, by increasing LDL cholesterol and triglyceride levels and decreasing HDL cholesterol levels. The HDL3 fraction decreases with cigarette smoking. The critical number of cigarettes smoked is 15 to 20 per day, regardless of sex. Caffeine has a mixed effect on lipoprotein measurements but should be avoided in the 12 hours prior to blood collection.

Exercise is an important variable in overall risk management for heart disease. Federal agencies have recognized that moderate levels of exercise are as important in overall cardiovascular health as control of hypertension and cessation of cigarette smoking. Strenuous exercise lowers the concentrations of triglycerides and LDL and increases HDL in the serum. To obtain accurate measurements, vigorous exercise should not be performed within 12 hours of obtaining blood samples.

Because of the diurnal variation of blood triglyceride levels, blood samples should be collected in the morning after a 12-hour fast. Excessive quantities of water should not be consumed before the blood is drawn. The patient should be sitting quietly for approximately 15 minutes prior to the blood draw. Patients who were placed in the supine position for 30 minutes and then required to stand for 30 minutes had a 9% increase in total cholesterol, LDL cholesterol, and VLDL cholesterol fractions, while the HDL cholesterol increased by 10% and triglyceride levels increased by 12%. Additionally, if the tourniquet time is more than 5 minutes, causing vascular stasis, all measurements increase by 10% to 15%. After even 2 minutes of venous occlusion, serum cholesterol increases can be 2% to 5%. Therefore, collection of the cholesterol sample should be done first if multiple blood samples are required. Finger-stick samples are approximately 8.5% lower for all component measurements than venous blood due to contamination of interstitial and lymph fluids.

Collection tube anticoagulants may have a profound effect on lipoproteins. The total cholesterol level has been observed to change depending on the anticoagulant used: ethylenediaminetetraacetic acid (EDTA) increases measurements by 3%, oxalate increases by 9%, citrate increases by 14%, and fluoride by 18%. EDTA is the standard anticoagulant for cholesterol measurement. If cholesterol measurements cannot be run in a reasonable time, the samples may be stored at 0°C for up to 4 days, at −20°C for 6 months, or at −50°C to −80°C indefinitely. Specimens transported by mail should be placed on dry ice.

One of the most important aspects of overall standardization of lipoprotein measurements is the laboratory used. Currently, laboratory levels should be within ±5% of CDC standards for lipoprotein measurements. Approximately 80% of laboratories in one study met this criteria (47). Therefore, to accurately assess cholesterol values, the clinician should be knowledgeable about the laboratory used. It may be useful to consult with the clinical pathologist of a hospital to determine if the laboratory complies with CDC standards for cholesterol and lipoprotein measurements.

### Disease States and Medication Effects

Certain disease states and medications have an impact on cholesterol measurements. As noted previously, diuretics and propranolol increase triglyceride and decrease HDL cholesterol levels. Diuretics may also increase total cholesterol levels. Patients with diabetes mellitus, especially those with poor control, may have very high levels of triglycerides, LDL cholesterol, and decreased HDL cholesterol. This may explain why they are prone to cardiovascular diseases. Diabetics under “tight” control generally have improved lipoprotein levels.

Pregnancy is associated with decreased total serum cholesterol in the first trimester with continuous increases of all fractions over the second and third trimesters (48). The LDL and triglyceride concentrations are the lipoproteins most affected by pregnancy. Limited studies have been done on standardization of lipid levels in pregnancy. Because of the short span, interventions would be of little clinical significance. Lastly, patients with hypothyroidism are also noted to have increased levels of total cholesterol and LDL cholesterol.

### Management

Once hyperlipidemia is confirmed on at least two separate occasions, secondary causes should be diagnosed or excluded by taking a detailed medical and drug history, measuring serum creatinine and fasting glucose levels, and performing thyroid and liver function tests. For obese patients, diet and weight loss is the first
level of therapy. Figure 9.4 shows a suggested algorithm for cholesterol control based on the LDL level. Cholesterol- and fat-lowering diets abound in most bookstores and allow the patient to choose a diet she will best follow. The role of exercise and cigarette cessation should be stressed to all patients. Patients with family history of cardiovascular disease (history of premature coronary artery problems and strokes) should be tested and started on conservative programs when they are in their twenties. After 3 to 6 months, if the LDL cholesterol level remains above 160 mg/dl, or above 130 mg/dl with risk factors, medical therapy should be initiated. Since the second report of the Adult Treatment Panel of the National Cholesterol Education Program (NCEP ATP II) was published in 1993, evidence from recent clinical trials has suggested a lower treatment threshold for patients with established coronary artery disease.

The bile acid-binding resin cholestyramine andcolestipol were the mainstay of therapy for years but are associated with constipation, bloating, nausea, and heartburn. These agents also may interfere with the absorption of many drugs, which has limited their usefulness. Nicotinic acid (500 mg 3 times a day) decreases triglyceride, LDL, and lipoprotein(a) levels and increases HDL levels more than any other drug. However, flushing, pruritus, and gastrointestinal distress are a few of the adverse effects ofnicotinic acid. Starting at a low dose and pretreating with aspirin (325 mg) or ibuprofen (200 mg) can minimize the facial flushing. Fibric acid derivatives like clofibrate and gemfibrozil are used mainly to lower triglycerides and increase HDL but may increase LDL levels in some patients. The 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors ("statins") include atorvastatin, fluvastatin, lovastatin, pravastatin, and simvastatin. These medicines inhibit HMG-CoA reductase, the enzyme that catalyzes the rate-limiting step in cholesterol synthesis. Several clinical trials have shown that pravastatin, simvastatin, and lovastatin have a beneficial effect in cardiovascular disease. Statins are generally better tolerated than other lipid-lowering drugs, but severe myalgias, muscle weakness with increases in creatine phosphokinase levels, and rarely rhabdomyolysis leading to renal failure have been reported. Symptomatic hepatitis is rare, but serum glutamic oxaloacetic transaminases should be measured 6 and 12 weeks after initiation of therapy, and semiannually once therapeutic levels are reached. The usual daily starting doses for the statin drugs are the following: atorvastatin (10 mg), fluvastatin (20 mg), lovastatin (20 mg), pravastatin (20 mg), and simvastatin (20 mg) (50).

**Diabetes Mellitus**

Diabetes mellitus (DM) is a chronic disorder of altered carbohydrate, protein, and fat metabolism from a deficiency in the secretion or function of insulin. The disease is defined by either fasting hyperglycemia or elevated plasma glucose levels after an oral glucose tolerance test (OGTT). The major complications of DM are primarily vascular and metabolic complications. Only 50% of an estimated 13 million Americans with DM have been diagnosed. The prevalence of DM is higher in women and certain ethnic groups, although a background rate in the general population is 2.5% (51). Risk factors for DM are (a) age greater than 46 years, (b) adiposity or obesity, (c) family history of diabetes, (d) race and ethnicity, (e) hypertension (140/90 or greater), (f) HDL cholesterol less than or equal to 35 mg/dl with or without a triglyceride level greater than or equal to 250 mg/dl, and (g) history of gestational diabetes or delivery of baby over 9 pounds. Lifestyle may be the most important variable for type 2 diabetes, as discussed below. Major complications of DM include blindness, renal disease, gangrene of an extremity, heart disease, and stroke. Diabetes is one of the four major risk factors for cardiovascular disease (51).

**Classification**

In January of 1999, the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus published a report revising the system that had been in use since 1979 (52). The goal of the revision is to provide guidelines for nomenclature and testing that may reduce diagnostic confusion and improve patient well-being (Table 9.9). The terms insulin-dependent diabetes mellitus (IDDM) and non–insulin-dependent diabetes mellitus (NIDDM) should be eliminated to reduce confusion regarding the meaning of each of these categories. These terms should be replaced by the designations of type 1 and type 2 diabetes mellitus.

<table>
<thead>
<tr>
<th>Type 1 Diabetes Mellitus</th>
</tr>
</thead>
<tbody>
<tr>
<td>The major metabolic disturbance of type 1 diabetes is the absence of insulin from destruction of b cells in the pancreas. Insulin is necessary for glucose metabolism and cellular function. When insulin is absent, ketosis results. The cause of type 1 diabetes is unknown; however, data suggest an autoimmune factor from either a viral infection or toxic components in the environment. Studies in the past decade have shown a correlation between many autoimmune diseases and the human leukocyte antigens (HLA). Insulin-sensitive tissues (muscle, liver, and fat) fail to metabolize glucose efficiently in the absence of insulin. In uncontrolled type 1 diabetes, additional excess of counterregulatory hormones (cortisol, catecholamines, and glucagon) contributes to further metabolic dysfunction. In the absence of adequate amounts of insulin, increasing breakdown products of muscle (amino acid proteinolysis), fat (fatty acid lipolysis), and glycogen (glucose glycoenolysis) are recognized. Additionally, there is an increase in glucose production from noncarbohydrate precursors from gluconeogenesis and ketogenesis in the liver. If not promptly treated, severe metabolic decompensation (i.e., diabetic ketoacidosis [DKA]) will occur and may lead to death.</td>

<tr>
<th>Type 2 Diabetes Mellitus</th>
</tr>
</thead>
<tbody>
<tr>
<td>Type 2 diabetes mellitus is a heterogeneous form of diabetes that commonly occurs in older age groups (&gt;40 years), and is more frequently noted to have familial tendency than type 1 diabetes. In contrast to an absence of insulin that occurs with type 1 diabetes, altered metabolism of insulin occurs in type 2 diabetes.</td>
</tr>
</tbody>
</table>
diabetes, resulting in insulin resistance. This condition is characterized by impaired glucose uptake in target tissues. A compensatory increase in insulin secretion results, with higher-than-normal circulating insulin levels (53). Obesity is present in 85% of affected patients. The cause of type 2 diabetes is unknown, but defects in both the secretion and action of insulin are suspected.

Many patients diagnosed with type 2 diabetes at an early age eventually exhaust endogenous pancreatic insulin and require injected insulin. When under severe stress, such as infection or surgery, they may develop DKA, or a hyperglycemic hyperosmolar nonketotic state (HHNS). Risk factors for type 2 diabetes include ethnicity, obesity, strong family history of DM, sedentary lifestyle, impaired glucose tolerance, upper body adiposity, history of gestational diabetes, and hyperinsulinemia. The presence of risk factors strongly influences the development of type 2 diabetes in susceptible populations.

**Diagnosis**

Three methods are available to diagnose diabetes mellitus in nonpregnant adults:

1. A single fasting blood glucose greater than or equal to 126 mg/dl on two separate occasions;
2. A random blood glucose equal to or above 200 mg/dl in an individual with classic signs and symptoms of diabetes (polydipsia, polyuria, polyphagia, and weight loss); and
3. A 2-hour OGTT (fasting sample, 60- and 120-minute samples) after a 75-gram load of glucose.

A 2-hour OGTT should not be performed if the first two criteria are present.

Diagnostic criteria for impaired glucose intolerance (IGT) testing are a fasting glucose ≥110 mg/dl but <126 mg/dl.

The 2-hour OGTT should be performed under the following conditions:

1. A 10-hour fast precedes morning testing,
2. The patient should sit throughout the procedure,
3. No smoking is permitted during the test interval,
4. Caffeinated beverages should not be consumed,
5. More than 150 grams of carbohydrates should be ingested for 3 days prior to the test,
6. No drugs should be taken prior to the test,
7. The patient should not be bedridden or under stress.

Patients should be considered for diabetes mellitus testing if the following factors are present:

- Age ≥45 years (repeat at 3-year intervals)
- Classic signs and symptoms of diabetes (i.e., polyuria, polydipsia, polyphagia, and weight loss)
- Ethnic groups at high risk (Pacific Islanders, Native Americans, African Americans, Hispanic Americans, Asian Americans)
- Obesity
- First-degree relative with diabetes
- Gestational diabetes or birth of a baby over 9 pounds
- Hypertension (≥140/90)
- HDL cholesterol levels ≤35 mg/dl or triglyceride level ≥250 mg/dl
- Impaired glucose tolerance based on previous testing

**Assessment of Glycemic Control**

The only acceptable method for assessment of glycemic control is by determination of blood glucose by the direct enzymatic method and not by urine values. Urine values have been proven not to reflect current blood values. In the past decade multiple adequate techniques using test strips and meters have been introduced. These machines work well but reflect whole blood determinations, not serum values. Upgrades of testing strips (in which blood does not need to be wiped away) and glucometers with memory storage have made home glucose monitoring more reliable. Urine tapes to test for ketones are useful and quick methods for assessing ketosis. If the urine is consistently positive for ketones and blood glucose values remain above 300 mg/dl, the patient should seek medical advice. A 10-year multicenter study for diabetes control and complication trial (DCCT) performed under the auspices of the National Institutes of Health (NIH) showed a marked reduction (40% to 50%) in complications of neuropathy, retinopathy, and nephropathy when patients with type 1 diabetes mellitus received intensive therapy (accomplished by a team approach) as compared with those who received standard therapy.

---

**Table 9.10. Physician Guidelines in the Therapy of Diabetes Mellitus**

**Table 9.11. Patient Guidelines for Treatment of Type 2 Diabetes**

---

Treatment of Type 2 Diabetes Mellitus
Diet is the most important component of diabetes mellitus management and usually the hardest way to achieve control. Three major strategies are used: weight loss, low fat diet (<30% of calories from fat), and physical exercise. Obese patients should reduce their weight to ideal body weight. Metabolic advantages of weight reduction are improved lipid profile and improved glucose control secondary to increased insulin sensitivity and decreased insulin resistance. The greater the weight loss, the greater the improvement in lipid disorders. Physical exercise promotes weight loss and improves insulin sensitivity and dyslipidemia in those who are in high-risk groups for cardiovascular and microvascular diseases (54).

Oral hypoglycemic agents (OHAs) are recommended for many type 2 diabetic patients (55). First- and second-generation sulfonylureas are currently the only agents approved by the FDA. Other classes of drugs like biguanides, thiazolidinediones, and α-glucosidase inhibitors have recently been introduced which have different effects in patients with type 2 diabetes than sulfonylureas. Currently available sulfonylurea formulations and biguanides are listed in Table 9.12. The mode of action of sulfonylureas is based on two different mechanisms, (a) enhanced insulin secretion from the pancreas, and (b) an extrapancreatic effect which is poorly understood. Endogenous insulin secretion (as measured by C peptide) is necessary for OHAs to work. Additionally, if the fasting blood glucose in a patient on an adequate diabetic diet is greater than 250 mg/dl, there is little effect. OHAs fail to control glucose in 3% to 5% of patients annually. Frequent evaluation to monitor control (every 3 months) is important. If glucose levels cannot be controlled with oral hypoglycemic agents like sulfonylureas, then insulin, metformin (a biguanide), or an α-glucosidase inhibitor should be started and referral should be considered because of the increased rate of complications experienced by this group.

**Thyroid Diseases**

Thyroid disorders are more common in women and some families, although the exact inheritance is unknown (56). In geriatric populations, the incidence may be as high as 5% (67). Unfortunately, the laboratory diagnosis of thyroid disease can be difficult because of altered hormonal states such as pregnancy and exogenous hormones. Thyroid hormones act in target tissues by binding to nuclear receptors, which induce changes in gene expression (58). Extrathyroidal conversion of thyroxine (T4) to triiodothyronine (T3) takes place in target tissue. T3 binds the nuclear receptor with higher affinity than T4, which makes T3 more biologically active. Pituitary thyroid-stimulating hormone (TSH) and hypothalamic thyrotropin-releasing hormone (TRH) regulate hormone production and thyroid growth by normal feedback physiology. Thyroid-stimulating immunoglobulins (TSIs), once known as long-acting thyroid stimulator (LATS), bind to the TSH receptor that results in hyperthyroid Graves’ disease.

Plasma proteins bind over 99% of circulating T3 and T4, predominately to thyroxine-binding globulin (TBG), and the remaining 1% of thyroid hormones are free. Free levels of thyroid hormones remain constant despite physiologic or pharmacologic alterations. Regardless of total serum rotein levels, active thyroid hormone remains stable. In women, transitions from puberty to menopause do not alter free thyroid hormone concentrations. Excess endogenous or exogenous sources of estrogens or TBG plasma concentrations because of hepatic clearance. Androgens (especially testosterone) and corticosteroids have the opposite effect by increasing hepatic TBG clearance.

Thyroid function tests may be misleading in women receiving exogenous sources of estrogen because of altered binding characteristics. In euthyroid individuals, elevations of thyroid hormone concentrations arise from three mechanisms, (a) increased protein binding because of altered albumin and estrogen states, (b) decreased peripheral conversion of T4 to T3, or (c) rarely occurring congenital tissue resistance to thyroid hormones. The most common alteration in laboratory findings is due to altered estrogen states (hormonal replacement therapy, pregnancy), which complicate interpretation of thyroid function studies. Most laboratories compensate for TBG plasma concentration by decreasing hepatic clearance. If a question arises, consultation with the clinical pathologist should be sought.

**Hypothyroidism**

Overt hypothyroidism occurs in 2% of women, and at least an additional 5% develop subclinical hypothyroidism. This is especially true in the elderly in whom many of the signs and symptoms are subtle. The principal cause of hypothyroidism is autoimmune thyroiditis (Hashimoto’s thyroiditis). A familial predisposition is observed in many cases, but the specific genetic or environmental trigger is unknown. The incidence of autoimmune thyroiditis increases with age, affecting up to 15% of women over 65 years of age. Many have subclinical hypothyroidism that is defined as an elevated serum TSH concentration with a normal serum free T3 level. Thyroid replacement therapy usually reverses this condition. Autoimmune thyroiditis may be associated with other endocrine (e.g., type 1 diabetes, primary ovarian failure, adrenal insufficiency, and hypoparathyroidism) and nonendocrine disorders (e.g., vitiligo and pernicious anemia) (59). Therefore, when autoimmune diseases are present, there should be a high degree of suspicion for concurrent thyroid disorders. Lateralizing causes of hypothyroidism occur after surgical removal or radioactive iodine therapy for hypothyroidism or thyroid cancer. Forty years ago, radiation was used to treat acne and other dermatologic disorders; these patients have an increased risk of thyroid cancer and require close monitoring. Hypothyroidism rarely occurs secondary to pituitary or hypothalamic diseases from TSH or TRH deficiency but must be considered if symptoms occur after neurosurgical procedures.

**Clinical Features**

Manifestations of hypothyroidism include a broad range of signs and symptoms including fatigue, lethargy, cold intolerance, nightmares, dry skin, hair loss, constipation, periorbital carotenoid deposition (causing a yellow discoloration), carpal tunnel syndrome, and weight gain (usually less than 5 to 10 kg). Menstrual dysfunction is common, either as menorrhagia or amenorrhea. Infertility may arise from anovulation, but exogenous thyroid hormone is not useful for women who are anovulatory and euthyroid. Empiric use of thyroid extract, common many years ago, should be discouraged. Common neuropsychiatric symptoms that may be early signs of hypothyroidism include depression, irritability, impaired memory, and dementia in the elderly.

**Diagnosis**

Hypothyroidism should always be confirmed with laboratory studies. Primary hypothyroidism is characterized by the combination of an elevated serum TSH with a low serum free T4 or free T3 index. Autoimmune thyroiditis can be confirmed by the presence of serum antithyroid peroxidase (formerly referred to as antimicrosomal) antibodies. Central hypothyroidism, although rare, is distinguished by a low or low-normal serum free T4 with either a low or inappropriately normal serum TSH concentration.
Therapy

L-thyroxine (T4) is the treatment of choice for hypothyroidism and is available as levothyroxine (Synthroid or Levothroid) (61). The mode of action is by conversion of T4 to T3 in peripheral tissues. A parenteral formulation is available but seldom needed because of the long half-life (7 days) of oral preparations. Absorption may be poor when taken in combination with aluminum hydroxide (common in antacids), cholestyramine, ferrous sulfate, or sucralfate because of binding or chelation. The usual T4 requirement is weight-related (approximately 1.6 μg/kg) but decreases for the elderly. Normal daily dosage is 0.1 to 0.15 mg, but should be adjusted to maintain TSH levels within the normal range.

In the early 1980s, many clinicians thought that by increasing the serum T4 to mildly elevated levels that conversion of T4 to T3 would be enhanced. Subsequent data has proven that even with a mild increase of T4 there was associated cortical bone loss and atrial fibrillation, particularly in older women (62). A low initial T3 dose (0.025 mg/day) should be initiated in patients with known or suspected coronary artery disease. Rapid replacement may worsen angina and, in some cases, induce myocardial infarction.

Hyperthyroidism

Hyperthyroidism affects 2% of women in their lifetime, most often during their childbearing years. Graves’ disease represents the most common disorder; it is associated with orbital inflammation causing the classic exophthalmos associated with the disease, and a characteristic dermopathy, pretibial myxedema. The cause of Graves’ disease in genetically susceptible women is unknown. Autonomously functioning benign thyroid neoplasias are less common causes of hyperthyroidism and are associated with toxic adenomas and toxic multinodular goiters. Transient thyrotoxicosis may be the result of unregulated glandular release of thyroid hormone in postpartum (painless, silent, or lymphocytic) thyroiditis and subacute (painful) thyroiditis. Other rare causes of thyroid overactivity include: human chorionic gonadotropin (HCG)–secreting choriocarcinoma, TSH-secreting pituitary adenoma, and struma ovarii. Facilitative ingestion or iatrogenic overprescribing should be considered in patients with eating disorders.

Clinical Features

Symptoms of thyrotoxicosis include fatigue, diarrhea, heat intolerance, palpitations, dyspnea, nervousness, and weight loss. In young patients there may be paradoxical weight gain from an increased appetite. Thyrotoxicosis may cause vomiting in pregnant women that may be confused with hyperemesis gravidarum (63). Thyrotoxicosis, regardless of dose, is associated with a higher risk of malignancy. Virtually all nodules require histologic evaluation. In the past decade, this is accomplished by fine-needle aspiration (FNA) biopsy rather than open surgical biopsy. Thyroid function tests should be performed prior to FNA, and if the results are abnormal the underlying disease should be treated. In many cases, the nodule will regress during therapy and eliminate the need for FNA. Nodules that persist after therapy, the patient should be placed on lifetime suppression and monitored by assessment of TBG levels. Radioiodine therapy or surgical ablation are the most common methods of therapy. After therapy, the patient should be placed on lifetime suppression. b-Adrenergic blocking agents such as propranolol are useful adjunctive therapy for control of sympathomimetic symptoms such as tachycardia (64). Tachycardia, lid lag, tremor, proximal muscle weakness, and warm, moist skin are classic physical findings on examination. The most dramatic physical changes are ophthalmologic and include lid retraction, periorbital edema, and proptosis. These eye findings, however, occur in less than one-third of women. In elderly adults, symptoms are often more subtle with presentations of unexplained weight loss, atrial fibrillation, or new-onset angina pectoris (64). Menstrual abnormalities span from regular menses to light flow, to anovulatory menstrual cycles and infertility. Goiter is common in younger women with Graves’ disease but may be absent in older women. Toxic nodular goiter is associated with nonhomogeneous glandular enlargement, while in subacute thyroiditis the gland is tender, hard, and enlarged.

Diagnosis

Most thyrotoxic patients have elevated total and free T4 and T3 (measured by radioimmun assay [RIA]) concentrations. In thyrotoxicosis, serum TSH concentrations are virtually undetectable, even with very sensitive assays (sensitivity measured to 0.1 units). Sensitive serum TSH measurements may aid in the diagnosis of hyperthyroidism. Radioiodine uptake scans are useful in the differential diagnosis of established hyperthyroidism. Scans with homogeneous uptake of radioactive iodine are suggestive of Graves’ disease, while those with a heterogeneous tracer uptake are suggestive of a diagnosis of nodular goiter. In distinction, thyrotoxicosis and medicated thyrotoxicosis are associated with diminished glandular radioscopes concentration.

Therapy

Antithyroid medications, either propylthiouracil (PTU) (50 to 300 mg every 6 to 8 hours) or methimazole (10 to 30 mg per day) are initial therapies used. After metabolic control is obtained, definitive therapy is obtained by thyroid ablation with radioiodine. This results in permanent hyperthyroidism. Both antithyroid drugs block thyroid hormone biosynthesis and may have additional immunosuppressive effects on the gland. The primary difference in oral medications is that PTU partially inhibits extrathyroidal T3-to-T4 conversion, while methimazole does not. However, methimazole has a longer half-life and permits single-daily dosing that may encourage compliance. Euthyroidism is typically restored in 3 to 10 weeks, and treatment with oral antithyroid agents is continued for 6 to 24 months, unless total ablation with radioiodine or surgical resection is performed. Surgery has become less popular, because it is invasive and may result in inadvertent parathyroid removal that commits the patient to lifelong calcium therapy.

The relapse rate with oral antithyroid medications is 50% over a lifetime. Lifelong follow-up is important when medical therapy is used solely because of the high relapse rate. Both medications have infrequent (5%) minor side effects that include fever, rash, or arthralgias. Major toxicity is rare (<1%) and includes hepatitis, vasculitis, and agranulocytosis. Agranulocytosis is not predictable by periodic complete blood counts; therefore, patients who have sore throats or fevers should stop the medication and call their physicians immediately.

Therapy with iodine-131 provides a permanent cure of hyperthyroidism in 70% to 80% of patients. The principal drawback to radioactive iodine therapy is the high rate of postablate hyperthyroidism, which occurs in at least 50% of patients immediately posttherapy, with additional cases developing at a rate of 2% to 3% per year.

Based on the assumption that thyrotoxicosis will develop, patients should be given lifetime thyroid replacement. b-Adrenergic blocking agents such as propranolol are useful adjunctive therapy for control of sympathomimetic symptoms such as tachycardia (65). An additional benefit of b-blockers is the blocking of peripheral conversion of T4 to T3. In rare cases of thyroid storm, PTU, b-blockers, glucocorticoids, and high-dose iodine preparations (SSKI, or intravenous sodium iodide) should be started immediately, and referral to an intensive care unit is advisable.

Thyroid Nodules and Cancer

Thyroid nodules are common and found on physical examination in up to 5% of patients. Nodules may be demonstrated ultrasonographically in as many as 30% of unselected patients. Most nodules, when discovered, are asymptomatic and benign; however, malignancy and hyperthyroidism must be excluded. Irradiation of the neck, regardless of dose, is associated with a higher risk of malignancy. Virtually all nodules require histologic evaluation. In the past decade, this is accomplished by fine-needle aspiration (FNA) biopsy rather than open surgical biopsy. Thyroid function tests should be performed prior to FNA, and if the results are abnormal the underlying disease should be treated. In many cases, the nodule will regress during therapy and eliminate the need for FNA. Nodules that persist after treatment should undergo biopsy. Because most nodules are “cold” on scanning, it is more cost effective to proceed with tissue sampling rather than scanning. Biopsy is successful and provides a diagnosis in 95% of cases; however, in the 5% without diagnosis, surgical biopsy is necessary. Only 20% of surgical biopsies of an “indeterminate aspiration” are found to be malignant (66).

Papillary thyroid carcinoma is the most common malignancy, found in 75% of cases. Patients who are less than 50 years of age with a primary tumor of less than 4 centimeters when discovered, even with associated cervical lymph node metastasis, usually are cured. Anaplastic tumors in the elderly have a poor prognosis and progress rapidly despite therapy. Radioiodine therapy or surgical ablation are the most common methods of therapy. After therapy, the patient should be placed on lifetime suppression and monitored by assessment of TGO levels.

Chapter 10  

Family Planning  

Phillip G. Stubblefield  

The history of contraception is a long one; however, the voluntary control of fertility is even more important in modern society (1). With each woman expected to have no more than one or two children, most of the reproductive years are spent trying to avoid pregnancy. Effective control of reproduction is essential to a woman’s ability to accomplish her individual goals. From a larger perspective, the rapid growth of the human population in this century threatens the survival of all. At its present rate, the population of the world will double in 47 years and that of many of the poorer countries of the world will double in about 20 years (2) (Fig. 10.1). For the individual and for the planet, reproductive health requires careful use of effective means to prevent both pregnancy and sexually transmitted diseases (STDs) (3).

Figure 10.1 Doubling time at different rates of population growth, with representative countries, and world population growth curve. (From Hatcher RA, Trussell J, Stewart F, et al. Contraceptive technology. 17th ed. New York: Ardent Media, 1998:768, with permission.)

From puberty until menopause, women are faced with concerns about childbearing or its avoidance: the only options are sexual abstinence, contraception, or pregnancy. The contraceptive choices made by American couples in 1995, when the last national fertility survey was conducted by the U.S. government from a large national probability sample, are shown in Table 10.1 (4). For couples older than 35 years of age, sterilization is the number one choice. For younger couples, oral contraceptives (OCs) are the most used method, and the condom ranks second. Although use of contraception is high, a significant proportion of sexually active couples do not use contraception: 5.2% in the 1995 National Fertility Survey (4). The percentage of women using no contraception is highest among the youngest group (i.e., adolescents).
Table 10.1. Percentage Distribution of Contraceptive Users Aged 15–44 Years, by Current Method, 1982–1995

It is estimated that 49% of births in the United States in 1994 were unintended, and that by 45 years of age, 43% of women will have at least one induced abortion (5). Abortion is an obvious indicator of unplanned pregnancy. Abortion ratios by age group indicate that the use of abortion is greatest for the youngest women and least for women in their late 20s and early 30s (Fig. 10.2). Use increases again as women become older. Young people are much more likely to experience contraceptive failure because their fertility is greater than that of older women and because they are more likely to have intercourse without contraception. The effect of age on pregnancy rates with different contraceptive methods is shown in Figure 10.3.

Figure 10.3 Percentage of women experiencing an accidental pregnancy, in the first 2 years of use, according to method, combined 1988 and 1995 National Survey of Family Growth. [From Ranjit N, Bankole A, Forrest JD, et al. Contraception failure in the first two years of use: differences across socioeconomic subgroups. Fam Plann Perspect 2001;33:25 (Table 6), with permission.]

Efficacy of Contraception

Factors affecting whether pregnancy will occur include the fecundity of both partners, the timing of intercourse in relation to the time of ovulation, the method of contraception used, the intrinsic effectiveness of the contraceptive method, and the correct use of the method. It is impossible to assess the effectiveness of a contraceptive method in isolation from the other factors. The best way to assess effectiveness is long-term evaluation of a group of sexually active women using a particular method for a specified period to observe how frequently pregnancy occurs. A pregnancy rate per 100 women per year can be calculated using the Pearl formula (dividing the number of pregnancies by the total number of months contributed by all couples, and then multiplying the quotient by 1,200). With most methods, pregnancy rates decrease with time as the more fertile or less careful couples become pregnant and drop out. More accurate information is provided by the life-table method, which calculates the probability of pregnancy in successive months, which are then added over a given interval. Problems relate to which pregnancies are counted: those occurring among all couples or those in women the investigators deem to have used the method correctly. Because of this complexity, rates of pregnancy with different methods are best calculated by reporting two different rates derived from multiple studies (i.e., the lowest rate) and the usual rate as shown in Table 10.2.

Table 10.2. Percentage of Women Experiencing a Contraceptive Failure During the First Year of Use and the Percentage Continuing Use at the End of the First Year

Safety

Some contraceptive methods have associated health risks; areas of concern are listed in Table 10.3. All of the methods are safer than the alternative (pregnancy with...
Periodic Abstinence or Natural Family Planning

With periodic abstinence methods, couples attempt to avoid intercourse during the fertile period around the time of ovulation. A variety of methods are available: the calendar method, the mucus method (Billings or ovulation method), and the symptothermal method, which is a combination of the first two methods. The calendar method is the least effective. With the mucus method, the woman attempts to predict the fertile period by feeling the cervical mucus with her fingers. Under estrogen influence, the mucus increases in quantity and becomes progressively more slippery and elastic until a peak day is reached. Thereafter, the mucus becomes scant and dry under the influence of progesterone until onset of the next menses. Intercourse may be allowed during the “dry days” immediately after menses until mucus is detected. Thereafter, the couple must abstain until the fourth day after the “peak” day.

In the symptothermal method, the first day of abstinence is predicted either from the calendar, by subtracting 21 from the length of the shortest menstrual cycle in the preceding 6 months, or the first day mucus is detected, whichever comes first. The end of the fertile period is predicted by use of basal body temperature. The woman takes her temperature every morning and resumes intercourse 3 days after the thermal shift, the rise in body temperature that signals that the corpus luteum is producing progesterone and that ovulation has occurred.

Efficacy

The ovulation method was evaluated by the World Health Organization in a five-country study. Women who successfully completed three monthly cycles of teaching were then enrolled in a 13-cycle efficacy study. Trussell and Grummer-Strawn calculated a 3.1% probability of pregnancy in 1 year for the small proportion of couples who used the method perfectly and 86.4% probability of pregnancy for the rest (11). Because sperm may survive several days in the female genital tract, even a week’s abstinence around the time of actual ovulation offers no guarantee against pregnancy. Also, ovulation can occur even in the absence of menstruation. Pregnancy has occurred after a single act of coitus 7 days before apparent ovulation indicated by basal body temperature. Vaginal infections increase vaginal discharge, complicating the use of the method.
Accurate advance prediction of the time of ovulation would greatly facilitate both the use and efficacy of periodic abstinence. Devices that combine an electronic thermometer with small computers are being explored in an effort to improve the accuracy of basal body temperature as a predictor of the fertile phase (14). Home monitoring of estrogen provides 4 or more days warning before ovulation and allows intercourse to be resumed 1 to 3 days after ovulation (15). Another approach is the identification of microcrystals in saliva as an indication of approaching ovulation (16).

Risks

Conceptions resulting from intercourse remote from the time of ovulation more often lead to spontaneous abortion than conceptions from midcycle intercourse (17). However, malformations are not more common (18).

Condoms

In the 1700s, condoms made of animal intestine were used by the aristocracy of Europe, but condoms were not widely available until the vulcanization of rubber in the 1840s (1). Modern condoms are usually made of latex rubber, although condoms made from animal intestine are still sold and are preferred by some who feel they afford better sensation. The condom captures and holds the seminal fluid, thus preventing its deposition in the vagina. Until recently, condoms in the United States were made with a relatively thick wall (0.065 to 0.085 mm) to prevent breakage. Japanese condoms as thin as 0.02 mm are now available in the United States (2). Condoms prelubricated with the spermicide nonoxynol-9 are more effective than condoms without spermicide (19). The risk for condom breakage is about 3% (20) and is related to friction. Water-based lubricants may reduce the risk for breakage. Petroleum-based products such as mineral oil must be avoided because even brief exposure to condoms markedly reduces their strength (21).

Sexually Transmitted Diseases

Latex condoms and other barrier methods reduce the risk for STDs. Gonorrhea, ureaplasma, and pelvic inflammatory disease (PID) and its sequelae (tubal infertility) are reduced with consistent use of barrier methods (22,23). A comparison of infertile women and postpartum women showed a 40% reduction in infertility with use of condoms or the diaphragm. The greatest benefit was noted with a combination of the barrier method and a spermicide (24).

Tested in vitro, Chlamydia trachomatis, herpes virus type 2, human immunodeficiency virus (HIV), and hepatitis B did not penetrate latex condoms but did cross through condoms made from animal intestine (25). Additional protection is provided by the addition of the spermicide nonoxynol-9 (26). Follow-up of sexual partners of HIV-infected individuals has shown considerable protection when condoms are used (27). Consistent condom use provides more protection than inconsistent use (28). Studies of HIV-negative, high-risk women who used both condoms and spermicidal suppositories of nonoxynol-9 demonstrated a high degree of protection from HIV seroconversion during follow-up (29). Vaginal spermicide should be used in addition to condoms when prevention of infection is of prime concern. Condoms also offer some protection from cervical neoplasia. In one study, the relative risk for severe dysplasia among users of condoms or diaphragms was 0.4 at 5 to 9 years of use and only 0.2 when the barriers had been used for 10 years or more, which is a 60% to 80% reduction (30). Another study compared women with invasive cervical cancer to controls. The relative risk for invasive cervical cancer was 0.4 when those who had used condoms or diaphragms were compared with those who had never used them (31).

Latex allergy could lead to life-threatening anaphylaxis in either partner from latex condoms. Blank has suggested that nonoxynol-9 used with latex condoms could increase risk for sensitization by leaching a latex protein from the condom (32). Nonlatex condoms of polyurethane and Tactylon are now available and should be offered to couples who have a history suggestive of latex allergy.

Female Condom

Vaginal pouches made of polyurethane are now available for use by women. Efficacy trials have not matched historical trials with other barrier methods, but no randomized trial of the new method has been published. Initial U.S. trials showed a pregnancy rate of 15% in 6 months, however, reanalysis suggests that with perfect use, the pregnancy rate may be only 2.6%. This rate is comparable to perfect use of the diaphragm and cervical cap, the other female barrier methods (33). Colposcopic studies of women using the female condom demonstrate no signs of trauma, and the bacterial flora is not changed (34).

Vaginal Spermicides

Vaginal spermicides combine a spermicidal chemical, either nonoxynol-9 or octoxynol, with a base of cream, jelly, aerosol foam, foaming tablet, film, or suppository. Spermicides are nonionic surface-active detergents that immobilize sperm. In simulated intercourse under laboratory conditions, aerosol foams provided rapid dispersal throughout the vagina and offered the best protection. Jellies and melting suppositories provided poor distribution (35). Spermicides alone appear considerably less effective than condoms or a diaphragm with spermicide. Nonoxynol-9 is known to reduce the risk for bacterial vaginosis and other STDs, including HIV (36).

Concerns have been raised about possible teratogenicity of spermicides. Nonoxynol-9 is not absorbed from the human vagina, however (37), and several large studies have found no greater risk for miscarriage, birth defects, or low birth weight in spermicide users than in other women (38-39). Nonoxynol-9 is toxic to the lactobacilli that normally colonize the vagina. Women who use spermicides regularly have increased vaginal colonization with the bacterium Escherichia coli and may be predisposed to E. coli bacteriuria after intercourse (40).

Vaginal Barriers

At the beginning of the 20th century, four types of vaginal barriers were used in Europe: vaginal diaphragm, cervical cap, vault cap, and vimule (Fig. 10.4). All of these barriers are still made and sold in England. Vaginal diaphragms and cervical caps are used in the United States. When used consistently, vaginal barriers can be highly effective. They are safe and, as condoms, they have the noncontraceptive benefit of relative protection from STDs, tubal infertility, and cervical neoplasia.

Figure 10.4 Vaginal barriers (left to right): Prentiff cavity rim cervical cap, plastic cap, vault cap, vimule, and vaginal diaphragm. (From Copeland LJ. Textbook of gynecology. Philadelphia: WB Saunders, 1993:159, with permission.)

Diaphragm

The diaphragm consists of a circular spring covered with fine latex rubber (Fig. 10.5). There are several types of diaphragm, as determined by the spring rim: coil, flat,
or arcing. Coil-spring and flat-spring diaphragms become a flat oval when compressed for insertion. Arcing diaphragms form an arc or half moon when compressed; they are easiest to insert correctly. The practitioner must not only fit the diaphragm for the patient, but also instruct her in its insertion and verify by examination that she can insert it correctly to cover the cervix and upper vagina. Spermicide is always prescribed for use with the diaphragm; however, whether this practice is necessary is not well studied. In a small trial, women using the diaphragm without spermicide had a higher (19.3 per 100 woman-years) but statistically not significant risk for pregnancy than those who used the diaphragm with spermicide (12.3 per 100 woman-years) (42). Conversely, a different study found that women who wore the diaphragm constantly, removing, washing, and reinserting the diaphragm daily without using a spermicide, had lower pregnancy rates than women who used the diaphragm in the conventional fashion, with a spermicide, only when needed (43). Proper fitting and proper use are key to its effectiveness.

Fitting Diaphragms

Fitting of a diaphragm should be performed as follows:

1. To fit a diaphragm properly, a vaginal examination should first be performed. With the first and second fingers in the posterior fornix, the thumb of the examining hand is placed against the first finger to mark where the first finger touches the pubic bone. The distance from the tip of the middle finger to the tip of the thumb is the diameter of the diaphragm that should first be tried.
2. A set of test diaphragms of various sizes is used, and the test diaphragm is inserted and checked by palpation. The diaphragm should open easily in the vagina and fill the fornices without pressure. The largest diaphragm that fits comfortably should be selected. A size 65, 70, or 75 diaphragm will fit most women.
3. The patient should practice insertion and should be reexamined to confirm proper position of the device. About 1 teaspoon of water-soluble spermicidal jelly or cream is placed in the cavity of the dome. The diaphragm is inserted with the dome downward so that the cervix will sit in a pool of the spermicide.
4. The diaphragm can be inserted several hours before intercourse. If intercourse is repeated, additional spermicidal jelly should be inserted into the vagina at the time of the second act. The diaphragm should be left in place at least 6 hours after intercourse to allow for immobilization of sperm. It is then removed, washed with soap and water, allowed to dry, and stored away from heat. It should not be dusted with talc because genital exposure to talc may predispose to ovarian cancer.

Risks

Diaphragm use, especially prolonged use during multiple acts of intercourse, appears to increase the risk for bladder infections. Risk for cystitis increases with the numbers of days the diaphragm is used in a week (relative risk, 1.42, 2.63, and 5.66 for use 1, 3, or 5 days in a week) (43). A smaller-sized, wide-seal diaphragm or a cervical cap can be used if cystitis is a problem, although the problem may relate not only to mechanical obstruction but also to alterations in vaginal flora produced by the spermicide. An epidemiologic study comparing cases of toxic shock with controls found no increased risk from diaphragm use (44).

Cervical Caps

The cap is much smaller than the diaphragm, does not contain a spring in the rim, and covers only the cervix. Caps are used with spermicide, but the contribution of the spermicide to the efficacy is not known. Studies of the efficacy of cervical caps have revealed a range of results. The Prentiff cap has a pregnancy rate of 8 per 100 women-years with the cap left in place for as long as 5 days at a time (45). A multicenter study of 3,433 women found a first-year pregnancy rate of 11.3 per 100 women. Women whose pattern of use was described as “near perfect” had a first-year pregnancy rate of 6.1 per 100, half that of the overall rate (45). The pregnancy rate increased when the cap was worn for more than 72 hours at a time. Dislodgment of the cap during intercourse or at other times was reported by 27.5% of the users after 3 months of use; dislodgment and accidental pregnancy were the main reasons that women discontinued use of the cap. By 1 year, 49% of women discontinued use or were lost to follow-up. In randomized trials, the cervical cap was as effective as the diaphragm overall, but the failure rates with “perfect use” were considerably higher for the cap than for the diaphragm (47). Parous women using the cap had more failures than nulliparous women. A new version of the cervical cap made of silicone rubber is being studied. It looks like a sailor’s hat with the dome covering the cervix and the rim fitting into the vaginal fornices (48). It is made in three sizes—24-, 28-, and 32-mm diameter—and can be expected to be reusable for 2 to 3 years. It is used with spermicide and is left in place as long as 48 hours.

Fitting Cervical Caps

The Prentiff cavity rim cervical cap is available in the United States in sizes 22, 25, 28, and 31 (internal diameter of the rim in millimeters). A cervical cap should be fitted as follows:

1. The cervical size is estimated by inspection and palpation. Nulliparous women usually require a size 22, whereas parous women generally are fitted with a size 25.
2. The cap is inserted by compressing it between finger and thumb and placing it through the introitus, dome outward. It is then removed, washed with soap and water, allowed to dry, and stored away from heat. It should not be dusted with talc because genital exposure to talc may predispose to ovarian cancer.
3. Before use, the cap should be one-third filled with spermicidal jelly or cream. It can be left in place as long as 72 hours. The patient is instructed to check for dislodgment of the cap after intercourse, and use of an additional contraceptive method such as a condom is advised until it is clear that the cap will not be dislodged.

Risks

In one large trial, negative cervical cytology progressed to dysplasia in 4% of cap wearers and in 2% of diaphragm wearers (49). Other studies have not found this effect (49); in contrast, Koch found cap wearers to be protected from dysplasia compared with controls using other methods (45). The results of cervical cytology appeared to improve during use (48). Cap use has not been associated with cystitis (45,48). Toxic shock has not been reported, even in large series (46).

Intrauterine Devices

IUDs are very important worldwide but play a minor role in contraception for the U.S. population because of a fear of infection that is no longer justified in most populations. The high-dose copper IUD sold in the United States (TCU380, or ParaGard) provides safe, long-term contraception with effectiveness equivalent to tubal sterilization. Two IUDs are now in use in the United States, and a third has been approved by the U.S. Food and Drug Administration (FDA). These IUDs are the copper T380A (ParaGard), the progesterone-releasing T (Progestasert), and the levonorgestrel-releasing T (Mirena). The copper T380A has bands of copper on the cross arms of the T in addition to copper wire around the stem, providing a total surface area of 380 mm of copper, almost double the surface area of copper of earlier copper devices (Fig. 10.6). The copper T380A is approved for up to 10 years of continuous use. The Progestasert must be replaced every year. The Mirena (Fig.
Mechanism of Action

IUDs cause the formation of "biologic foam" within the uterine cavity that contains strands of fibrin, phagocytic cells, and proteolytic enzymes. Copper IUDs continuously release a small amount of the metal, producing an even greater inflammatory response. All IUDs stimulate the formation of prostanoids in the uterus, consistent with both smooth muscle contraction and inflammation. Scanning electron microscopy studies of the endometrium of women wearing IUDs show alterations in the surface morphology of cells, especially of the microvilli of ciliated cells (51). There are major alterations in the composition of proteins within the uterine cavity, and new proteins and protease inhibitors are found in washings from the uterus (52). The altered intrauterine environment interferes with sperm passage through the uterus, preventing fertilization. The natural progestosterone in the Progestaset and the levonorgestrel in the Mirena is much more potent than natural progesterone. Blood levels of the hormone are about half that seen with the levonorgestrel subdermal implant (Norplant) and are sufficient to block ovulation in many women (49).

The IUD is not an abortifacient. The contraceptive effectiveness does not depend on interference with implantation, although this phenomenon also occurs and is the basis for using copper IUDs for emergency contraception. Sperm can be obtained by laparoscopy in washings from the fallopian tubes of control women at midcycle, whereas no sperm are present in the tubal washings from women wearing IUDs (63). Ova flushed from the tubes at tubal sterilization showed no evidence of fertilization in women wearing IUDs (54), and studies of serum b-human chorionic gonadotropin do not indicate pregnancy in women wearing IUDs (55).

Effectiveness

The copper T380A and the levonorgestrel T have remarkably low pregnancy rates, less than 0.2 per 100 woman-years. Total pregnancies over a 7-year period were only 1.1 per 100 for the levonorgestrel T and 1.4 for the copper T380A in a comparative study (49). Twelve-year data on the copper T380A showed a cumulative pregnancy rate of only 1.9 per 100 women (56). The Progestaset has a higher failure rate, about three pregnancies per 100 women per year.

Benefits

Modern IUDs provide excellent contraception, independent of coitus, without continued effort by the user. During use, both the ParaGard and the Mirena IUDs protect against ectopic pregnancy. The Progestaset and Mirena, by releasing progestosterone or levonorgestrel, reduced menstrual bleeding and cramping. The Mirena has been used extensively to treat heavy menstrual bleeding and is used in Europe and the United Kingdom as an alternative to hysterectomy for menorrhagia (57).

Risks

Infection The Women's Health Study (58) found the Dalkon Shield device (now withdrawn from the market) to increase the risk for PID by eightfold when women hospitalized for PID were compared with control women hospitalized for other illnesses. In contrast, risk from the other IUDs was markedly less: relative risk for PID was 2.2 for the Progestaset, 1.9 for the Copper 7, 1.3 for the Saf-T-Coil, and 1.2 for the Lippes Loop (59). Increased risk was detectable only within 4 months of insertion of the IUD. A still larger, prospective World Health Organization study revealed that PID increased only during the first 20 days after insertion. Thereafter, the rate of diagnosis of PID was about 1.6 cases per 1,000 women per year, the same as in the general population (59).

Exposure to sexually transmitted pathogens is a more important determinant of PID than the wearing of an IUD. In the Women's Health Study, women who were currently married or cohabiting and who said they had only one sexual partner in the past 6 months had no increase in PID (59). In contrast, previously married or single women had marginal increase in risk, even though they had only one partner in the previous 6 months (60). The only pelvic infection that has been unequivocally related to IUD use is actinomycosis (61). It appears that PID with actinomycosis has been reported only in women wearing an IUD. Rates of colonization with actinomycosis increase with duration of use for plastic devices but appear to be much less for copper-releasing IUDs.

Pelvic Inflammatory Disease When PID is suspected in an IUD-wearing woman, the IUD should be immediately removed, appropriate cultures should be obtained, and high-dose antibiotic therapy should be started. Pelvic abscess should be suspected and ruled out by ultrasound examination.

Ectopic Pregnancy If pregnancy occurs in an IUD wearer, it will be ectopic in about 5% of cases. This is because the fallopian tubes are less well protected against pregnancy than the uterus. Compared with women using no contraception, however, women wearing either the copper T380A or the levonorgestrel T have an 80% to 90% reduction in the risk for ectopic pregnancy (69), which is a greater reduction than that seen for users of barrier methods. Women using OCs have a 90% reduced risk (62). In contrast, the Progestaset increases risk slightly, probably because the progestosterone affects tubal motility and does not inhibit ovulation (63). One study reported an increased risk for ectopic pregnancy among past users of older IUDs, but it did not include the current higher-dose copper IUD (ParaGard) or the levonorgestrel T (Mirena) (64).

Fertility Case-control studies of infertile women in the United States have revealed that a history of IUD use is associated with a twofold increase in the risk for infertility associated with tubal factors. The risk applies to methods other than the copper IUD, for which there is no increased risk (65,66 and 67). Risk was not increased among women who reported only one sexual partner (65). The Oxford Study found that women gave birth just as promptly after IUD removal as they did after discontinuing use of the diaphragm (69). Exposure to sexually transmitted pathogens confers risk for infertility. Modern IUDs confer a small increased risk for...
Clinical Management

Contraindications to IUD use include pregnancy, a history of PID, undiagnosed genital bleeding, uterine anomalies, and large fibroid tumors. Chronic immune suppression should be considered a contraindication. Women with such conditions are considered to be at greater risk for PID; in addition, the effectiveness of the IUD may be compromised. A number of pregnancies have occurred in renal transplant recipients soon after IUD insertion. Copper allergy and Wilson's disease are contraindications to the use of copper IUDs.

Insertion

At the initial visit, the patient's history is obtained; a physical examination, cervical culture for Neisseria gonorrhoeae, and a test for chlamydia are performed; detailed counseling regarding risks and alternatives is also provided. The patient should avoid intercourse until returning for insertion of the device at a second visit. Premedication with oral prostaglandin inhibitors such as ibuprofen is strongly advised. Antibiotic prophylaxis has not been found beneficial, probably because the risk for pelvic infection with IUD insertion is so low. A large randomized trial of 1,985 patients receiving either oral azithromycin or placebo found no difference in rates of IUD removal during the first 90 days after insertion and no difference in rate of salpingitis (89). These women were screened for STDs only by self-history. The IUD is usually inserted during menses in order to be sure the patient is not pregnant, but it can be inserted at any time in the cycle if the patient is already using effective contraception (79).

The technique of insertion is as follows:

1. The cervix is exposed with a speculum. The vaginal vault and cervix are cleansed with a bacteriocidal solution, such as an iodine-containing solution.
2. The uterine cavity should be measured with a uterine sound. The depth of the cavity should measure at least 6 cm from the external os. A smaller uterus is not likely to tolerate currently available IUDs.
3. A paracervical block with 10 ml of 1% lidocaine mixed with atropine (5 mg) can be used to avoid vasovagal syncope and minimize discomfort. In some women, serious cardiac arrhythmia can occur with cervical stimulation and can be avoided by these measures.
4. Use of a tenaculum for insertion is mandatory to prevent perforation. The cervix is grasped with a tenaculum and gently pulled downward to straighten the angle between the cervical canal and the uterine cavity. The IUD, previously loaded into its inserter, is then gently introduced through the cervical canal.
5. With the ParaGard and the Progestasert, the outer sheath of the inserter is withdrawn a short distance to release the arms of the T and is then gently pushed inward again to elevate the new-opened T against the fundus (71). The outer sheath and the inner stylet of the inserter are withdrawn, and the strings are cut to project about 2 cm from the external cervical os.
6. With the Mirena IUD, insertion is somewhat different. The inserter tube loaded with the IUD is introduced into the uterus until the preset sliding flange on the inserter is 1.5 to 2 cm from the external os of the cervix. The arms of the T device are then released upward into the uterine cavity, and the inserter is pushed up under them to elevate the IUD up against the uterine fundus.

Intrauterine Devices in Pregnancy

A woman with an IUD in place who has amenorrhea should have a pregnancy test and pelvic examination. If an intrauterine pregnancy is diagnosed and the IUD strings are visible, the IUD should be removed as soon as possible in order to prevent later septic abortion, premature rupture of the membranes, and premature birth (72). When the strings of the IUD are not visible, an ultrasound examination should be performed to localize the IUD and determine whether expulsion has occurred. If the IUD is present, there are three options for management:

1. Therapeutic abortion
2. Ultrasound-guided intrauterine removal of the IUD
3. Continuation of the pregnancy with the device left in place

If the patient wishes to continue the pregnancy, ultrasound evaluation of the location of the IUD is advised (73). If the IUD is not in a fundal location, ultrasound-guided removal using small alligator forceps is advised. If the location is fundal, the IUD should be left in place. If pregnancy continues with an IUD in place, the patient must be warned of the symptoms of intrauterine infection and should be cautioned to seek care promptly for fever or flulike symptoms, abdominal cramping, or bleeding. At the earliest sign of infection, high-dose intravenous antibiotic therapy should be given and the pregnancy evacuated promptly.

Duration of Use

Annual rates of pregnancy, expulsions, and medical removals decrease with each year of use (74,75). Therefore, a woman who has had no problem by year 5, for example, is very unlikely to experience problems in the subsequent years. As noted, the Progestasert should be replaced at the end of 1 year, but the copper T380A is approved for 10 years and the levonorgestrel T for 5 years. Actinomycosis can be detected by cervical cytology. Should actinomycoses-like particles be found, removal of the IUD and treatment with oral penicillin is recommended.

Choice of Devices

Of the three IUDs approved in the United States, the copper T380A and levonorgestrel T are preferred. They provide protection for many years, have remarkably low pregnancy rates, and reduce risk for ectopic pregnancy substantially. The Progestasert must be replaced annually, theoretically exposing the patient to some risk for infection with each insertion, and increasing cost markedly. It is less effective and increases the risk for ectopic pregnancy slightly. Both the Progestasert and Mirena IUDs reduce the amount of menstrual bleeding and dysmenorrhea. The copper T380A can be expected to increase menstrual bleeding.

Hormonal Contraception

Hormonal contraceptives are female sex steroids, synthetic estrogen and synthetic progesterone (progestin), or progestin only. They can be administered in the form of OCs, implants, and injectables.

The most widely used hormonal contraceptive is the combination OC. Combination OCs can be monophasic, with the same dose of estrogen and progestin administered each day, or multiphasic, in which varying doses of steroids are given through a 21-day cycle. Typically, they are administered for 21 days beginning on the Sunday after a menstrual period, then discontinued for 7 days to allow for withdrawal bleeding that mimics the normal menstrual cycle. The 28-day version provides placebo tablets for the last 7 days of the cycle so the user simply takes one pill a day and starts a new pack as soon as the first pack is completed. Progestin-only formulations contain no estrogen. These are taken every day without interruption. Other forms of hormonal contraception include injectable progestins and estrogen-progesterin combinations, subdermal implants releasing progestin, and the experimental vaginal rings that release either estrogen-progesterin or progestin alone.

Silastic rings worn in the vagina release steroid hormones that are absorbed at a constant rate, allowing contraception with blood levels of steroids well below the peak levels that are seen with OCs. Rings containing levonorgestrel or combinations of levonorgestrel and estrogens are being studied (76).

Steroid Hormone Action

Sex steroids were originally defined by their biologic activity. They are characterized by their affinity for specific estrogen, progesterone, or androgen receptors as well as by their biologic effects in different systems (79). Steroids are rapidly absorbed in the gut but go directly into the liver through the portal circulation, where they are rapidly metabolized and inactivated. Therefore, large doses of steroids are required when they are administered orally. The addition of the ethinyl group to carbon-17 of the steroid molecule hinders degradation by the liver enzyme 17-hydroxysteroid dehydrogenase.

Progestins
Progestins are synthetic compounds that mimic the effect of natural progesterone but differ from it structurally (Fig. 10.8). There are three classes: the estranes and gonanes, which are 19-nor progestins and are structurally similar to testosterones but lacking a carbon at position 19, and the pregnane or 17-acetoxy compounds, which are structurally similar to progesterone. Only the estrane and gonane compounds are used in oral contraceptives in the United States, but norgestimate and desogestrel are the major injectable progestins. The progestins differ from each other in their affinities for estrogen, androgen, and progesterone receptors; their ability to inhibit ovulation; and their ability to substitute for progesterone and antagonize estrogen. Some are directly bound to the receptor (levonorgestrel, norethindrone), whereas others require bioactivation as, for example, desogestrel, which is converted in the body to its active metabolite, 3-keto-desogestrel. The 17-acetoxy progestins (e.g., medroxyprogesterone acetate) are bound by the progesterone receptor. Norgestrel exists as three stereoisomers, identified as 17α-norgestrel and levonorgestrel. Only levonorgestrel is biologically active. Three newer progestins (norgestimate, desogestrel, and gestodene) are viewed as more "selective" than the other 19-nor progestins, in that they have little or no androgenic effect at doses that inhibit ovulation (78). The FDA has approved norgestimate- and desogestrel-containing OCs, and gestodene is available in Europe. Gestodene is a derivative of levonorgestrel that is more potent than the other preparations (i.e., very little of it is required for antifertility effects). Androgen potency is considered undesirable because of the adverse effect of androgen and androgenic progestins on lipid and glucose metabolism. Androgenic progestins reduce levels of circulating high-density lipoprotein (HDL), elevate low-density lipoprotein (LDL), and adversely effect glucose tolerance in a dose-dependent fashion (79).

**Figure 10.8 Progestins of interest for contraception.** (From Copeland LJ, Jarrell JF. Textbook of gynecology. 2nd ed. Philadelphia: WB Saunders, 2000:303, with permission.)

### Estrogens

In the United States, OCs contain either of two estrogens: mestranol or ethinyl estradiol (EE). Mestranol is EE with an extra methyl group. It requires bioactivation in the liver, where the methyl group is cleaved, releasing the active agent, EE. OCs with 35 mg of EE provide the same blood levels of hormone as do OCs containing 50 mg of mestranol (80).

### Antifertility Effects

#### Combination Oral Contraceptives

Ovulation can be inhibited by oral estrogen or by oral progestin alone, but large doses are required. Pharmacologic synergism is exhibited when the two hormones are combined and ovulation is suppressed at a much lower dose of each agent. Combination OCs suppress basal follicle-stimulating hormone (FSH) and LH. Oral contraceptives diminish the ability of the pituitary gland to synthesize gonadotropins when it is stimulated by the hypothalamic gonadotropin-releasing hormone (GnRH) (81). Ovarian follicles do not mature, little estradiol is produced, and there is no midcycle LH surge. Ovulation does not occur, the corpus luteum does not form, and progesterone is not produced. This blockade of ovulation is dose related. Newer low-dose OCs do not provide as dense a block and allow somewhat higher base-line FSH and LH levels than higher-dose formulations (82). This makes ovulation somewhat more likely to occur if pills are missed or if the patient takes another medication that interferes with OC action.

#### Progestin-only Preparations

The mode of action of progestin-only contraceptives depends very much on the dose of the compound (83). At low blood levels of progestin, ovulation will occur part of the time. With the progestin-only "minipill," which supplies 0.3 mg of norethindrone per day (Micronor), 40% of cycles are ovulatory. 25% have inadequate luteal function, 18% have follicular maturation without ovulation, and 18% have complete suppression of follicular development. At moderate blood levels of progestin, normal basal levels of FSH and LH are present, and some follicle maturation may occur. Estradiol production is present, and the surge of estradiol that would normally trigger pituitary release of LH occurs; there is no answering LH surge, however, and hence no ovulation. At higher blood levels of progestin, basal FSH is reduced, and there is less follicular activity, less estradiol production, and no LH surge.

### Hormonal Implants

With the subdermal implant that releases levonorgestrel (Norplant), there is some follicular maturation and estrogen production, but LH peak levels are low and ovulation is often inhibited. In the first year of use, ovulation is believed to occur in about 20% of cycles. The proportion of ovulatory cycles increases with time, probably as a result of the decline in hormone release. By the fourth year of use, 41% of cycles are ovulatory. The mechanisms of contraception with low-dose progestins are believed to include effects on the cervical mucus, endometrium, and tubal motility. The scant, dry cervical mucus in women using these preparations inhibits sperm migration into the upper tract. Progestins decrease nuclear estrogen receptor levels, decrease progesterone receptors, and induce activity of the enzyme 17-hydroxysteroid dehydrogenase that metabolizes natural estradiol 17β (84).

The sustained release offered by contraceptive implants allows for highly effective contraception at relatively low blood levels of the steroid. Figure 10.9 depicts expected steroid blood levels with implants, injectables, and oral contraceptives. An additional mechanism for contraception has been discovered with the antiprogestrone mifepristone (RU486). In the normal cycle, there is a small amount of progesterone production from the follicle just before ovulation. This progesterone appears essential to ovulation, because if the antiprogestrone is given before ovulation, it can be delayed for several days (85).

**Figure 10.9 Schematic representation of the expected pharmacokinetic profiles of progestogens administered in different formulations.** (From Landgren BM. Mechanism of action of gestagens. Int J Gyneco Obstet 1990;32:95–110, with permission.)
Oral Contraceptives

When used consistently, combination OCs have pregnancy rates as low as two to three per 1,000 women per year. Progestin-only OCs are less effective, with best results of three to four pregnancies per 100 woman-years. Both methods have the potential for user error; therefore, there may be a 10-fold difference between the best results and results in typical users for pregnancy prevention. Injectable progestins and implants are much less subject to user error. The difference between the best results and results in typical users is small and is comparable to pregnancy rates after tubal sterilization (Table 10.2).

Metabolic Effects and Safety

Venous Thrombosis Older studies linked OC use to venous thrombosis and embolism, cerebral vascular accidents, and heart attack (86,87). More recent studies have found a much lower risk (88). Rereading of the older literature on venous thrombosis reveals that absolute risk was strongly determined by other very obvious predisposing causes of thrombosis that are now considered contraindications to OC use: previous thrombosis, preexisting vascular disease, coronary artery disease, leukemia, cancer, and serious trauma (89).

Normally, the coagulation system maintains a dynamic balance of procoagulant and anticoagulant systems in the blood. Estrogens affect both systems in a dose-related fashion. For most women, fibrinolysis (anticoagulation) is increased as much as coagulation, maintaining the dynamic balance at increased levels of production and destruction of fibrinogen (80,91) (Fig. 10.10). Current low-dose OCs have less measurable effect on the coagulation system, and fibrinolytic factors increase at the same rate as procoagulant factors (92,93). The lower estrogen dose (30 to 35 mg EE) reduces the risk for a thromboembolic event when compared with higher-dose (50 mg estrogen) OCs (94) (Table 10.5). Theoretically, thrombosis risk should be still less with current OCs containing only 20 mg of EE, but this has not been demonstrated. Smokers taking low-dose OCs demonstrate more marked activation of the coagulation system than nonsmokers—shortening of the prothrombin time, increased fibrinogen levels, and decreased antithrombin III—but also have increased fibrinolysis as measured by plasminogen activity (94).

The absolute risk for thrombosis in OC users taking pills containing 30 to 35 mg EE is 3 per 10,000 per year, compared with 1 per 10,000 reproductive-aged women not using OCs and 6 per 10,000 in pregnancy (95). Thrombosis risk is apparent by 4 months after starting estrogen-containing OCs and does not increase further with continued use. Risk is highest during the first year of use (96).

Thrombophilia Changes in the coagulation system are detectable in all women, even those taking lower-dose OCs; however, some are genetically predisposed to thrombosis when challenged by pregnancy or administration of exogenous estrogen. Bloemenkamp and colleagues studied hemostatic variables in women given low-dose OCs who had previous thrombosis with OCs and compared them with women with no thrombosis (97). Women known to have inherited thrombophilic disorders were excluded. Both groups of women had significant changes in clotting factors: increased factor VII, factor VIII, and protein C, and a decrease in antithrombin, activated protein C sensitivity ratio, and protein S. However, the women with a history of thrombosis who were taking OCs had more pronounced changes. They were “high hemostatic responders” when exposed to OCs. Women with inherited deficiencies of antithrombin III, protein C, or protein S are at very high risk for thrombosis with pregnancy or estrogen therapy, but they make up a very small proportion of potential OC users. A much more common variation has been identified, factor V Leiden. This genetic variation exists in 3% to 5% of the white population. It codes for a one amino acid mutation in the factor V protein, inhibiting cleavage of the protein by activated protein C, an essential step in maintaining the balance between coagulation and fibrinolysis (98). A study of risk for a first thromboembolic episode among women using OCs found it to be 2.2 per 10,000 woman-years for women without the factor V mutation and 27.7 per 10,000 woman-years for women with the mutation (99). In women homozygous or heterozygous for factor V Leiden who do not use OCs, the risk is estimated to be 4.9 per 10,000 woman-years. The effect of estrogen dose was not examined. Cigarette smoking did not affect this risk. There are pronounced ethnic differences in the presence of this mutation. The Leiden allele is found in 5% of whites but is rare in Africans, Asians, Amerindians, Eskimos, and Polynesians (100). A similar mutation is found in the prothrombin gene at position 20210 and is described as prothrombin G20210A. It is found in 3% of a European population and is also strongly associated with venous thrombosis in women taking OCs (101).

Pregnancy is an even greater challenge for women with inherited defects of anticoagulation (102). A woman who sustains a venous event while using OCs should be evaluated thoroughly after she has recovered. Assessment should include measurement of antithrombin III, protein C, and protein S levels, resistance to activated protein-C, genetic testing for factor V Leiden mutation and the prothrombin G20210A mutation, and testing for antiphospholipid antibody. It should not be assumed that OCs are the unique cause of the thrombotic episode.

Vandenbroucke and colleagues have explored the issue of routine screening for factor V Leiden (103). They conclude that routine screening of OC patients is not justified because effective contraception would be denied to 5% of white women, while preventing only a small number of fatal pulmonary emboli. Furthermore, if pregnant women were screened and those who screened positive were then treated with heparin, the number of cases of fatal bleeding might equal or exceed the number of fatal pulmonary emboli (104). Screening based on personal or family history of deep vein thrombosis before starting OCs or at the first antenatal visit was considered worthwhile.

Several studies have found a modest increased risk for venous thrombosis when users of OCs containing newer agents (i.e., progestins, desogestrel, or gestodene) were compared with users of older progestins (105). Physiologically, this was hard to understand because the estrogen and its dose are the same, and a 1993 review of desogestrel-containing OCs had found only minimal changes in coagulation and fibrinolysis (106). Lewis and colleagues have concluded that the biases “attrition of
susceptibles’ and “adverse selection” explain the apparent increase in thrombosis. Most cases of venous thrombosis attributable to OCs occur during the initial months of use (107). Hence, comparing new users to women already taking OCs for some time without incident will demonstrate an apparent increase with the new product that is artificial. Also, physicians may presume that newer drugs are safer, and prescribe them selectively for women with risk factors. Analysis of data from a large European study of thrombosis with different OCs has shown that apparent risk for thrombosis was lowest with the first low-dose pills introduced and highest with those recently introduced, even though the newest pill had the lowest estrogen dose (106) (Fig. 10.11).

Ischemic Heart Disease Ischemic heart disease and stroke were the major causes of death blamed on OC use in the past. It is now known that the principal determinants of risk are advancing age and cigarette smoking (108). With the higher-dose OCs used in the 1980s, smoking had a profound effect on risk. Women smoking 25 or more cigarettes per day had a 30-fold increased risk for myocardial infarction if they used OCs, compared with nonsmokers not using OCs (109) (Fig. 10.12). Use of OCs is now much safer because most women are taking low-dose pills and because physicians prescribe selectively, excluding women with major cardiovascular risk factors. A very large U.S. study confirms the safety of OCs as currently prescribed. A total of 167 women aged 15 to 44 years with confirmed myocardial infarction were identified during 3.6 million woman-years of observation in the Kaiser Permanente Medical Care Program in California between 1991 and 1994. This is a rate of 3.2 per 100,000 woman-years (110). Nearly all current users took OCs with less than 50 mg of EE. After adjusting for age, illness, smoking, ethnicity, and body mass index, risk for myocardial infarction was not increased [odds ratio (OR), 1.14; 95% confidence interval (CI), 0.27 to 4.72]. Of heart attack victims, 61% were smokers; only 7.7% were current OC users. In a later study, the same investigators pooled results from the California study with a similar study from Washington State. The results were the same. Current users of low-dose OCs had no increased risk for myocardial infarction, after adjustment for major risk factors and sociodemographic factors (111). That past use of OCs does not increase risk for myocardial infarction later has already been clearly established (112).

Oral Contraceptives and Stroke In the 1970s, OC use appeared to be linked to risk for both hemorrhagic and thrombotic stroke, but these studies failed to take into consideration preexisting risk factors (113). Although a rare form of cerebrovascular insufficiency, moyamoya disease, is clearly linked to OC use (115), new information shows no risk for women who are otherwise healthy and who use currently available low-dose pills. Petitti and colleagues identified all Kaiser Permanente Medical Care Program patients aged 15 to 44 years who sustained fatal or nonfatal stroke in California from 1991 to 1994 (116). Hypertension, diabetes, obesity, current cigarette smoking, and black race were strongly associated with stroke risk, but neither current nor past OC use was associated with stroke in this study. A World Health Organization (WHO) study of cases from 1989 to 1993 from 17 countries in Europe and the developing world included women on higher-dose OCs as well as low-dose OCs. European women using low-dose OCs had no increased risk for either type of stroke, thrombotic or hemorrhagic. Those on higher-dose OCs did have measurable risk (117,118). Women in developing countries had an apparent modest increase in risk, but this finding was attributed to undetected existing risk factors. Another study from Europe found less stroke risk from low-dose pills than from older higher-dose pills, and that risk was less if the patient’s blood pressure was checked before starting OCs. The authors concluded that a small risk from low-dose OCs could be controlled if women with hypertension were not given OCs (119).

Smokers and women with hypertension and diabetes are clearly at increased risk for cardiovascular disease whether or not they use oral contraceptives. The important question is whether risk is further increased if they use low-dose OCs, and if so, by how much. The World Health Organization study described previously provides some insight. Smokers taking OCs had 7 times the risk for ischemic (thrombotic) stroke when compared with smokers who did not use OCs, and hypertensive women had 10-fold increased risk if they took OCs, but a 5-fold risk if they did not (117). Similarly, Lidegaard reported from Denmark that diabetic women had a 5-fold increase risk for stroke, which increased to 10-fold if they took OCs (120). Unfortunately, Lidegaard’s data were not limited to low-estrogen OCs. The data suggest that although risk is primarily determined by the predisposing condition—hypertension, diabetes, or cigarette smoking—the risk can be magnified by OC use, even when the OCs are low dose. The current U.S. practice of limiting OC use by women older than 35 years of age to nonsmokers without other cardiovascular disease risk factors is prudent.

Blood Pressure Oral contraceptives have a dose-related effect on blood pressure. With the older high-dose pills, as many as 5% of patients could be expected to have blood pressure levels of higher than 140/90 mm Hg. The mechanism is believed to be an estrogen-induced increase in renin substrate in susceptible individuals. Current low-dose pills have minimal blood pressure effects, but surveillance of blood pressure is still advised to detect the occasional idiosyncratic response.

Glucose Metabolism Oral estrogen alone has no adverse effect on glucose metabolism, but progestins exhibit insulin antagonism (121). Older OC formulations with higher doses of progestins produced abnormal glucose tolerance tests with elevated insulin levels in the average patient. The effect on glucose metabolism, similar to the effect on lipids, is related to androgenic potency of the progestin and to its dose (7972).
Lipid Metabolism

Higher-dose OCs could have significant adverse effects on lipids (122). Androgens and estrogens have competing effects on hepatic lipase, a liver enzyme critical to lipid metabolism. Estrogens depress LDL and elevate HDL, which are changes that can be expected to reduce the risk for atherosclerosis (123).

Androgens and androgenic progestins can antagonize these beneficial changes, reducing HDL and elevating LDL levels. Estrogens elevate triglyceride levels. Low-dose formulations have minimal adverse effect on lipids (124), and the newer formulations (with desogestrel and norgestimate as the progestin) produce potentially beneficial changes by elevating HDL and lowering LDL (79) (Fig. 10.13). Although average values of a large group show only small lipid changes with current OCs, an occasional patient may have exaggerated effects. Women whose lipid values are higher than the mean before treatment are more likely to experience abnormalities during treatment (125).

Other Metabolic Effects

Oral contraceptives can produce changes in a broad variety of proteins synthesized by the liver. The estrogen in OCs increases circulating-thyroid-binding globulin, thereby affecting tests of thyroid function that are based on binding, increasing total thyroxine (T4), and decreasing triiodothyronine (T3) resin uptake. The results of actual thyroid function tests, as measured by free T3, and radioiodine tests, are normal (125).

Oral Contraceptives and Neoplasia

Endometrial Cancer and Ovarian Cancer

Combination OCs reduce the risk for subsequent endometrial cancer and ovarian cancer (126,127). A recent study found that as little as 1 year of OC use was protective (OR, 0.57; 95% CI, 0.87 to 1.03), and continued use reduced risk by 7% per year. Benefit persisted for 15 years after last use, with little change (128). A 50% reduction in ovarian cancer risk was observed for women who took OCs for 3 to 4 years, and an 8% reduction was seen for users of 10 or more years of OC use. This reduction occurred as early as 3 to 11 months of use. The benefit continued for at least 12 years since last use, and it does not diminish even at 15 years from use (126). National vital statistics data from England support these observations. Ovarian cancer mortality is declining in England and Wales in women younger than 55 years of age, and this decline has been attributed to OC use (129). Use of OCs after 1980, when low-dose pills predominated, provides protection equivalent to older, higher-dose OCs (130).

Two years of OC use reduces the risk for subsequent endometrial cancer by 40%, and 4 or more years of use reduces the risk by 60% (127).

Cervical Cancer

There may be a weak association between OC use and squamous cancer of the cervix. Important risk factors are early sexual intercourse and exposure to human papillomavirus (131). Women who have used OCs typically started sexual relations at younger ages than women who have not used OCs and, in some studies, report having had more partners. These factors also increase one's chance of acquiring human papillomavirus (HPV), the most important risk factor for cervical cancer. Because barrier contraceptives reduce the risk for cervical cancer, use of alternative choices for contraception can compound the difficulty in establishing an association with OC use alone. The presence of HPV types 16 or 18 is associated with a 50-fold increase in risk for preneoplastic lesions of the cervix (132). If a woman already has HPV, OC use does not further increase her risk for cervical neoplasia, but among women who are HPV negative, OC use doubles the risk of having such a lesion. This apparent adverse effect could be explained entirely by OC users being less likely to use barrier contraception.

Adenocarcinoma of the cervix is rare, but they are not as easily detected as other lesions by screening cervical cytology, and the incidence appears to be increasing. A 1994 study found a doubling of risk for adenocarcinoma with OC use that increased with duration of use, reaching a relative risk of 4.4 if total use of OCs exceeded 12 years (133). The results of this study were adjusted for history of genital warts, number of sexual partners, and age at first intercourse. Because barrier contraceptives reduce the risk for cervical cancer, use of alternative choices for contraception can compound the difficulty in establishing an association with OC use alone. The presence of HPV types 16 or 18 is associated with a 50-fold increase in risk for preneoplastic lesions of the cervix (132). If a woman already has HPV, OC use does not further increase her risk for cervical neoplasia, but among women who are HPV negative, OC use doubles the risk of having such a lesion. This apparent adverse effect could be explained entirely by OC users being less likely to use barrier contraception.

Use of OCs is, at most, a minor factor in causation of cervical cancer; however, women who have used OCs should have annual Papnicolaou (Pap) tests. To reduce risk, women who are not in mutually monogamous relationships should be advised to use barrier methods in addition to hormonal contraception.

Breast Cancer

There is a large volume of conflicting literature on the relationship between OC use and breast cancer. Generally, no increase in overall risk is found from OC use, but some studies have found that risk may increase in women who used OCs before their first term pregnancy (135) or who used OCs for many years, who are nulligravid, who are young at the time of diagnosis, and who continue using OCs in their 40s (136). A large British study found a small but statistically stable increase in breast cancer diagnosed before 36 years of age among OC users, but that risk was less for OCs with less than 50 mg of estrogen. Progestin-only OCs appeared to have a protective effect. Significantly, OC users who developed breast cancer were more likely to be diagnosed in early stages and were less likely to have lymph node involvement than were controls (136). Women with a family history of breast cancer were not found at increased risk with OC use in one study (137). Some of the findings are difficult to interpret; for example, risk does not increase with prolonged exposure. This finding would not be expected if OCs were truly causal (137).

The best information to date comes from a metaanalysis of 54 studies of breast cancer and hormonal contraceptives. The Collaborative Group on Hormonal Factors in Breast Cancer reanalyzed data on 53,297 women with breast cancer and 100,239 controls from 25 countries, representing about 90% of the epidemiologic data available worldwide (138). Current use of OCs was associated with a very small but statistically significant 24% increased risk [relative risk (RR), 1.24; 95% CI, 1.15 to 1.33]. The risk fell rapidly after discontinuation, to 1.6% 1 to 4 years after stopping and to 1.7% 5 to 9 years after stopping. Risk disappeared 10 years after cessation (RR, 1.01; 95% CI, 0.96 to 1.05). Breast cancers diagnosed while women were taking OCs were less advanced clinically than those in women who had never used OCs. Results did not differ in any important way by ethnic group, reproductive history, or family history. There was a greater risk in women who started OC use before 20 years of age relative to women who started OCs later, but because breast cancer is so rare before 20 years of age, there was no increase in actual numbers of breast cancer cases among women who started use of OCs at a young age. A term pregnancy also causes a short-term increase in breast cancer risk, thought to be from the growth-enhancing effects of estrogen, but there is a longer-term reduction in risk, perhaps the result of pregnancy-induced terminal differentiation of breast cells (139). The effects of OCs may be the same and may promote growth of existing cancers, leading to their presentation and diagnosis at an earlier age, rather than actually causing cancers to form. Most breast cancers are seen after 50 years of age, and only now are large numbers of women with OC exposure entering this age group. At present the risk, if it is increased, is small, and is not present 10 years after cessation of use. Reassurance is provided by a 1999 Swedish study that compared 3,016 women aged 50 to 74 years who had invasive breast cancer with 3,263 controls of the same age. No relation between past use of OCs and breast cancer was found (140).

In the Collaborative Group's study, oral contraceptive use by women with a first-degree relative who had breast cancer did not increase risk regardless of the duration of use before first-term pregnancy (138). In contrast, a recent historical cohort study of 426 families with breast cancer found that sisters and daughters of women with breast cancer had a threefold increase risk for breast cancer if they had used OCs before 1975. Granddaughters and nieces or women who married into the families

Figure 10.13 Percentage differences in HDL and LDL cholesterol levels and in the incremental area for insulin in response to the oral glucose tolerance test (OGTT) between women taking one of seven combination oral contraceptives and those not taking oral contraceptives. The T bars indicate 1 standard deviation, and the double daggers (p < 0.05) indicate significant differences between users and nonusers in the mean values for the principal metabolic variables. EE, ethinyl estradiol; LG, levonorgestrel; NE, norethindrone; DG, desogestrel. (From Godland IF, Crook D, Simpson R, et al. The effects of different formulations of oral contraceptive agents on lipid and carbohydrate metabolism. N Engl J Med 1990;323:1375–1382, with permission.)
had no increased risk. There were too few cases among women who used the lower-dose OCs available after 1975 to determine whether there is risk (141).

Liver Tumors OCs have been implicated as a cause of benign adenomas of the liver. These hormonally responsive tumors can cause fatal hemorrhage. They usually regress when OC use is discontinued; risk is related to prolonged use (142). There is a strong correlation between OC use and hepatocellular adenoma. Fortunately, the tumors are rare; about 30 cases per 1,000,000 users per year have been predicted with older formulations. Presumably, newer low-dose products pose less risk. A link to hepatic carcinoma has been proposed, but a large study from six countries in Europe found no association between use of OCs and subsequent liver cancer (143).

Health Benefits of Oral Contraceptives

OCs have important health benefits (Table 10.6). As noted earlier, OC use produces strong and lasting reduced risk for endometrial and ovarian cancer. In addition, protection has been found for women with known hereditary ovarian cancer. Any past use of OCs conferred a 50% reduction in ovarian cancer risk when women with this history who took OCs were compared with their sisters as controls (OR, 0.5; 95% CI, 0.3 to 0.8). Protection increased with increasing duration of use (144). The mechanism of action of OCs in the prevention of ovarian cancer is unknown but may involve selective induction of apoptosis (programmed cell death). Macaques treated with EE plus levonorgestrel or levonorgestrel alone showed an increase in the proportion of ovarian epithelial cells in apoptosis in comparison with animals fed a diet containing no hormones (145).

Table 10.6. Noncontraceptive Benefits of Oral Contraception

Chlamydial colonization of the cervix appears more likely in OC users than in nonusers but, despite this, there is a 40% to 50% reduction in risk for chlamydial PID (146). Combination OCs confer marked reduction in risk for ectopic pregnancy, although the progestin-only OCs appear to increase risk.

Other documented benefits of OC use include a significant reduction in the need for biopsies for benign breast disease and surgery for ovarian cysts. Use of OCs also helps relieve dysmenorrhea and associated anemia from menstrual blood loss (147). All combination OCs offer some protection from functional ovarian cysts, but multiphasic preparations offer less protection than other forms of combination OCs (148). If progestin-only OCs are truly protective against breast cancer, the levonorgestrel implants also could be expected to confer this benefit.

There is growing evidence that OC use is also protective against colon cancer. A case-control study in Italy comparing women with colon cancer with controls found a 37% reduction in colon cancer and a 34% reduction in rectal cancer (colon cancer OR, 0.63; 95% CI 0.45 to 0.87; rectal cancer OR, 0.66; 95% CI 0.43 to 1.01). Longer use produced more protection against colon cancer (149). Results of the U.S. Nurses Health Study also disclosed some degree of protection. Women who had used OCs for 96 months or more had a 40% lower risk for colorectal cancer (RR, 0.60; 95% CI, 1.15 to 2.14) (150). The mechanism of protection has not been identified.

Fertility after OC Use After discontinuing OCs, return of ovulatory cycles may be delayed for a few months. Women who have amenorrhea more than 6 months after discontinuation of OCs should undergo a full evaluation because of the risk for prolactin-producing pituitary tumors. This risk is not related to OC use but rather to the probability that the slow-growing tumor was already present and produced menstrual irregularity, prompting the patient to take OCs (151).

Sexuality In a study that recorded all episodes of female-initiated sexual behavior throughout the menstrual cycle, an increase in sexual activity at the time of ovulation was noted. This increase was not present in women who were taking OCs (152).

Teratogenicity A metaanalysis of 12 prospective studies, including 6,102 women who used OCs and 85,167 women who did not, revealed no increase in overall risk for malformation, congenital heart defects, or limb reduction defects with the use of OCs (153). Progestins have been used to prevent miscarriage. A large study compared women showing signs of threatened abortion who were treated with progesterona (primarily medroxyprogesterone acetate) with women who were not treated. The rate of malformation was the same among the 1,146 exposed infants as among the 1,608 unexposed infants (154). Conversely, estrogens taken in high doses in pregnancy can induce vaginal cancer in exposed female offspring in utero.

Interaction of Oral Contraceptives with Other Drugs

Some drugs reduce the effectiveness of oral contraceptives (e.g., rifampin); conversely, OCs can augment or reduce the effectiveness of other drugs (e.g., benzodiazepines). Phenytoin, phenobarbital, and rifampin induce synthesis of cytochrome P450 enzymes in the liver and reduce plasma levels of EE in women taking OCs, which may cause contraceptive failure (155). The antifungal agents griseofulvin, ketoconazole, and draconazole also induce these hepatic enzymes and may reduce OC efficacy (156). Ampicillin and tetracycline have been implicated in numerous case reports of OC failure. They kill gut bacteria (primarily clostridia) that are responsible for hydrolysis of steroid glucuronides in the intestine, which allows reabsorption of the steroid through the enterohepatic circulation. In human studies, however, it has not been possible to demonstrate reduced plasma levels of EE. Although women taking OCs who will be treated with antibiotics are commonly advised to use condoms as well, controlled studies of OC users have found no difference in pregnancy rates with exposure to penicillins, cephalosporins, and tetracyclines (157).

Certain drugs actually appear to increase plasma levels of contraceptive steroids. Ascorbic acid (vitamin C) and acetaminophen may elevate plasma EE.

An example of OCs affecting the metabolism of other drugs is seen with diazepam and related compounds. OCs reduce the metabolic clearance and increase the half-life of those benzodiazepines that are metabolized primarily by oxidation: chlor Diazepoxide, alprazolam, diazepam, and nitrazepam. Caffeine and theophylline are metabolized in the liver by two of the P450 isozymes, and their clearance is also reduced in OC users. Cyclosporine is hydroxylated by another of the P450 isozymes, and its plasma concentrations are increased by OCs. Plasma levels of some analgesic drugs are decreased in OC users. Saliicylic acid and morphine clearances are enhanced by OC use; therefore, higher doses could be needed for adequate therapeutic effect. Clearance of ethanol may be reduced in OC users (158).

Oral Contraceptives and Clinical Chemistry Alterations

Oral contraceptives have the potential to alter a number of clinical laboratory tests as a result of estrogen-induced changes in hepatic synthesis; however, a large study comparing OC users to pregnant and nonpregnant controls found minimal changes (159). Hormone users took a variety of OCs containing 50 to 100 mg of estrogen, higher doses than are used today. Compared with nonpregnant women who were not using OCs, the OC users had an increase in T, that is explained by increased circulating thyroid-binding protein, no change in creatinine, a slight reduction in mean fasting glucose values, a reduction in total bilirubin, a modest reduction in serum glutamic oxaloacetic transaminase, a decrease in alkaline phosphatase, and no change in globulin.

Choice of Oral Contraceptives
The oral contraceptives currently available in the United States are listed in Table 10.7. With the introduction of OCs containing the new progestins, new preparations with 20 mg of EE, new variations of multiphasic preparations, plus branded generic formulations of older OCs, an array of choices are possible.

Table 10.7. Composition of Oral Contraceptives in Current Use in the United States, 2001

The lowest-dose OCs all contain the same amount of the same estrogen, 20 mg of EE. However, the progestins differ: norethindrone acetate, levonorgestrel, desogestrel, or norgestimate (Table 10.7). The first 20-mg EE OC (LoEstrin 1-20) contained 1 mg norethindrone acetate. A comparison of this OC to a triphasic OC with 35 mg of EE and norgestimate (NGM)/Ortho Tri-Cylen) found considerable more breakthrough bleeding and spotting and more episodes of missed menses with the 20-mg norethindrone acetate/EE than with the higher-estrogen OC containing norgestimate. There was no difference in compliance, discontinuation rates, or adverse events (159). In a three-way trial, the 35-mg NGM/EE triphasic OC (Ortho Tri-Cylen) was compared with two new 20-mg EE pills, one containing 100 mg of levonorgestrel (Allese), the other containing 150 mg desogestrel, followed by 2 hormone-free days then 5 days of 10 mg EE per day (Mircette) (160). Contraceptive efficacy was not significantly different. Women starting on OCs had more breakthrough bleeding and bleeding in the second half of the cycle with Allese than with the other two OCs in the first two cycles, but thereafter there was little difference, except that Mircette users had more breakthrough bleeding in cycle 4. Women taking Tri-Cylen consistently experienced more frequent estrogenic side effects of bloating, breast tenderness, and nausea than did women on either 20-mg EE OC. These authors concluded that for the specific OCs evaluated, changing to the lowest estrogen dose was beneficial.

For the average patient, the first choice of preparation for contraceptive purposes is a low-estrogen OC (20 to 35 mg of EE) or a very low-estrogen OC (20 mg EE).

1. Breakthrough bleeding and spotting are common at first and generally improve with time. If the problem persists, it may be relieved by changing from a multiphasic to monophasic version at the same estrogen level.
2. If bleeding remains a problem, a temporary increase in estrogen should be tried: 20 mg of EE daily for 7 days while continuing the OC (161).

Side effects—nausea, breast tenderness, mood changes, and weight gain—are less common with current formulations than with previous OCs and usually resolve after the first few cycles.

1. If symptoms persist, the lowest-dose highly effective formulations could be tried: those containing only 20 mg of EE.
2. If patients have persistent breast tenderness, the type of OC could be changed to one with a more progestin activity, for example, the 20- to 30-mg EE pills that contain levonorgestrel. High-potency progestin OCs produce fewer breast symptoms (162).
3. Nausea is generally related to the estrogen component, and changing to the 20-mg EE preparation may be beneficial.

Injectable Hormonal Contraceptive:

Depomedroxyprogesterone Acetate

Depomedroxyprogesterone acetate (DMPA), a suspension of microcrystals of a synthetic progestin, was approved for contraception in 1992. A single 150-mg intramuscular dose will suppress ovulation in most women for 14 weeks or longer (163). The regimen of 150 mg every 3 months is highly effective, producing pregnancy rates of about 0.3 per 100 women per year. Probably because of the high blood levels of the progestin, efficacy appears not to be reduced by administration of other drugs and is not dependent on the patient’s weight. Women treated with DMPA experience disruption of the menstrual cycle and have initial spotting and bleeding at irregular intervals. Eventually, total amenorrhea develops in most women who take DMPA, with continued administration, amenorrhea develops in 50% of women by 1 year and in 80% by 3 years (Fig. 10.14). Persistent irregular bleeding is treated by adding low-dose estrogen temporarily; for example, conjugated estrogens, 1.25 mg per day, can be given for 10 to 21 days at a time. DMPA persists in the body for several months in women who have used it for long-term contraception, and return to fertility may be delayed. In a large study, however, 70% of former users desiring pregnancy conceived within 12 months, and 90% conceived within 24 months (164).

Figure 10.14 Bleeding pattern and duration of use of depomedroxyprogesterone acetate (DMPA): percentage of women who have bleeding, spotting, or amenorrhea while taking DMPA 150 mg every 3 months. (From Schwallie PC, Assenzo JR. Contraceptive use-efficacy study utilizing medroxyprogesterone acetate administered as an intramuscular injection once every 90 days. Fertil Steril 1973;24:331–339, with permission.)

Safety

Long-term users of DMPA may have lower bone density than nonusers, probably reflecting reduced estrogen levels; however, this effect has not been associated with increased fractures (165). Other investigators have not detected bone loss during 3 years or more of DMPA use (166). A small study comparing DMPA to implant or OC users found that DMPA blocked the usual rapid increase in bone density normally seen in adolescents (167). This may suggest that DMPA may be less desirable for young adolescents. The effect of DMPA on plasma lipids has been inconsistent; in general, DMPA users appear to have reduced total cholesterol and triglycerides, slight reduction in HDL cholesterol, and no change or slight increase in LDL cholesterol, all of which are consistent with a reduction in circulating estrogen levels. In some studies, the decrease in HDL and increase in LDL are statistically significant, although the values remain within normal ranges (168). The use of DMPA has not been associated with myocardial infarction. Glucose tolerance tests disclose a small elevation of glucose in DMPA users. There is no change in hemostatic parameters, with the exception that antithrombin III levels are sometimes found to be reduced with chronic therapy (169). DMPA has not been linked to thrombotic episodes in women of reproductive age. However, thrombotic episodes have occurred in elderly women with advanced cancer who were treated with a

Emergency Contraception

Table 10.8. Pregnancy Rates with Norplant: Gross Cumulative Pregnancy Rates at 5 Years by Patient's Weight and Type of Tubing

A two-rod version of Norplant, Norplant II, has undergone extensive testing. It is as effective as Norplant and is easier to insert and remove (185). Single-rod systems containing a new progestin, 3-keto-desogestrel (Implanon) are in the final phase of U.S. trials. In preliminary studies, Implanon appeared to be more effective than Norplant (186). It is intended for 3 years of use.

Bleeding Patterns

The implant produces endometrial atrophy. The normal menstrual cycle is disrupted, resulting in a range of possible bleeding patterns, from reasonably regular withdrawal bleeding, to frequent spotting and almost daily bleeding, to complete amenorrhea. The bleeding pattern changes over time and eventually tends to become more like a normal menstrual pattern. Women who have monthly bleeding are more likely to be ovulating and should be evaluated for pregnancy if they become amenorrheic. Irregular bleeding and spotting can be treated with low-dose oral estrogen, low-dose oral levonorgestrel, or ibuprofen (179). Implants have no adverse effect on lactation and can be used by lactating women. Their effects are immediately reversed by removing the implants, and the return to fertility is generally prompt.

Metabolic Effects

Implants do not alter glucose metabolism. There are minimal lipid changes. Total cholesterol and triglycerides are reduced, and there is either no change or minimal decrease in HDL, but the same ratio of total cholesterol to HDL is maintained. Therefore, it is very unlikely that implants promote development of atherosclerosis (180). Implants have no adverse effect on bone density. A cross-sectional comparison of long-term implant users with IUD-wearing women found no differences in bone density as assessed by dual-energy x-ray absorptiometry (181).

Adverse Events and Side Effects

Irregular bleeding and headache are the main reasons given for discontinuing use of implants. Side effects that are occasionally reported include acne, weight gain or loss, mastalgia, mood change, depression, hyperpigmentation over the implants, hirsutism, and galactorrhea. Symptomatic functional cysts occasionally occur. These usually resolve spontaneously over a few weeks without surgery. If pregnancy occurs, the probability of it being ectopic is increased compared with conceptions in other women; however, because pregnancy is so rare in women using implants, the total rate of ectopic pregnancies (0.28 per 1,000 woman-years) is well below that of the U.S. population (181). Serious side effects resulting in hospitalization or disability reported to the FDA from 1991 to 1993 included 24 women with infection at the implantation site, 14 with difficulties in removing the capsules, 14 with stroke, 3 with thrombotic thrombocytopenic purpura, 6 with thrombocytopenia, and 29 with pseudofumor cerebri (182). The rate of occurrence of these illnesses did not exceed that expected in women in the reproductive years, and no causal connection was implied. The hospitalizations from problems of insertion and removal can be totally prevented by using proper technique with these procedures (183).

Insertion

Implants are inserted just beneath the skin of the inner surface of the upper arm using a 10-gauge trocar as an inserter. Insertion is readily accomplished in a few minutes with local anesthesia. It is important to place the trocar just beneath the skin, inserted parallel to the skin, all the way to the second mark on the trocar before loading the rod for insertion. In this way, the rods are inserted without tension and will not migrate. Difficult removals generally are the result of poor insertion technique. Removal of implants can be time consuming. The end of the rod should be manipulated into a small incision in the skin, using a scalpel to nick the fibrous sheath that forms around the rod and then pushing it out with finger pressure (183). With the Emory technique, a somewhat longer (10-mm) incision is used, and hemostats forceps are used to disrupt the fibrous capsule around the ends of all of the implants before removal with an instrument (184). With the “U” technique, an incision is made over the midportion of the middle implant, and a special grasping forceps developed for vasectomy procedures is advanced subcutaneously to grasp the midportion of each rod and extract it (184).
Implantation of the fertilized ovum is believed to occur on the sixth day after fertilization. This interval provides an opportunity to prevent pregnancy even after fertilization occurs. This can be accomplished using hormonal agents singly or in combination, or IUDs.

**Estrogens**

High-dose estrogen taken within 72 hours of coitus prevents pregnancy. The mechanism of action of postcoital estrogen use may involve altered tubal motility, interference with corpus luteum function mediated by prostaglandins, or alteration of the endometrium. In an analysis of more than 3,000 women treated after coitus with 5 mg of EE daily for 5 days, the pregnancy rate was 0.15% (187).

**Estrogen and Progestin in Combination**

High-dose estrogen has largely replaced the combination of EE 0.200 mg and levonorgestrel 2 mg (2 Ovral tablets followed by 2 more tablets 12 hours later), as first described by Yuzpe (165). The average pregnancy rate with this method is 1.8%, but it is 1.2% if treatment is started within 12 hours of intercourse (189). Nausea and vomiting are common with both regimens, and an antiemetic is usually prescribed. A comparable dosing of EE and levonorgestrel is provided by taking 4 tablets of LoOvral, Nordette, Levlen, Triphasil, or TriLevlen, or 5 tablets of Allese, instead of 2 tablets of Ovral. A kit containing four tablets, each containing 50 mg of EE and 250 mg of levonorgestrel, is marketed in the United States under the name Preven specifically for emergency contraception.

**Levonorgestrel Alone**

A new and better alternative for emergency contraception is using levonorgestrel alone, 0.75 mg initially, followed by another 0.75 mg 12 hours later. This preparation is sold in the United States as Plan B. The World Health Organization carried out a randomized trial with 1998 women assigned to the Yuzpe method or to levonorgestrel alone, started within 72 hours of intercourse. The pregnancy rate was 3.2% with the Yuzpe method, and only 1.1% with levonorgestrel alone (RR for pregnancy, 0.32; 95% CI, 0.18 to 0.70). Nausea and vomiting occurred much less frequently with levonorgestrel alone (23.1% versus 50.5%, and 5.6% versus 18.8%) (190). The efficacy of both methods declines as time increases since intercourse. Even after 49 to 72 hours, however, the pregnancy rate with the levonorgestrel treatment was only 2.7%, and it is likely that considerable efficacy would be found beyond 72 hours (Fig. 10.15). Because of greater efficacy and less nausea, levonorgestrel used alone appears to be the best hormonal method for emergency contraception currently available in the United States.

![Figure 10.15 Emergency contraception: pregnancy rates by treatment group and time since unprotected coitus. LNG is levonorgestrel, 0.75 mg × 2. Yuzpe method is ethinyl estradiol, 0.100 mg plus levonorgestrel 0.50 mg × 2, 12 hours later. (From Anon. Randomized controlled trial of levonorgestrel versus the Yuzpe regimen of combined oral contraceptives for emergency contraception. Task Force on Postovulatory Methods of Fertility Regulation. Lancet 1998;352:430 (modified from Table 3), with permission.)](image)

**Copper Intrauterine Device**

Postcoital insertion of a copper IUD within 72 hours appears to be even more effective than steroids (191). In 879 patients treated with an IUD, only one pregnancy occurred (187). No pregnancies occurred during the first month after insertion of copper IUDs as long as 7 days after coitus. It is likely that the levonorgestrel IUD would also work for this purpose, but there are as yet no studies of its use after coitus.

**Danazol**

A weak androgen, danazol has also been used for emergency contraception. The pregnancy rate was 2% among 998 women (187). In general, the oral contraceptive preparations are more desirable because they are less costly and have fewer side effects.

**Mifepristone**

The antiprogestrone mifepristone (RU486) is also highly effective for postcoital contraception and appears to have no significant side effects. A three-way trial of the Yuzpe method—danazol, 600 mg repeated after 12 hours, and mifepristone, 600 mg as a single dose, yielded pregnancy rates of 2.62, 4.66, and 0%, respectively (192). Much lower doses of mifepristone have been studied. Doses as low as 10 mg are effective (193). Mifepristone is also highly effective in inducing menstruation when taken on day 27 of the menstrual cycle, well beyond the 72-hour window usually considered for postcoital contraception. Of 92 women treated in this fashion, only 1 conceived (187).

**Contraception for Women with Chronic Illness**

Women with chronic illness may present special problems that should be considered in the choice of a method of contraception. The illness may make pregnancy more complicated and dangerous for these women, thus making effective contraception all the more important. Some common conditions and considerations about contraception are listed in Table 10.9.

---

**Table 10.9. Contraception for Women with Chronic Illness**
Sterilization

Surgical sterilization is the most common method of fertility control used by couples in the United States (4). Laparoscopic techniques for women and vasectomy for men are safe and readily available throughout the United States. The mean age at sterilization is 30 years. Age younger than 30 years when sterilized and divorce and remarriage are predictors of sterilization regret, which may lead to a request for reversal of sterilization (200).

Female Sterilization

Hysterectomy is no longer considered for sterilization because morbidity and mortality are too high in comparison with tubal sterilization. Four procedures are common in the United States.

1. Tubal sterilization at the time of laparotomy for a cesarean delivery or other abdominal operation
2. Postpartum minilaparotomy soon after vaginal delivery
3. Interval minilaparotomy
4. Laparoscopy

Vaginal tubal sterilization, which has been associated with occasional pelvic abscess, is rarely performed in the United States.

Postpartum tubal sterilization at the time of cesarean delivery adds no risk, other than a slight prolongation of operating time; however, cesarean birth has more risk than vaginal birth, and planned sterilization should not influence the decision to perform a cesarean delivery. Sterilization is no more likely to fail if done with a cesarean delivery than at other times (201).

Postpartum minilaparotomy can be performed in the immediate postpartum state. The uterus is enlarged, and the fallopian tubes lie in the midabdomen, easily accessible through a small, 3- to 4-cm subumbilical incision.

Interval minilaparotomy, first described by Uchida (202), was rediscovered and popularized in the early 1970s in response to the increased demand for sterilization procedures as a simpler alternative to laparoscopy. In the nongravid state, the uterus and tubes lie deep in the pelvis. A short transverse suprapubic incision is made, and the uterus and tubes are then elevated upward, just beneath the incision by use of a uterine-elevating probe placed into the uterine cavity through the vagina. Interval minilaparotomy is usually performed as an outpatient procedure and can be accomplished readily with local anesthesia and conscious sedation.

Surgical Technique

The tubal lesion usually elected is the Pomeroy or modified Pomeroy technique (Fig. 10.16). In the classic Pomeroy procedure, a loop of tube is excised after ligating the base of the loop with a single absorbable suture. A modification of the procedure is excision of the midportion of the tube after ligation of the segment with two separate absorbable sutures. This modified procedure has several names: partial salpingectomy, Parkland Hospital technique, separate sutures technique, and modified Pomeroy. In the Madlener technique, now abandoned because of too many failures, a loop of tube is crushed by cross-clamping its base, ligated with permanent suture, and then excised. Pomeroy and partial salpingectomy procedures have failure rates of 1 to 4 per 1,000 cases (203). In contrast, pregnancy is almost unheard of after tubal sterilization by the Irving or Uchida methods (201,202). In the Irving method, the midportion of the tube is excised, and the proximal stump of each tube is turned back and led into a small stab wound in the wall of the uterus and sutured in place, creating a blind loop (203). With the Uchida method, a saline-epinephrine solution (1:1,000) is injected beneath the mucosa of the midportion of the tube, separating the mucosa from the underlying tube. The mucosa is incised along the antimesenteric border of the tube, and a tubal segment is excised under traction so that the ligated proximal stump will retract beneath the mucosa when released. The mucosa is then closed with sutures, burying the proximal stump and separating it from the distal stump. In Uchida's personal series of more than 20,000 cases, there were no pregnancies (202).

Figure 10.16 Pomeroy technique for tubal sterilization.

Laparoscopy

In the standard laparoscopy technique, the abdomen is inflated with a gas (carbon dioxide or nitrous oxide) through a special needle inserted at the lower margin of the umbilicus (204). A hollow sheath containing a pointed trocar is then pushed through the abdominal wall at the same location; the trocar is removed; and the laparoscope is inserted into the abdominal cavity through the sheath to visualize the pelvic organs. A second, smaller trocar is inserted in the suprapubic region to allow the insertion of special grasping forceps. Alternatively, an operating laparoscope that has a channel for the instruments can be used; thus, the procedure can be performed through a single small incision. Laparoscopic sterilization is usually performed in the hospital under general anesthesia but can be performed under local anesthesia with conscious sedation. Overnight hospitalization for laparoscopy is rarely needed.

Open Laparoscopy Standard laparoscopy carries with it a small but definite risk for injury to major blood vessels with insertion of the sharp trocar. With the alternative technique of open laparoscopy, neither needle nor sharp trocar is used; instead, the peritoneal cavity is opened directly through an incision at the lower edge of the umbilicus (205). A special funnel-shaped sleeve, the Hasson cannula, is then inserted, and the laparoscope is introduced through it.

Techniques of Laparoscopic Sterilization Sterilization is accomplished by any of four techniques: bipolar electrical coagulation, application of a small Silastic
rubber band (Falope ring) (206), the plastic and metal Hulka clip (204), or the Filshie clip (207). The Filshie clip is new to the United States, although it has been used extensively in the United Kingdom and Canada (208). It is a hinged device made of titanium with a liner of silicone rubber tubing. In the bipolar electrocoagulation technique, the midisthmic portion of the tube and adjacent mesosalpinx are grasped with special bipolar forceps, and radiofrequency electric current is applied to three adjacent areas, coagulating 3 cm of tube (Fig. 10.17). The tube alone is then recoagulated in the same places. The radiofrequency generator must deliver at least 25 watts into a 100-ohm resistance at the probe tips to ensure coagulation of the complete thickness of the fallopian tube and not just the outer layer; otherwise, the sterilization will fail (209). To apply the Falope ring, the midisthmic portion of the tube is grasped, with forceps advanced through a cylindrical probe that has the ring stretched around it. A loop of tube is pulled back into the probe, and the outer cylinder is advanced, releasing the Silastic ring around the base of the loop of tube, producing ischemic necrosis (Fig. 10.18). If the tube cannot be pulled easily into the applicator, the operator should stop and change to electrical coagulation rather than persist and risk lacerating the tube with the Falope ring applicator. The banded tube must be inspected at close range through the laparoscope to demonstrate that the full thickness of the tube has been pulled through the Falope ring. The Hulka clip is also placed across the midisthmus, ensuring that the applicator is at right angles to the tube and that the tube is completely contained within the clip before the clip is closed. The Filshie clip (Fig. 10.19) is also placed at right angles across the midisthmus, taking care that the anvil of the posterior jaw can be visualized through the mesosalpinx beyond the tube to ensure that the complete thickness of the tube is completely within the jaws of the clip before it is closed.

The electric and band or clip techniques each have advantages and disadvantages. Bipolar coagulation can be used with any fallopian tube. The Falope ring and Hulka and Filshie clips cannot be applied if the tube is thickened from previous salpingitis. There is more pain during the first several hours after Falope ring application. This can be prevented by bathing the tubes with a few milliliters of 2% lidocaine just before ring placement. Failures of the Falope ring or the clips generally result from misapplication, and pregnancy, if it occurs, is usually intrauterine. After bipolar sterilization, pregnancy may result from tuboperitoneal fistula and is ectopic in more than 50% of cases. Complications were from complications of general anesthesia, usually related to the use of mask ventilation (212). The last U.S. national study was of sterilizations performed in 1979 to 1980. There were a total of 9 to 10 deaths per 100,000 sterilizations, but only 1 to 2 per 100,000 were attributed to the sterilization procedure alone (213). When general anesthesia is used for laparoscopy, endotracheal intubation is mandatory because the pneumoperitoneum increases the risk for aspiration. Complications were from complications of general anesthesia, usually related to the use of mask ventilation (212). The last U.S. national study was of sterilizations performed in 1979 to 1980. There were a total of 9 to 10 deaths per 100,000 sterilizations, but only 1 to 2 per 100,000 were attributed to the sterilization procedure alone (213). When general anesthesia is used for laparoscopy, endotracheal intubation is mandatory because the pneumoperitoneum increases the risk for aspiration.
Benefits of Tubal Sterilization

In addition to providing excellent contraception, tubal ligation is associated with reduced risk for ovarian cancer that persists for as long as 20 years after surgery (217).

Sterilization Failure

Many "failures" occur during the first month after laparoscopy and are the result of a pregnancy already begun when the sterilization was performed. Conception should be continued until the day of surgery, and a sensitive pregnancy test should be routinely performed on the day of surgery. Because implantation does not occur until 6 days after conception, however, a woman could conceive just before her surgery and there would be no way to detect it.

Scheduling sterilization early in the menstrual cycle obviates the problem but adds to the logistic difficulty. Another cause of failure is the presence of anatomic abnormalities, usually adhesions surrounding and obscuring one or both tubes. An experienced laparoscopic surgeon with proper instruments can usually lyse the adhesions, restore normal anatomic relations, and positively identify the tube. In some circumstances, however, successful sterilization will not be possible by laparoscopy, and the surgeon must know before surgery whether the patient is prepared to undergo laparotomy, if necessary, to accomplish sterilization.

Most studies of sterilization failure are short term. The Centers for Disease Control and Prevention's Collaborative Review of Sterilization (CREST) reported on a cohort of 10,685 women sterilized between 1978 and 1986 at 16 participating centers in the United States who were followed from 8 to 14 years (218). The true failure rates for 10 years obtained by the life-table method are given in Table 10.10. The percentages for pregnancies resulting from sterilization during the luteal phase of the cycle in which the surgery was performed are excluded. Only 33% of all remaining pregnancies were ectopic. The most effective methods at 10 years were unipolar coagulation at laparoscopy and postpartum partial salpingectomy, generally a modified Pomeroy procedure. Bipolar tubal coagulation and the Hulka-Clemens clip were least effective. Younger women had higher risk for failure, as would be expected because of their greater fecundity.

Reversal of Sterilization

Reversal of sterilization is more successful after mechanical occlusion than after electrocoagulation because the latter method destroys much more of the tube. With modern microsurgical techniques and an isthmus-to-isthmus anastomosis, pregnancy follows in about 75% of cases (220). A substantial risk for ectopic pregnancy exists after reversal.

Late Sequelae of Tubal Sterilization

Increased menstrual irregularity and pain have been attributed to previous tubal sterilization. In patients who underwent the older laparoscopy technique with unipolar electrical destruction of a major portion of the tube, these concerns may be warranted (221). Study of the problem is complicated by the facts that many women develop these symptoms even though they have not had tubal surgery, and OCs reduce pain and create an artificially normal menstrual cycle. Therefore, women who discontinued OC use concurrent with tubal sterilization will experience more dysmenorrhea, which is entirely unrelated to the sterilization. The best answer presently available also comes from the CREST study (222). A total of 9,514 women who had undergone tubal sterilization were compared with 573 women whose partners had undergone vasectomy. Both groups were followed up to 5 years with annual standardized telephone interviews. Women who had undergone tubal sterilization were no more likely to report consistent changes in intermenstrual bleeding or length of the menstrual cycle than women whose partners had vasectomy. The sterilized women, in fact, reported decreases in days of bleeding, amount of bleeding, and menstrual pain but were slightly more likely to report cycle irregularity (OR, 1.6; 95% CI, 1.1 to 2.3). Hence, this study found no evidence to support the existence of a posttubal ligation syndrome.

Vasectomy

Vasectomy, excision of a portion of the vas deferens, is readily accomplished with local anesthesia in an office setting. It does not decrease sexual performance (223). The basic technique is to palpate the vas through the scrotum, grasp it with fingers or atraumatic forceps, make a small incision over the vas, and pull a loop of the vas into the incision. A small segment is removed, and then a needle electrode is used to coagulate the lumen of both ends. Improved techniques include the no-scalpel vasectomy, in which the pointed end of the forceps is used to puncture the skin over the vas. This small variation reduces the chance of bleeding and avoids the need to suture the incision. Another variation is the open-ended vasectomy, in which only the abdominal end of the severed vas is coagulated while the testicular end is left open. This is believed to prevent congestive epididymitis (224).

Reversibility

Vasectomy must be regarded as a permanent means of sterilization; however, with microsurgical techniques, vasovasostomy will result in pregnancy about half the time. The longer the interval since vasectomy, the poorer the chance of reversal.

Safety

Operative complications include scrotal hematomas, wound infection, and epididymitis, but serious sequelae are rare. There have been no reports of deaths from vasectomy in the United States in many years, and the death rate in a large Third World series was only 0.5 per 100,000. Studies of vasectomized monkeys showed accelerated atherosclerosis, but several large-scale human studies have found no connection between vasectomy and vascular disease (225–225). Concerns about long-term safety recurred with the report of a possible association between prostate cancer and vasectomy (227). Prostate cancer is largely a disease of the Western world and is strongly linked to dietary animal fat, family history, and race (228). In the West, it is more common in men of African American ancestry and rare in men of Asian descent. Recent studies are reassuring. A large mulitethnic case-control study from the United States and Canada compared 1,842 men with prostate cancer...
Abortion

Given the desire in developed countries to limit families to one or two children and the efficacy of contraception in general use, it is extremely likely that any normal couple will experience at least one unwanted pregnancy at some time during their reproductive years. In Third World countries, desired family size is larger, but access to effective contraception is limited. As a result, abortion is common. Worldwide, about 26 to 31 million legal abortions and an estimated 10 to 22 million clandestine abortions are performed every year (230). Where abortion is legal, it is generally reasonably safe; where it is illegal, complications are common, and about 150,000 women die every year from these complications (231). Societies cannot prevent abortion, but they can determine whether it will be illegal and dangerous or legal and safe. Many countries in which abortion is completely illegal have very high rates of clandestine abortion. Abortion rates in representative countries are given in Table 10.11 (232).

Table 10.11. Rates of Induced Abortion in Representative Countries, 1985–1991 per 1,000 Women Aged 15–44 Years

Death from illegal abortion was once common in the United States. In the 1940s, more than 1,000 women died each year of complications from abortion (233). In 1992, the last year for which complete data are available, there were 17 deaths from spontaneous abortion, 10 deaths from legally induced abortion, and no deaths from illegal abortion (abortion induced by a nonprofessional) in the entire United States. (234) The American Medical Association’s Council on Scientific Affairs has reviewed the impact of legal abortion and attributes the decline in deaths during this century to the introduction of antibiotics to treat sepsis; the widespread use of effective contraception beginning in the 1960s, which reduced the number of unwanted pregnancies; and, more recently, the shift from illegal to legal abortion (235). Much of the continued decline in non–abortion-related maternal mortality of recent years can be attributed to choice of legal abortion by women at high risk for pregnancy mortality. The United States has a serious problem with teenage pregnancy. Without legal abortion, there would be almost twice as many teenage births each year. The number of abortions reported each year in the United States—1,186,039 in 1997 according to the Centers for Disease Control and Prevention—has been decreasing since 1990. In 1997, the national abortion ratio was 306 abortions for every 1,000 live births, and the national abortion rate was 20 per 1,000 women aged 15 to 44 years (236). Most women who obtain abortions are unmarried (79% in 1997), and the ratio of abortions to live births is 9 times higher for unmarried women than for married women. Use of abortions varies markedly with age. In 1997, 20% of women obtaining abortions were 19 years of age or younger, and 51.8% were 24 years of age or younger. In 1997, the last year for which detailed information is available, the abortion ratio for women younger than 15 years of age was 729 per 1,000 live births, almost as many abortions as births (Fig. 10.2). The lowest abortion ratio, 161 per 1,000 live births, is for women aged 30 to 34 years. Legal abortion rates and ratios reached their highest in the early 1980s as they replaced illegal abortions, and both have declined since, especially for the youngest women (Fig. 10.20) (29).

![Figure 10.20](image)

Regardless of personal feelings about the ethics of interrupting pregnancy, health professionals have a duty to know the medical facts about abortion and to share them with their patients (237). Providers are not required to perform abortions against their ethical principles, but they have a duty to help patients assess pregnancy risks and to make appropriate referrals.

Safety Issues

The risk for death from legal abortion was 0.7 per 100,000 induced abortions in 1996 (234). In contrast, total maternal mortality is about 7 or 8 per 100,000 live births. The risk for death from legal abortion before 16 weeks is 10-fold less than that from continuing the pregnancy to delivery. As shown in Table 10.12, the risk for death increases with gestational age (238). For individual women with high-risk conditions (e.g., cyanotic heart disease), even late abortion is a safer alternative to birth. Because of the availability of low-cost, out-of-hospital first-trimester abortion, 88% of legal abortions are performed during the first trimester (before 13 weeks of amenorrhea), when abortion is the safest (238). The type of procedure is another determinant of risk. First-trimester abortions are virtually all performed by vacuum curettage; however, in the midtrimester, a variety of techniques can be used. Risk for death from abortion by the various techniques at different gestational ages is given in Table 10.13. The data clearly show the greater safety of instrumental evacuation of the uterus [dilation and evacuation (D & E)] performed in the early midtrimester. Another determinant of risk is anesthesia. Use of general anesthesia increases the risk for perforation of the uterus, visceral injury, hemorrhage, hysterectomy, and death (239). The preferred alternative is paracervical block with local anesthetic, augmented with conscious sedation when needed.
Techniques for Abortion

Most abortions are performed by vacuum curettage. Early procedures (5 to 7 weeks from beginning of last normal menses) can be readily performed in an office setting using simple instruments: a 5- to 6-mm flexible plastic cannula and a modified 50-mL plastic syringe as vacuum source (240). After 7 weeks, somewhat larger rigid plastic cannulas (8 to 12 mm in diameter) are generally used, depending on gestational age, with an electric pump as the vacuum source. Most abortions in the United States are performed outside of hospitals, usually in freestanding specialty clinics, at a cost far below that of hospital services. General anesthesia is unnecessary. Adequate pain relief is provided by infiltrating the cervix with local anesthetic, augmented with intravenous sedatives and analgesics for conscious sedation (241).

Medical Means for Abortion

Mifepristone (RU486), an analogue of the progestin norethindrone, has strong affinity for the progesterone receptor but acts as an antagonist, blocking the effect of natural progesterone. Given alone, the drug was moderately effective in causing abortion of early pregnancy; however, the combination of mifepristone with a low dose of prostaglandin proved very effective. In a series of almost 17,000 cases, 600 mg of mifepristone orally followed in 36 to 48 hours by either sulprostone or gemeprost produced complete abortion in 95% of cases (242). The only significant complications of this method to date have been three myocardial infarctions, with one death. All three myocardial infarctions occurred in women older than 35 years of age who were heavy smokers and occurred at the time of administration of sulprostone, a prostaglandin E2 analogue (243). No myocardial infarctions have occurred with the prostaglandin E2 analogue gemeprost. Misoprostol, another prostaglandin E2 analogue, appears to have fewer side effects and a greater margin of safety than sulprostone. It is very effective when combined with mifepristone and is the prostaglandin used with mifepristone in the United States (244).

The 600-mg dose of mifepristone used initially is actually far more than needed. Several investigators have shown that a 200-mg dose is equally effective (245,246,247 and 248). Initially, misoprostol was given orally, but the vaginal route of administration is more effective, probably because it provides sustained blood levels of the drug over several hours (249). The combination of 200 mg mifepristone orally followed by 800 mg of vaginal misoprostol produced complete abortion in 98% of women treated, after up to 63 days of amenorrhea, and appears to be the regimen of choice (246). Misoprostol can be given 1 to 3 days after the mifepristone with no loss of efficacy (245). Initially, patients returned to the clinics to receive misoprostol and remained on site for several hours. Half or more expel the pregnancy within 4 to 5 hours after misoprostol is given. However, it has been shown that patients may safely be given the misoprostol for self-administration at home (250).

Methotrexate and Misoprostol

The antifolate methotrexate provides another approach to pregnancy termination. Widely used to treat ectopic pregnancies without surgery (251), it can also be used with intrauterine gestations. Methotrexate, 50 mg/m2 given intramuscularly, followed by misoprostol, 800 mg inserted vaginally, produced abortion in six pregnancies up to 66 days from the last menstrual period (252). Methotrexate used alone without the misoprostol is also successful, although bleeding does not begin until an average of 24 days after treatment (253). In a large multicenter trial, 53% of patients aborted after the first dose of misoprostol and an additional 15% after the second dose. A total of 92% had successful abortion by 35 days after the initial methotrexate injection (254). The methotrexate-misoprostol regimen takes longer than mifepristone-methotrexate and is not as effective, but it is much less expensive. Methotrexate is usually given as an intramuscular injection, but a 50-mg oral dose is equally effective (255).

Second-trimester Abortion

Most legal abortions are performed before 13 menstrual weeks. Abortions performed after 13 weeks include those done because of fetal defects, medical or psychiatric illness that had not manifested earlier in pregnancy, and changed social circumstances, such as abandonment by the spouse. Young age is the single greatest factor determining the need for late abortion. In 1997, 24.9% of abortions for women younger than 15 years of age were midtrimester, whereas 16.8% of abortions for women 15 to 19 years of age and only 9.3% of abortions for women 30 to 34 years of age were performed after 12 weeks of gestation (236). These proportions have changed little in a decade.

Dilation and Evacuation

D & E is the most commonly used method of midtrimester abortion in the United States (238). Typically, the cervix is prepared by insertion of hygroscopic dilators, stems of the seaweed Laminaria japonica (laminaria). Placed in the cervical canal as small sticks, these devices take up water from the cervix and swell, triggering dilation. When these are removed the following day, sufficient cervical dilation is accomplished to allow insertion of strong forceps and a large-bore vacuum cannula to extract the fetus and placenta (256,257). Ultrasound guidance during the procedure is helpful (258). For more advanced procedures, sequential insertion of laminaria over 2 or more days is practiced, in order to achieve a greater degree of cervical dilation (259). At the end of the midtrimester, procedures that combine serial multiple laminaria dilation of the cervix with intrafetal injection of digoxin, induction of labor, and assisted expulsion of the fetus are used (260).

Labor-induction Methods

**Hypertonic Solutions** Amnioinfusion of hypertonic saline is historically important as one of the oldest labor-induction methods for abortion. Saline has serious

hazards: cardiovascular collapse, pulmonary and cerebral edema, and renal failure occur if the solution is injected intravenously. All patients are at risk for serious disseminated intravascular coagulopathy (281). However, attention to proper technique for amnioinfusion, with the saline instilled by gravity flow through connecting tubing from a single-dose bottle under ultrasound guidance, reduces the frequency of such mishaps. Hypertonic urea is safer than saline. It is combined with low doses of prostaglandin to increase efficacy and shorten the interval from injection to abortion.

Prostaglandins. Prostaglandins, oxygenated metabolites of C20 carboxylic acid, are found naturally in most biologic tissues, where they act as modulators of cell function. They act through specific receptors of the G-protein family that are coupled to a variety of intracellular signal mechanisms, which may stimulate or inhibit adenyl cyclase, or phosphatidylinositol (282). Prostaglandins of the E and F series can cause uterine contraction at any stage of gestation. These agents can be given by intraamniotic infusion, by intramuscular injection, or by vaginal suppository. The 15 methyl analogues of prostaglandin F (carboprost) and prostaglandin E, (dinoprost) are highly effective but frequently produce side effects of vomiting and diarrhea. Vaginal misoprostol (200 mg every 2 hours) has been shown to be as effective as dinoprost suppositories (20 mg every 3 hours) in patients with fetal death or intact pregnancy at 12 to 22 weeks of gestation (263). In this study, patients with a living fetus were treated with ultrason-guided intracardiac injection of potassium chloride to ensure fetal death before administration of misoprostol. Misoprostol patients experienced fewer side effects of fever, uterine pain, vomiting, and diarrhea. Misoprostol was much less expensive and easier to administer. A comparison of 200-, 400-, and 600-mg doses of misoprostol at 12-hour intervals produced rates of abortion of 70.6%, 82%, and 96%, respectively, with 48 hours; however, the side effects of vomiting, diarrhea, and fever increased with increasing dose (264). Doses as high as 400 mg vaginally every 3 hours have been used (252), but caution is needed because there is risk for uterine rupture with higher doses used in the latter midtrimester. More investigation is needed to determine the ideal dosage; one regimen is 400 mg of misoprostol at 6-hour intervals.

There is also interest in midtrimester abortion induced with combinations of mifepristone and misoprostol. Mifepristone would undoubtably increase the effect of misoprostol, reducing the necessity of the second drug. A French protocol used 600 mg of mifepristone, followed at 26 hours with placement of laminaria into the cervix, after which misoprostol was administered. The method was highly effective, with very short time intervals from the onset of misoprostol administration to abortion; however, one case of uterine rupture occurred in a patient with a uterine scar (266).

About one third of patients treated with 20-mg doses of dinoprost have a temperature elevation of 1°C or more. This phenomenon is not seen with carboprost tromethamine, which slightly reduces body temperature. The effect of misoprostol on body temperature is dose related; generally, there is no effect at 200 mg given every 12 hours, but the effect increases as the dose increases and intervals are shortened.

Transient fetal death can be a problem with all prostaglandin methods used in the midtrimester. To prevent this problem, and to shorten the interval to abortion and avoid failed abortion, many centers use a fetal intracardiac injection of potassium chloride (3 mL of a 2-mmol solution) or 1.5 mg of digoxin. Others perform amniocentesis and inject a small volume of intraamniotic hypertonic saline (60 mL of a 23% solution). Retained placenta is common with all prostaglandin abortions. Instrumental extraction is necessary in about half of cases.

Oxytocin in very high doses is as effective as dinoprost at 17 to 24 weeks of pregnancy (267). Patients initially receive an infusion of 50 units of oxytocin in 500 mL of 5% dextrose and normal saline over 3 hours, 1 hour of no oxytocin, followed by a 100-unit, 500-mL solution over 3 hours, another hour of rest, and then a 150-unit, 500-mL solution over 3 hours, alternating 3 hours of oxytocin with 1 hour of rest. The oxytocin is increased by 50 units in each successive period until a final concentration of 300 units per 500 mL has been reached.

Complications. The labor-induction methods share common hazards: failure of the primary procedure to produce abortion within a reasonable time, incomplete abortion, retained placenta, hemorrhage, infection, and embolic phenomena. Failed abortion can lead to serious infection and continued blood loss. If fetal expulsion has not occurred after 24 to 36 hours, consideration should be given to a D & E procedure.

Selective Reduction. Multifetal pregnancies are at risk for extremely premature birth, with major neonatal complications resulting. To prevent this, selective reduction of higher-order multiple gestation to twins is often practiced. In a series of 463 pregnancies treated with ultrasound-guided fetal intracardiac injection of potassium chloride (0.2 to 0.4 mL of a 2-mmol solution in the first trimester, 0.5 to 3.0 mL in the second trimester), 83% of the surviving fetuses delivered at 33 weeks or later (268). Another indication for selective reduction is one anomalous fetus of a multifetal gestation. A 1999 series reported 402 patients treated as described for this indication (269). Rates of pregnancy loss after the procedure by gestational age at the time of procedure were 5.4% at 9 to 12 weeks, 8.7% at 13 to 18 weeks, 6.8% at 19 to 24 weeks, and 9.1% at 25 weeks or more. No maternal coagulopathy occurred, and no ischemic damges or coagulopathies were seen in the surviving neonates. Selective induction should not be attempted with monoamniotic twins or with twin–twin transfusion syndrome because of the possibility of embolic phenomena and infarction in the surviving twin. Maternal serum a-fetoprotein remains elevated into the second trimester after first-trimester procedures.

Induced Abortion and Subsequent Reproduction. Legal abortion, as currently practiced in the United States, has no measurable adverse effect on later reproduction (270). Even two or more induced abortions have no detectable adverse effect (271). Abortion as practiced in the United States is not associated with low birth weight, premature birth, or increased perinatal loss (272). Concerns about infertility as a result of induced abortion are unfounded, except for the rare severe complication managed by hysterectomy (273). The lack of adverse effects on later pregnancy probably reflects the safety of current abortion technology in the United States.

The Future. Contraceptive development is extremely slow in the United States because of the legal climate, the great cost of meeting regulatory requirements, and the low priority given this area by the medical community. On the international scene, a number of new approaches to contraception are in development. The two-rod version of Norplant (Norplant II) should soon be available. Levonorgestrel in a biodegradable rod of caprooleatone that does not require removal is currently being tested, as is the single-rod implant releasing 3-eto desogestrel. The GyneFix, a frameless copper IUD now available in Europe, consists of a surgical suture with small copper cylinders crimped to it. The knot on the proximal end of the suture is pushed 1 cm into the uterine wall with a special inserter. Comparative trials have found it more effective than the copper 738A and to have fewer expulsions and fewer removals for pain and bleeding (274). It is of considerable interest for these reasons and also because of excellent retention after postcastral insertion.

Silastic vaginal rings releasing either progestin or progestin-estrogen combinations have been studied for years and are now undergoing field trials in a number of countries. A patch for transdermal release of estrogen and progestin for contraception is being tested in the United States. Both of these methods for steroid delivery have the advantage of greater ease of compliance for the user. There is great interest in developing compounds that could be used as a vaginal contraceptive and that would be protective against HIV. One such compound is a phenyl phosphate derivative of zidovudine. It has both spermicidal and antiretroviral activity and has proved nontoxic in short-term trials in mice (275).

Current methods of tubal sterilization require abdominal surgery. To meet the coming demand for vast numbers of sterilizations worldwide, easier means must be devised. Considerable effort has gone into developing transuterine methods of female sterilization that would avoid the need to open the abdominal cavity to gain access to the fallopian tubes. Hysterectomy with tubes. Hysterolysis and electrofulguration of the injection of Sylastic that forms in place into tubal plugs has been explored and largely abandoned (276). A simpler option is placement of quinacrine pellets in the uterus through an IUD inserter. It has been known for years that intrauterine quinacrine can produce sclerosis of the proximal fallopian tube. This method has recently been rediscovered and is being seriously explored. A pellet containing 252 mg of quinacrine is inserted into the uterus during the proliferative phase of the cycle and again 1 month later. In a large trial, the 1-year pregnancy rate for 9,461 women who received two doses was 2.63 per 100 woman-years. The rate of ectopic pregnancy was 0.89 per 1,000 woman-years (277).

Immunologic contraception sterilization has been pursued for many years. Talwar and colleagues in India have worked for many years toward vaccination against human chorionic gonadotropin (HCG) and have performed trials in humans (278). Another area of interest is in vaccinating men or women against specific sperm

Sexuality, Sexual Dysfunction, and Sexual Assault

Sexuality is an important and integral part of every woman's life. Questions and concerns about sexuality span a woman's entire lifetime, from questions about puberty to concerns about change in sexual function with menopause and aging. The obstetrician-gynecologist, as a primary health care provider for women, should include a sexual history as a routine part of a woman's periodic health assessment.

Concerns about sexuality and sexual dysfunction are common in the general population. Surveys have found that almost two thirds of the women questioned had concerns about their sexuality (1,2,3,4 and 5). One third of women lacked interest in sex, 20% said sex was not always pleasurable, 15% experienced pain with intercourse, up to 50% experienced difficulty becoming aroused, 50% noted difficulty reaching orgasm, and up to 25% were unable to experience orgasm.

In addition, obstetrician-gynecologists should routinely inquire about a history of childhood sexual abuse or adult sexual assault because these experiences are common and often have a lasting and profound effect on a woman's mental and sexual function as well as her general health and well-being. One of eight American women will be forcibly raped during her lifetime (6), and nearly half of women in the United States report some type of contact sexual victimization (7). Fifty percent of American women report uninvited sexual attention in the workplace (7).

Despite the importance of these issues to their health care, many women find it difficult to talk to their physicians about sexual concerns, and many physicians are uncomfortable discussing sexual issues with their patients (6). In a recent survey, 71% of adults said they thought their doctor would dismiss any concerns about sexual problems they might bring up, and 68% said they were afraid that discussing sexuality would embarrass their physician (9). Surveys of primary care physicians reveal that fewer than half ask their new patients about sexual practices and concerns and that many physicians make incorrect assumptions about their patients' sexual activity based on marital status, profession, age, race, or socioeconomic status (10,11).

Sexuality

Physicians may be concerned that patients will be offended by questions about their sexual practices or may believe that little useful information will be gained by asking patients about sexual concerns or a history of sexual assault. In addition, some physicians may have anxiety about their perceived inability to treat sexual concerns, may believe that they have too little time to obtain a sexual history, may be distressed by their patient's history of sexually related violence, or may experience personal discomfort when discussing sexual matters with their patients (12). However, surveys of patients reveal that they expect their physician to be able to address sex-related concerns and believe it is appropriate for questions about sexuality to be included as a routine part of the gynecologic history (6). Not asking about sexuality suggests to the patient that sexuality is not important and is not to be discussed. Furthermore, not discussing sexual abuse implies that sexual assault has no long-term consequences.

Physicians will feel more comfortable talking to their patients about sex if they have an understanding of the normal sexual response and know how to approach the evaluation and treatment of common sexual dysfunctions. Asking about sexual concerns gives physicians an opportunity to educate patients about the risk for sexually transmitted infections (STIs), counsel patients about safe sex practices, evaluate patients' needs for contraception, and dispel sexual myths and misconceptions. Furthermore, patients are given permission to address sexual issues in a professional, confidential, and nongenital setting (13). Even if patients are initially uncomfortable discussing these sensitive and private issues, they know that their physician will be receptive if they want to discuss sexual concerns in the future.

When taking a sexual history, it is important to allow patients to feel comfortable and safe (14). The physician's personal values and potential biases should be left out of the discussion. Physicians should use a private location for the interview and let the patient know that the conversation will be confidential. Good listening skills and attention to nonverbal cues are helpful. It is important to use straightforward language that the patient can understand and acknowledge that many people find it difficult to discuss sensitive and intimate issues. Most sexual concerns can be resolved by providing factual information, reassurance, and appropriate medical intervention. Only a few open-ended questions are required to elicit a basic sexual history from patients. These questions should be a part of the medical history taken during a routine examination and can be obtained in either a face-to-face interview or in a written history the patient completes before seeing the physician (15):

"Are you currently sexually active?" "With men, women, or both?"
"Are you or your partner having any sexual difficulties?"
"Has there been any change in your sexual activity?"
"Have you ever experienced any unwanted or harmful touching or sexual activity?"

If a positive response is elicited by any of these questions, further evaluation of the patient may be warranted. Follow-up questions might include:

"Are you having difficulty initiating a sexual encounter or becoming aroused when you want to be sexual?"
"Do you experience as much arousal as you would like?"
"Do you experience vaginal dryness during intercourse?"
"Do you have orgasms when you want to?"
"Are you satisfied with your sexual relationship?"
"Do you have pain with intercourse?"
"Has this difficulty always been present, or is it new to you?"
"Have you had this difficulty with all of your partners or just with the current one?"
"Is the difficulty always there or just some of the time?"
"Does anything make it better or worse?"
Sexual Practices

Two recent comprehensive surveys provide an interesting and useful description of the sexual behavior of Americans (2,3,17). Sexual activity among adolescents in the United States has increased significantly during the past 20 years. The average age for first intercourse in both men and women is 16 years. By 19 years of age, 66% to 75% of women and 79% to 86% of men will have had intercourse. Most young men and women have multiple, serial sexual partners. They use condoms infrequently and inconsistently, thus exposing themselves to STIs and unintended pregnancy. A survey of American men and women between the ages of 18 and 59 years revealed the following findings (2):

- Most men and women are satisfied with their sex lives, even those who rarely have sex. Among married men and women, 87% reported that they were satisfied with their sexual relationship.
- Sexual dysfunction was reported in 43% of women and was more likely in women with poor physical and emotional health, unmarried women, younger women, uneducated women, women who had experienced sexual victimization, women who were sexually inexperienced, and women with negative experiences in prior sexual relationships (3).
- Women have sex with a partner from a few times per month (47%), to 2 to 3 times per week (32%), to 4 or more times per week (7%). Twelve percent of women have sex a few times per year, and 3% have never been sexually active.
- The most appealing sexual activity for both men and women is vaginal intercourse. Watching their partner undress and receiving and giving oral sex were also considered very pleasurable.
- Most Americans are monogamous. Of married men and women, 75% and 85%, respectively, said they had never been unfaithful.
- There may be fewer homosexuals than previously believed—2.7% of men and 1.3% of women had a homosexual partner in the past year. Since puberty, 7.1% of men and 3.8% of women had same-gender sexual partners.
- Twenty-two percent of women said they had been forced to do something sexual, usually by someone they loved, but only 3% of men admitted to forcing themselves on a woman. Perhaps men and women have different ideas about what constitutes sexual coercion.

The Sexual Response Cycle

The sexual response cycle in women is mediated by the complex interplay of psychological, environmental, and physiologic (hormonal, vascular, muscular, and neurologic) factors. The initial phase of the sexual response cycle is interest and desire, followed by the four successive phases originally described by Masters and Johnson (18): arousal, plateau, orgasm, and resolution. There is wide variability in the way women respond sexually, and each phase can be affected by aging, illness, medication, alcohol, illicit drugs, and relationship factors.

An attempt has been made to redefine the linear progression of sexual response described by Masters and Johnson. The Basson model postulates that the sexual cycle in women is cyclical rather than linear and that arousal and desire are interchangeable (19,20). In this model, the starting point for sexuality is the desire for intimacy and closeness rather then a need for physical sexual release. Many women are satisfied with an intimate encounter that does not necessarily include intercourse or orgasm.

For most women, the clitoris is the most sexually sensitive part of their anatomy, and stimulation of the clitoris produces the greatest sexual arousal and the most intense orgasms. Other sexually sensitive areas are the nipples, breasts, labia, and, to a lesser extent, the vagina. Although the lower third of the vagina is responsive to touch, the upper two thirds of the vagina is sensitive primarily to pressure.

There has been speculation about the existence of a G spot (named after Ernest Grafenberg, who first described it in 1944), an area of the vagina located anteriorly midway between the symphysis pubis and the cervix that is believed to be exquisitely sensitive to deep pressure. This area, believed to be similar to the male prostate, has been described as glandular tissue capable of secreting prostatic acid phosphatase into the urethra, sometimes in such copious amounts that women seem to ejaculate during orgasm. However, analysis of the fluid “ejaculate” has proved that it is probably urine, not prostatic fluid. It is not uncommon for women who are normally continent to leak urine during orgasm. These women should be reassured that this is a common phenomenon and does not require medical intervention.

Desire Phase

Sexual desire is the motivation and the inclination to be sexual. It is a “subjective feeling state” that may be triggered by both internal (fantasy) and external (an interested partner) sexual cues and is dependent on adequate neuroendocrine functioning (20). The sensation of desire is under the influence of dopamine-sensitive excitatory centers located in the limbic system. Testosterone is responsible for desire and arousal in both men and women. Drive is the biologic component of desire and is characterized by sexual thoughts, erotic interest in others, genital tingling, and seeking out of sexual activity (20). Desire is influenced by sexual orientation, preferences, psychological mindset, beliefs and values, expectations, willingness to behave sexually, and environmental setting.

Arousal (Excitement) Phase

The arousal (excitement) phase is mediated by the parasympathetic nervous system and is characterized by erotic feelings and the appearance of vaginal lubrication. Sexual arousal increases blood flow to the vagina, and the resulting vasocongestion and changes in capillary permeability create a condition that increases the capillary filtration fraction. The filtered capillary fluid transudates between the intercellular spaces of the vaginal epithelium, causing droplets of fluid to form on the walls of the vagina. In addition to feelings of sexual tension, sexually excited women experience tachycardia, rapid breathing, an elevation in blood pressure, a generalized feeling of warmth, breast engorgement, generalized muscle tension (myotonia), nipple erection, mottling of the skin, and a maculopapular erythematous rash (“sex flush”) over the chest and breasts. During this phase, the clitoris and labia become swollen; the vagina lengthens, distends, and dilates; and the uterus elevates out of the pelvis (18,20).

During the latter stages of arousal, sexual tension and erotic feelings intensify, and vasocongestion reaches maximum intensity (plateau). The skin becomes more mottled, the breasts become more engorged, and the nipples become more erect. The labia become more swollen and turn dark red, and the lower third of the vagina swells and thickens to form the “orgasmic platform” (18,20). The clitoris becomes more swollen and elevates to lie nearer the symphysis pubis. The uterus elevates fully out of the pelvis. With adequate sexual stimulation, women reach the point of orgasmic inevitability (threshold point).

Orgasm Phase

Orgasm is a myotonic response mediated by the sympathetic nervous system. It is experienced as a sudden release of the tension that has built up during the arousal. Orgasm is the most intensely pleasurable of the sexual sensations. It consists of multiple (3 to 15) 0.8-second reflex rhythmic contractions of the muscles (pubococcygeal) surrounding the vagina, perineum, anus, and orgasmic platform. Uterine contractions are also experienced by many women during orgasm (18). Thus, some women describe the sensation of an orgasm as different after hysterectomy. Many women who are orgasmic prefer to have orgasms before intercourse, during the time when clitoral stimulation is most intense. Unlike men, who are relatively unresponsive to sexual stimulation after orgasm (refractory period), women are potentially multimorphic and capable of experiencing more than one orgasm during a single sexual cycle. Thus, they can experience orgasms both before and during intercourse if adequate clitoral stimulation is provided.

Resolution Phase

Following the sudden release of sexual tension brought about by orgasm, women experience a feeling of relaxation and well-being. The physiologic...
A variety of prescription and nonprescription medications, including alcohol and illicit drugs, can alter the normal sexual response (Table 11.3). The sexual expectations of the aging patient and her partner and an assessment of their current level of sexual functioning should also be evaluated. Myths they may have heard about sexuality in the elderly should be dispelled. If the couple is interested in retaining sexual function, they should be instructed in alternative forms of lovemaking that can be adapted to a new (noncoital) way of lovemaking. Other factors include privacy issues (such as living in a nursing home), reluctance to masturbate, and the negative attitudes of society toward sexuality in older women (3). Aging men and women may experience performance anxiety as they enter into new relationships (24,25 and 26). As women age, many tend to be less fit. Improved physical fitness is positively related to the frequency of sexual intimacy, which in turn is related to longevity (27). Suggestions for aging patients might include taking a warm bath before lovemaking to loosen stiff joints, making love in the morning when the couple is less fatigued, and experimenting with oral or manual sexual stimulation to orgasm without having intercourse.

Management of sexual difficulties in older women should include estrogen or testosterone supplementation (27,28 and 29). Local or systemic estrogen supplementation can alleviate vaginal dryness, urinary tract symptoms, and dyspareunia. Estrogen replacement restores vaginal cells, decreases pH, and increases vaginal blood flow, thus alleviating vaginal dryness, urinary tract symptoms, and dyspareunia. Estrogen replacement also seems to benefit sexual desire, sexual fantasy, arousal, sexual enjoyment, and orgasmic frequency in postmenopausal women (27). In addition, estrogen supplementation improves insomnia, hot flushes, and other menopausal symptoms (e.g., sense of well-being) that may interfere with sexual function. The addition of progesterone to the hormone replacement therapy regimen partially opposes the beneficial effects of estrogen by decreasing vaginal blood flow (28). Estrogen supplementation also decreases free testosterone levels by nearly 50% by increasing levels of sex hormone–binding globulin, thus decreasing free testosterone levels (29,31).

Testosterone levels gradually decrease in women as they age (29). Testosterone supplementation, either alone or in combination with estrogen, has been demonstrated to improve libido, arousal, sexual responsiveness, frequency of sexual fantasies and dreams, clitoral sensitivity, and frequency of orgasm in women who are testosterone deficient (<30 ng/mL) from surgical or natural menopause. In addition, restoration of normal testosterone levels can benefit muscle tone, physical energy, mood, sense of well-being, and genital atrophy not responsive to estrogen supplementation (27,32). Side effects of testosterone include acne, hirsutism, deepening of the voice, clitoromegaly, hepatotoxicity, alopecia, and undesirable changes in lipoprotein levels. Patients taking androgens should be prescribed the lowest effective dose of medication and carefully monitored for side effects.

Sildenafil, effective for treating erectile dysfunction in men, has been investigated for the treatment of sexual dysfunction in women (33,34). One study demonstrated the effectiveness of sildenafil in reversing female sexual dysfunction induced by selective serotonin reuptake inhibitors (SSRIs) (34). Another study failed to demonstrate any improvement in sexual function in postmenopausal women but did note improvement in vaginal lubrication and clitoral sensitivity. The effectiveness of sildenafil and other recently developed pharmacologic agents in the treatment of sexual dysfunction in women has yet to be documented.

The sexual expectations of the aging patient and her partner and an assessment of their current level of sexual functioning should also be evaluated. Myths they may have heard about sexuality in the elderly should be dispelled. If the couple is interested in retaining sexual function, they should be instructed in alternative forms of sexual expression and ways of alleviating discomfort. However, aging patients may have difficulty changing their sexual expectations and ways of making love. They may not easily adapt to change and may resist reevaluating long-held sexual beliefs, attitudes, behavior, and gender roles.

**Factors Affecting Sexual Response**

**Aging**

Aging and the cessation of ovarian function accompanying menopause have a significant effect on the sexual response cycle of women. Sexual desire and the frequency of intercourse decrease gradually as women age, although women retain interest in sex and continue to have the potential for sexual pleasure for their entire lives. The need for closeness, love, and intimacy does not change with age. The way women function sexually as they grow older is largely dependent on health status, partner availability, and how frequently they had sex and how much they enjoyed sex when they were younger (21). Results of a study of healthy men and women aged 80 to 101 years living in retirement communities indicated that these elderly people were still very sexually active (22). Sexual touching and caressing, followed by masturbation and then intercourse, were the most common sexual activities in this population.

Anatomic changes that accompany aging are noted in Table 11.1. These changes predispose women to more frequent episodes of vulvovaginitis and urinary tract infections that, along with decreased vaginal lubrication, may cause dyspareunia. The effects of aging on sexual physiology are noted in Table 11.2. Women who remain coitally active after menopause have less vulvar and vaginal atrophy than abstinent women (23). Illnesses that accompany aging may also have an impact on sexual function. Arteriosclerosis may decrease vaginal blood flow and cause decreased arousal, lubrication, and orgasmic intensity. Chronic obstructive pulmonary disease may cause lowered testosterone levels, impairing sexual desire. Pain from an arthritic hip may make it difficult for a woman to find a comfortable position for intercourse.

**Table 11.1. Anatomic Changes of Aging**

**Table 11.2. Sexual Physiology—Effects of Aging**

Several psychosocial factors may influence an older woman's sexual activity. Older women may lack a sexual partner, or their partner may develop erectile dysfunction. The couple may have had an unsatisfactory sexual relationship earlier in life and may not be able to negotiate the changes and possible sexual dysfunctions that can come with aging. Couples may find that they can no longer function sexually as they did in the past and are unable to make the transition or adapt to a new (noncoital) way of lovemaking. Other factors include privacy issues (such as living in a nursing home), reluctance to masturbate, and the negative attitudes of society toward sexuality in older women (23). Aging men and women may experience performance anxiety as they enter into new relationships (24,25 and 26). As women age, many tend to be less fit. Improved physical fitness is positively related to the frequency of sexual intimacy, which in turn is related to longevity (27). Suggestions for aging patients might include taking a warm bath before lovemaking to loosen stiff joints, making love in the morning when the couple is less fatigued, and experimenting with oral or manual sexual stimulation to orgasm without having intercourse.

Management of sexual difficulties in older women should include estrogen or testosterone supplementation (27,28 and 29). Local or systemic estrogen supplementation can alleviate vaginal dryness, urinary tract symptoms, and dyspareunia. Estrogen replacement restores vaginal cells, decreases pH, and increases vaginal blood flow, thus alleviating vaginal dryness, urinary tract symptoms, and dyspareunia. Estrogen replacement also seems to benefit sexual desire, sexual fantasy, arousal, sexual enjoyment, and orgasmic frequency in postmenopausal women (27). In addition, estrogen supplementation improves insomnia, hot flushes, and other menopausal symptoms (e.g., sense of well-being) that may interfere with sexual function. The addition of progesterone to the hormone replacement therapy regimen partially opposes the beneficial effects of estrogen by decreasing vaginal blood flow (27). Estrogen supplementation also decreases free testosterone levels by nearly 50% by increasing levels of sex hormone–binding globulin, thus decreasing free testosterone levels (29,31).

Testosterone levels gradually decrease in women as they age (29). Testosterone supplementation, either alone or in combination with estrogen, has been demonstrated to improve libido, arousal, sexual responsiveness, frequency of sexual fantasies and dreams, clitoral sensitivity, and frequency of orgasm in women who are testosterone deficient (<30 ng/mL) from surgical or natural menopause. In addition, restoration of normal testosterone levels can benefit muscle tone, physical energy, mood, sense of well-being, and genital atrophy not responsive to estrogen supplementation (27,32). Side effects of testosterone include acne, hirsutism, deepening of the voice, clitoromegaly, hepatotoxicity, alopecia, and undesirable changes in lipoprotein levels. Patients taking androgens should be prescribed the lowest effective dose of medication and carefully monitored for side effects.

Sildenafil, effective for treating erectile dysfunction in men, has been investigated for the treatment of sexual dysfunction in women (33,34). One study demonstrated the effectiveness of sildenafil in reversing female sexual dysfunction induced by selective serotonin reuptake inhibitors (SSRIs) (34). Another study failed to demonstrate any improvement in sexual function in postmenopausal women but did note improvement in vaginal lubrication and clitoral sensitivity. The effectiveness of sildenafil and other recently developed pharmacologic agents in the treatment of sexual dysfunction in women has yet to be documented.

The sexual expectations of the aging patient and her partner and an assessment of their current level of sexual functioning should also be evaluated. Myths they may have heard about sexuality in the elderly should be dispelled. If the couple is interested in retaining sexual function, they should be instructed in alternative forms of sexual expression and ways of alleviating discomfort. However, aging patients may have difficulty changing their sexual expectations and ways of making love. They may not easily adapt to change and may resist reevaluating long-held sexual beliefs, attitudes, behavior, and gender roles.

**Drugs**

A variety of prescription and nonprescription medications, including alcohol and illicit drugs, can alter the normal sexual response (35,36,37,38 and 39).
The patient's use of these drugs should be assessed as part of the medical history, and adjustments in dosage or formulation may be suggested, if appropriate. With some medications, like the SSRIs, it may be appropriate to suggest a short medication holiday to allow for temporary return of sexual function.

### Sexual Dysfunction

Types of sexual dysfunctions include (59,60):

1. **Dyspareunia**: Pain during or immediately before or after sexual intercourse.
2. **Vaginismus**: Spasms of the pelvic muscles that interfere with intercourse.
3. **Anorgasmia**: Inability to achieve orgasm despite sexual activity.
4. **Vulvar vestibulitis**: Inflammation of the skin of the vulva and the inner aspects of the thighs.

**Symptoms and causes**:

- **Physicians can help their patients by acknowledging and discussing the normal fluctuations in sexual desire and frequency of intercourse that occur during and after pregnancy.**
- **Testosterone and estrogen levels**: Although many couples begin to have intercourse 6 to 8 weeks after delivery, many couples may wait as long as a year to resume intercourse.
- **Breastfeeding**: Compared with women who bottle feed, women who breastfeed are more likely to experience decreased sexual desire and dyspareunia as a result of lower vaginal injury or infection, physical discomfort, fear of waking the baby, decreased sense of attractiveness, change in body image, or postpartum depression.
- **Postpartum depression**: Women may be hesitant to resume having intercourse because of lack of sexual desire, fear of conception, fatigue, and lack of interest in sexual activity.
- **Hormonal changes**: After delivery, many women experience fatigue, weakness, vaginal bleeding and discharge, perineal discomfort, hemorrhoids, sore breasts, and decreased vaginal lubrication and dyspareunia secondary to decreased estrogen levels. Women who function well sexually before surgery and have a positive self-image will be better able to cope with the sexual difficulties caused by gynecologic cancer treatment than women with poor precancer sexual adjustment.
- **Physical, emotional, and economic stresses of pregnancy often affect a couple's sexual and marital relationship**: Physical stresses of pregnancy include frequent sexual activity and physical discomfort during intercourse. Women who experience dyspareunia during pregnancy may have intercourse because of lack of sexual desire, fear of vaginal injury or infection, physical discomfort, fear of wakening the baby, decreased sense of attractiveness, change in body image, or postpartum depression.
- **Breast cancer diagnosis and treatment**: Breast cancer diagnosis and treatment can affect sexuality (52,43). However, most women cope well with the stress of treatment and do not develop major psychiatric disorders or significant sexual dysfunction. A number of studies have compared women who undergo hysterectomies with women who have conservative surgery (lumpectomy) with breast conservation. These studies have revealed little difference between the two groups in postoperative marital satisfaction, psychological adjustment, frequency of sex, or incidence of sexual dysfunction.

**Conclusion**: Physicians should discuss sexual concerns with the patient and her partner before surgery, attempt to dispel myths and misconceptions, and continue to offer counseling to patients after treatment. Specific technical advice (the use of water-based lubricating jelly, noncoital sexual activity for patients with severe dyspareunia, the use of vulvar dilators, and Kegel exercises) should also be provided. Women who function well sexually before surgery and have a positive self-image will be better able to cope with the sexual difficulties caused by gynecologic cancer treatment than women with poor precancer sexual adjustment.
1. Sexual desire disorders (hypoactive or inhibited sexual desire and sexual aversion)
2. Sexual arousal disorders
3. Orgasmic disorders
4. Sexual pain disorders (vaginismus, dyspareunia, and noncoital sexual pain)
5. Sexual disorders resulting from general medical conditions and substance abuse

Each disorder can be further classified as either (59):

1. Lifelong or acquired (after a period of normal sexual functioning)
2. Generalized (i.e., not limited to a specific partner or situation) or situational
3. Caused by psychological or medical factors

When evaluating patients with sexual dysfunction, it is important to obtain the following information (60,61 and 62):

1. A specific description of the dysfunction and an analysis of current sexual functioning
2. When the dysfunction began and how it progressed over time
3. Any precipitating factors
4. The patient’s theory about what caused the dysfunction
5. What effect the dysfunction has had on her relationship
6. Past treatment and outcomes
7. Expectations and goals for treatment
8. Understanding of sexual physiology and sexual behavior
9. Any myths or misinformation

Although many physicians have some anxiety about discussing sexual issues with their patients and believe that they lack the basic skills to provide sexual counseling, most sexual concerns can be treated by the general gynecologist. The PLISSIT model is a useful sexual counseling and therapy method consisting of four levels of therapeutic intervention (63). Using the first three levels of this model, 80% to 90% of sexual concerns can be addressed (63). The PLISSIT model is as follows:

1. Permission validates the patient’s feelings and gives her permission to address her sexual concerns.
2. Limited Information provides the patient with information about sexual physiology and behavior.
3. Specific Suggestions involve specific reeducation regarding the patient’s sexual attitudes and practices.
4. Referral for Intensive Therapy is reserved for those patients who do not respond to the first three levels of intervention and who may require intensive individual or couple therapy.

As an example of a specific suggestion, a woman with primary anorgasmia is first given permission to look at her genitalia and touch her clitoris. She is then given limited information about genital anatomy and the physiology of the sexual response. Specific suggestions are then offered about using fantasy and directed masturbation, encouraging her to use self-help books (64). Patients who have been sexually abused or who have significant anxiety or depression, sexual aversion, or significant marital dysfunction should be referred to a therapist who specializes in these areas.

### Hypoactive Sexual Desire Disorder

Hypoactive sexual desire disorder (HSDD) is a recurrent deficiency or absence of sexual fantasies or thoughts or desire for sexual activity causing marked distress and interpersonal difficulty (65,66). Patients with HSDD have little interest in seeking sexual stimuli but often retain the ability to become sexually aroused and experience orgasm if they are approached sexually by their partner. This disorder usually develops in adulthood, often after a period of adequate sexual interest and functioning. HSDD is the most common sexual dysfunction in both women and men and is the most difficult to treat (57,68). It often is accompanied by another sexual disorder, such as dyspareunia or anorgasmia. Some individuals may experience sexual aversion, a complete avoidance of all sexual activity with a partner (59).

Physiologic causes of HSDD include medications (Table 11.3), chronic medical illnesses, depression, stress, substance abuse, aging, and hormonal alterations (36,69). Serum testosterone and prolactin levels should be evaluated in any patient presenting with the recent onset of HSDD because elevated prolactin levels (from a pituitary adenoma) or low testosterone levels (sometimes following natural or surgical menopause) could be responsible. Some postmenopausal patients who experience dyspareunia secondary to vaginal atrophy may avoid intercourse. This condition will resolve with systemic or vaginal estrogen replacement therapy. Some women with HSDD benefit from testosterone supplementation.

Individual causes of HSDD include religious orthodoxy, anhedonic or obsessive-compulsive personality (these patients may lack the capacity for play and find it difficult to display emotion and let themselves go), masked sexual deviance (e.g., transvestism), fear of pregnancy or STIs, and object choice issues (i.e., the patient may be a homosexual trying to function sexually in a heterosexual relationship).

Some individuals experience an unconscious and involuntary suppression of sexual desire and actively avoid sexual situations. They may suppress their desire by evoking negative thoughts or by allowing spontaneous negative thoughts to intrude when they have a sexual opportunity (antifantasies) (66). Sexual desire can also be inhibited by performance anxiety, negative body image, chronic stress, low self-esteem, depression, the anticipation of an unpleasant sexual experience, fear of intimacy, or residual guilt about sex and pleasure. Women who have been sexually abused as children or sexually assaulted as adults may experience sexual aversion or victimization. Some patients may fear loss of control over their sexual feelings and, therefore, may suppress them completely. If a patient is experiencing another form of sexual dysfunction, such as dyspareunia or anorgasmia, she may also be experiencing HSDD (69).

The way a couple functions sexually is often a good barometer of how things are going in the rest of the relationship. Therefore, whenever a woman presents with sexual concerns or sexual dysfunction, it is important to inquire about the relationship in general. If significant relationship problems exist in addition to sexual concerns, the couple should be referred for counseling. Relationship causes of HSDD include lack of sexual attraction for the partner (due to factors such as poor hygiene), poor lovemaking skills, sexual inexperience of one or both partners, marital conflict, lack of commitment, or discomfort with physical closeness owing to distress of the partner or a sense of vulnerability. Some couples experience sexual difficulties because of differences in feelings regarding how close one partner would like to be to the other. One partner may want to be very close, whereas the other desires more distance (70). Couples may be sexually incompatible, with one partner making sexual demands the other is unable or unwilling to accommodate. Couples may have difficulty with the timing or the way they initiate sexual activity, or they may have incompatible or very different levels of sexual desire (71). Spouse abuse, financial problems, concerns about children, and marital power and control issues can significantly affect the way a couple functions sexually. It is difficult for anyone to feel sexual if they feel unloved or are depressed, overwhelmed with career and household responsibilities, unhappy about their relationship, or afraid of or angry with their partner.

Treatment of patients with HSDD may require both individual therapy and relationship counseling. Insight-oriented psychotherapy may allow the patient to identify the negative feelings that inhibit her erotic impulses and to gain insight into the underlying causes of her low sexual desire (60). Individual “homework” assignments include identifying erotic feelings, body awareness exercises, reading about human sexuality and sexual techniques, and fantasy training (72). In addition, the couple may benefit from learning how to perform structured sexual exercises known as sensate focus exercises (73). These behavior-modification exercises are designed to reduce sexual anxiety and to provide the couple with a nonthreatening, nonintrusive, and reassuring environment in which they can address performance anxiety, sexual communication issues, and lack of sexual experience and knowledge.

Meeting with a couple for a few sessions to assess their sexual knowledge, attitudes, and practices is often beneficial. Many of the sexual problems couples experience are due to a lack of sexual knowledge or experience deficit, sexual misconceptions, or the inability of the couple to communicate about what they would like to give and to receive in the sexual part of their relationship. Brief counseling and education by the obstetrician-gynecologist regarding the sexual response cycle and encouragement to communicate openly and honestly are often all that is needed to help couples achieve a fulfilling sexual relationship.

Arousal phase disorders, in which women experience sexual desire and orgasm but lack vaginal lubrication and other signs of sexual stimulation, are relatively rare.## Arousal phase disorders

Arousal phase disorders, in which women experience sexual desire and orgasm but lack vaginal lubrication and other signs of sexual stimulation, are relatively rare.
Lack of lubrication may lead to dyspareunia and eventually may impair a woman’s subjective sense of arousal and pleasure. These women may benefit from the use of intravaginal lubricants, estrogen replacement therapy, or both.

Orgasmic Dysfunction

Orgasmic dysfunction in women is characterized by persistent or recurrent delay in or absence of orgasm following a normal sexual excitement phase, resulting in distress or interpersonal difficulty. Orgasmic dysfunction is more prevalent in younger and less sexually experienced women. Primary (lifelong) anorgasmia is found in about 5% to 10% of women (68) and is more common than secondary (acquired) anorgasmia. Some women develop secondary anorgasmia owing to relationship problems, depression, substance abuse, prescription medication (e.g., fluoxetine, SSRIs), chronic medical illness (e.g., diabetes), estrogen deficiency, and other factors (e.g., medical conditions associated with masturbation). These women may be distressed because they are not orgasmic during intercourse, do not have multiple orgasms or an orgasm with every sexual encounter, or do not have an orgasm at the same time as their partner. Surveys of female sexual behavior demonstrate, however, that most couples do not experience orgasm simultaneously and that many women are more likely to be orgasmic during foreplay, when they receive more direct and intense clitoral stimulation, than during intercourse (69).

The most common psychological cause of anorgasmia is obsessive self-observation and monitoring during the arousal phase, often accompanied by anxiety and distracting, negative, and self-defeating thoughts (74,75). A woman with orgasmic dysfunction may be so busy monitoring her own and her partner's response and so concerned about “failing” that she is unable to relax, and unable to alter her natural reflex not to take over and trigger an orgasm (69,76). Masters and Johnson call this form of performance anxiety “spectatoring” (73). Inhibited orgasm may be related to a history of sexual abuse, negative feelings toward sexuality, relationship problems, an inattentive partner, ineffective sexual communication, low self-esteem, poor body image, or fear of losing control (75).

Numerous programs have been proposed for the treatment of orgasmic dysfunction (75). Approaches include evaluation and treatment of medical and psychiatric disorders (including substance abuse), sex education, communication and sexual skills training, marital therapy, group therapy, erotic fantasy, and counseling to reduce sexual anxiety and performance anxiety.

The most effective treatment for primary anorgasmia is employing a program of directed masturbation accompanied by erotic fantasy. Success rates of 80% to 90% have been reported using this technique (76). Several excellent self-help books are available to help women learn how to become orgasmic through masturbation (66,77). These self-help books instruct women how to increase their self-awareness by exploring their genital area in a nondemanding way. Once a woman has identified the most sensitive and pleasurable parts of her body, she can manually stimulate her clitoris and other erogenous areas while incorporating erotic fantasy until she reaches orgasm. A vibrator may be useful if the patient is unable to have an orgasm without one. Once the patient has experienced orgasm through masturbation, she may want to teach the technique to her partner, showing him how and where she likes to be touched during lovemaking. Manual stimulation of the clitoris by the woman or her partner while having intercourse (the bridge technique) may help women become orgasmic during intercourse.

Sexual Pain Disorder

Vaginismus

Vaginismus is the recurrent or persistent involuntary contraction of the perineal muscles surrounding the outer third of the vagina when vaginal penetration with a penis, finger, tampon, or speculum is attempted (69). Vaginismus is an involuntary reflex precipitated by real or imagined attempts at vaginal penetration. It can be global, in which the woman is unable to place anything inside her vagina, or situational, in which she is able to use a tampon and can tolerate a pelvic examination but cannot have intercourse. Many women with vaginismus have normal sexual desire, experience vaginal lubrication, and are orgasmic but are unable to have intercourse. Vaginismus can be primary, in which the woman has never been able to have intercourse, or secondary, which is often due to acquired dyspareunia. Some couples may cope with this difficulty for years before they seek help. They usually seek treatment because they desire children or decide they would like to consummate their relationship. Vaginismus is relatively rare, affecting about 1% of women (69).

Vaginismus can be a conditioned response to an unpleasant experience such as past sexual trauma or abuse, a painful first pelvic examination, or a painful first attempt at intercourse. It may occur secondary to religious orthodoxy, negative sexual upbringing, or sexual orientation concerns (78,79). Many women with vaginismus have an extreme fear of penetration and misconceptions about their anatomy and about the size of their vagina. They may believe that their vagina is too small to accommodate a tampon or penis and that great physical harm will result from placing anything inside the vagina.

Although medical conditions are rarely the cause of vaginismus, conditions such as endometriosis, chronic pelvic inflammatory disease, partially imperforate hymen, and vaginal stenosis must be ruled out by a careful pelvic examination. The pelvic examination, which should be performed, if possible, in the presence of the woman’s partner, allows the physician to help educate the couple about normal female anatomy and may help dispel misconceptions about the size of the introitus and vagina. Providing the patient with a mirror to observe the examination is helpful. Because the etiology of vaginismus is usually psychophysiological, patients with this condition should not have surgery to “enlarge” their introitus unless they have a partially imperforate hymen or other valid indication for surgery.

Treatment of vaginismus is directed toward extinguishing the conditioned involuntary vaginal spasm. This can be accomplished by the following:

1. Help the woman become more familiar with her anatomy and more comfortable with her sexuality.
2. Teach her techniques to help her relax when she anticipates vaginal penetration.
3. Instruct her in the use of Kegel exercises in order to gain control over the muscles surrounding her introitus.
4. Instruct her how to use graduated rubber dilators (fingers can also be used as dilators).

The protocol for use of the dilators is explained to the patient while she is in the office, but the actual placement of the dilators is done by the patient when she is at home. It is important for the patient to maintain total control over the use the dilators and to use them in an environment that is comfortable and safe. The dilators should be covered with a warm, water-soluble lubricant. She should initially try to place the dilators (or her finger) in her vagina when she is alone and relaxed. If she is unable to relax enough to place to the smallest dilator in her vagina, she may be able to reduce her anxiety by learning relaxation or self-hypnosis techniques. Medications, such as propanolol or alprazolam, may also help reduce anxiety. Once the patient has been able to place the smallest dilator in her vagina, she can progressively insert the larger dilators, practicing Kegel exercises while the dilators are in place. When she is comfortable inserting the larger dilators, she can teach her partner how to place the dilators in her vagina while she maintains control over how quickly and deeply the dilators are placed. She may then be ready to proceed to intercourse. Again, this must be under her control, with her sitting or kneeling over her partner and inserting his penis herself. Most couples (90%) who follow this protocol are successful and able to have intercourse.

Dyspareunia

Dyspareunia (“difficult mating”) is genital pain that occurs before, during, or after intercourse in the absence of vaginismus.

Dyspareunia is one of the most common sexual dysfunctions seen by gynecologists and is estimated to affect about two thirds of women during their lifetime (80,81). Women with dyspareunia usually discuss the pain with their sexual partner, but fewer than half of these women consult a physician. Because dyspareunia is a psychophysiological condition, both psychological and physical factors must be considered in patient assessment. Many women with dyspareunia report more physical symptoms, psychological distress, and relationship issues than women who do not have pain during intercourse (82).

A careful history should be directed to a complete chronological of the discomfort, an assessment of the impact of the dyspareunia on the patient and her partner, and any prior attempts to treat the condition (78,79 and 80). The patient should be asked about the specific location of the pain, when in the course of lovemaking the pain occurs, how long the pain lasts, the nature and quality of the pain, what factors relieve or aggravate the discomfort, and the severity of the pain. It is useful to ask the patient her theory about how the pain began and to assess her expectations and goals for treatment. Patients should be carefully asked about a history of childhood sexual or physical abuse or adult sexual assault because these situations may be associated with dyspareunia. Patients who are anxious about sexuality because of sexual misconceptions, guilt, fear of pregnancy or STIs, or prior unpleasant sexual experiences may be unable to relax during lovemaking, leading to
impaired arousal and lubrication.

During the physical examination, attempts should be made to identify any organic factors contributing to the discomfort. Physiologic changes that take place during sexual arousal may account for pain that is present during intercourse but absent at other times, such as during a routine pelvic examination. Examples are Bartholin gland cysts, which swell during intercourse, and adhesive bands that form between portions of the hymenal ring only during arousal (78).

Causes of pain on stimulation of the external genitalia include chronic vulvitis and clitoral irritation and hypersensitivity. Pain at the introitus caused by penile entry can be caused by a rigid hymenal ring; scar tissue in an episiotomy repair; a müllerian abnormality; and vaginitis caused by one of the many common vaginal pathogens, such as Candida, Trichomonas, or Gardnerella species, or by irritation from over-the-counter vaginal sprays, douches, or contraceptive devices. Other causes include Bartholin gland inflammation, radiation vaginitis, infection with human papillomavirus, urethral syndrome, cystitis, vaginal trauma, chronic constipation, or proctitis. Vaginal infection is the most common cause of successfully treated dyspareunia (81). Another common cause of dyspareunia is friction due to inadequate sexual arousal. This situation can be resolved by counseling the couple to spend more time with foreplay, ensuring that the woman has adequate lubrication before intercourse. Use of a water-soluble lubricant (e.g., Astroglide) is also helpful. Vaginal atrophy resulting from hypoestrogenic states (menopause and lactation) can be treated with systemic or vaginal estrogen replacement.

Vulvar vestibulitis syndrome is a constellation of symptoms consisting of severe pain or burning on touching the vestibule and attempting vaginal entry (83). Women with vulvar vestibulitis report difficulty with sexual arousal, decreased lubrication, dyspareunia, and negative emotions during sexual encounters (84,85). On examination, diffuse or focal vulvar erythema is noted around the orifices of Bartholin, Skene, periurethral, or vestibular glands. This syndrome may be caused by an infection (subclinical human papillomavirus, bacterial vaginosis, or chronic candidiasis), irritants (soaps, detergents, douches, vaginal sprays), or altered vaginal pH secondary to a decrease in lactobacilli. Vulvar vestibulitis may be secondary to treatment of human papillomavirus with podophyllin, trichloroacetic acid, or laser.

The treatment of vulvar vestibulitis syndrome is empirical because the cause is unknown (83). A comprehensive multimodality approach may be necessary, as outlined in Chapter 14. Associated infections should be treated, vulvovaginal irritants should be eliminated, and surgery (vestibulectomy with vaginal advancement) should be reserved for patients with severe dyspareunia who have not responded to conservative management (83).

Causes of midvaginal pain include a congenitally shortened vagina, interstitial cystitis, and urethritis. Pain with orgasm may be associated with uterine contractions. Dyspareunia with deep vaginal penetration can be associated with inadequate vaginal lengthening and lubrication secondary to inadequate sexual arousal, chronic pelvic inflammatory disease, endometriosis, a fixed retroverted uterus, a pelvic mass, an enlarged uterus as a result of myomas or adenomyosis, inflammatory bowel disease, irritable bowel syndrome, or pelvic relaxation (90).

Psychological factors contributing to dyspareunia include:

1. Developmental factors (e.g., an upbringing that invested sex with guilt and shame)
2. Traumatic factors (e.g., childhood sexual abuse or other sexual assault)
3. Relationship factors (e.g., anger or resentment toward a sexual partner)

Lazarus uses the mnemonic BASIC ID to describe his multimodal approach to the assessment of dyspareunia (84). This approach addresses the issues noted in Table 11.4.

Sexual Assault

Sexual assault of children and adult women has reached epidemic proportions in the United States and is the fastest growing, most frequently committed, and most underreported crime (68,67 and 83). Sexual assault is a crime of violence and aggression, not passion, and encompasses a continuum of sexual activity that ranges from sexual coercion to contact abuse (unwanted kissing, touching, or fondling) to forcible rape. In a survey of female family practice patients, 47% reported some type of contact sexual victimization during their lifetime. Twenty-five percent reported attempted rape, and 13% had been forcibly raped, many as children (78,89). Among battered women, about 35% experience marital rape as an element of their repetitive abuse. Spousal rape is infrequently reported because of fear of retribution and economic dependency (90). The terms sexual abuse survivor and assault survivor are preferable to victim.

Childhood Sexual Abuse

Childhood sexual abuse has a profound and potentially lifelong effect on the survivor. Although most cases of childhood sexual abuse are not reported by the survivor or her family, it is estimated that as many as one third of adult women were sexually abused as children. Childhood sexual abuse is often accompanied by another type of household dysfunction, such as physical abuse, violence against other family members, or substance abuse by parental figures (89). Younger children are more often exposed to genital fondling or noncontact abuse (exhibitionism, forced observation of masturbation, or posing in child pornography), and children older than 10 years of age are more likely to be forced to have intercourse or oral sex (91). As children age, they are more likely to experience sexual abuse outside the home and more likely to be victimized by strangers. As adolescents, women survivors of childhood sexual abuse are at risk for early unplanned pregnancy, STIs, prostitution, antisocial behavior, running away from home, lying, stealing, eating disorders, and multiple somatic symptoms. These women are more likely to engage in health risk behaviors such as smoking, substance abuse, and early sexual activity with multiple partners (92). They may be less likely to use contraception. Survivors often avoid pelvic examinations and are less likely to have Papanicolau (Pap) tests because of the association between vaginal examinations and pain. They often receive inadequate prenatal care and are more likely than women who have not been abused to experience suicidal ideation and depression and to deliver smaller and less mature babies (88).

Obstetrician-gynecologists can assist their sexual assault patients by validating their feelings and concerns and giving them control over their examination. It is important to ask the patient for permission to perform the examination, give her the opportunity to have an advocate in the room with her, and let her know that she has the right to stop the examination at any time (88).

Survivors may be unable to trust or establish rapport with adults. Some women blame themselves for the abuse and come to believe that they are not entitled to assistance from others. Thus, they risk continuing to enter abusive relationships. Women survivors of childhood sexual abuse often develop feelings of powerlessness and helplessness and may become chronically depressed. There is a high incidence of self-destructive behavior, including suicide and deliberate self-harm, such as cutting or burning themselves (88,65,14). The most extreme mental health symptoms in assault survivors are associated with the onset of abuse at an early age, frequent abuse over a long period, use of force, or abuse by a parent. Survivors are also at a long term risk for being victimized again later in life (93). Fifty percent of women who report being abused as children are abused again as adults. Women who are sexually abused as children carry the effects of abuse into adulthood. As adults, they have the same level of physical symptoms and psychological distress as women who do not report childhood sexual abuse but are currently experiencing sexual
Women who have been sexually abused as children or sexually assaulted as adults often experience sexual dysfunction and difficulty with intimate relationships and parenting (97). Chronic sexual concerns may include fear of intimate relationships, lack of sexual enjoyment, difficulty with desire and arousal, and anorgasmia. Compared with women who have not been sexually assaulted, they are more likely to experience depression, suicide attempts, chronic anxiety, anger, substance abuse problems, dissociative personality disorder, borderline personality disorder, fatigue, low self-esteem, feelings of guilt and self-blame, and sleep disturbance (96,98,99). They often experience social isolation, phobias, feelings of vulnerability, fear, humiliation, grief, and loss of control (8,100). Survivors of sexual assault represent a disproportionate number of patients with chronic headaches and chronic pelvic pain (they have a lower pain threshold) and are more likely to have somatic symptoms that do not respond to routine medical treatment (99,101). Women with common gynecologic symptoms, such as dysmenorrhea, menorrhagia, and sexual dysfunction, are much more likely to have a history of sexual assault (102). If they have been forced to perform oral sex, they may have a dental phobia and avoid preventive dental care.

Survivors may develop posttraumatic stress disorder (PTSD), defined as development of characteristic symptoms following a psychologically traumatic event outside of normal human experience. Symptoms of PTSD include blunting of affect, denial of symptoms, intrusive reexperiencing of the incident, avoidance of stimuli associated with the assault, and intense psychological distress and agitation in response to reminders of the event (96,93). Women affected by PTSD are more likely to commit suicide. The cognitive sequelae include flashbacks, nightmares, disturbances in perception, memory loss, and dissociative experiences (103). These women may not be able to tolerate pelvic examinations and may avoid seeking routine gynecologic care because these examinations may remind them of the sexual abuse they experienced as children. However, they are more likely to use the medical care system for nongynecologic concerns (104). Women with PTSD are at greater risk for being overweight and having gastrointestinal disturbances (52).

Rape

Although the legal definition of sexual assault may vary from state to state, most definitions of rape include:

1. The use of physical force, deception, intimidation, or the threat of bodily harm
2. Lack of consent or inability to give consent because the survivor is very young or very old, impaired by alcohol or drug use, unconsciousness, or mentally or physically impaired
3. Oral, vaginal, or rectal penetration with a penis, finger, or object

The National Women's Study provides the best statistics available about the incidence of forcible rape in the United States (8). This study revealed that 13%, or one of eight adult women, are survivors of at least one completed rape during their lifetime. Of the women they surveyed, 0.7% had been raped during the past year, equating to an estimated 683,000 adult women who were raped during a 12-month period. Of the women surveyed, 39% were raped more than once. Most disturbing, however, is the finding that most rapes occurred during childhood and adolescence: 29% of all forcible rapes occurred when the survivor was younger than 11 years of age, and 32% occurred between the ages of 11 and 17 years. Indeed, “rape in America is a tragedy of youth” (6). Twenty-two percent of rapes occurred between the ages of 18 and 24 years, 7% between the ages of 25 and 29 years, and only 6% occurred when the survivor was older than 30 years of age.

There are many myths about rape. Perhaps the most common is that women are raped by strangers. In fact, only about 20% to 25% of women are raped by someone they do not know. Most women are raped by a relative or acquaintance (9% by husbands or ex-husbands, 11% by fathers or stepfathers, 10% by boyfriends or ex-boyfriends, 16% by other relatives, and 29% by other nonrelatives) (9). Although acquaintance rape may seem to be less traumatic than stranger rape, survivors of acquaintance rape often take longer to recover. Another common misconception about rape is that most survivors sustain serious physical injury. Seventy percent of rape survivors report no physical injury, and only 4% sustain serious injury. Serious injury is rare, although almost half of the rape survivors report being fearful of serious injury or death during the assault (6). The most common injuries from a sexual assault are vaginal lacerations resulting in bleeding and pain. Infrapenileal extension of a vaginal laceration or damage to the anal mucosa is rare (105). Common nongenital injuries in survivors include cuts, bruises, scratches, broken bones and teeth, and knife or gunshot wounds (106). About 0.1% of sexual assaults result in death. Common causes of death during a sexual assault include mechanical asphyxiation, trauma, lacerations, drowning, and gunshot wounds (105).

There are at least four types of rapists (107):

1. Opportunistic rapists (30%) exhibit no anger toward the women they assault and usually use little or no force. These rapes are impulsive and may occur in the context of an existing relationship (“date” or acquaintance rape). The highest incidence of acquaintance rape is among women in the twelfth grade of high school and in the first year of college (108). Up to half of college women report date rape. Many of these women may have been unable to give consent because of impairment by alcohol or rohypnol, the “date rape drug.” Date rape may have even greater psychological consequences than rape by a stranger because it involves a violation of trust (105).
2. Anonymous rapists (40-44%) usually batter the survivor and use more physical force than is necessary to overpower her. This type of sexual assault is episodic, impulsive, and spontaneous. An anger rapist often physically assaults his victim, sexually assaults her, and forces her to perform degrading acts. The rapist is angry or depressed and is often seeking retribution—for perceived wrongs or injustices he imagines have been done to him by others, especially women. He may rape the very young or the very old.
3. Power rapists (25%) do not intend to physically harm their victim but rather to possess or control her in order to gain sexual gratification. However, a power rapist may use force or the threat of force to overcome his victim. These assaults are premeditated and repetitive, and they may increase in aggression over time. The rapist is usually anxious and may order him to her victim, ask her personal questions, or inquire about her response during the assault. This assault may occur over an extended period of time while the victim is held captive. These rapists are insecure about their virility and are trying to compensate for their feelings of inadequacy and low self-esteem.
4. Sadistic rapists (5%) become sexually excited by inflicting pain on their victim. These rapists may have a thought disorder and often exhibit other forms of psychopathology. This type of assault is calculated and planned. The victim is often a stranger. The rapist may involve bondage, torture, or bizarre acts and may occur over an extended period of time. The survivor often suffers both genital and nongenital injuries and may be murdered or mutilated. Other rapists may act out of impulse, as when they encounter a victim during the course of another crime such as burglary. Some rapists believe they are entitled to their victim, as in acquaintance rape or father–daughter incest (8). A consistent finding among all types of rapists is a lack of empathy for the survivor.

Even when sexual assaults are reported (only 16% of rapes are ever reported to the police), few rapists are arrested, and even fewer are brought to trial and convicted. Fewer than 1% of rapists ever serve a prison term (107). Many women do not report the assault to the police because they are concerned about their name being disclosed by the news media, fear retaliation from the perpetrator, are afraid they will not be believed, or do not trust the judicial process. Only 17% of rape survivors seek medical attention after an assault. Many rape survivors do not inform their physicians about the assault and may never volunteer information about the assault unless they are directly asked. Therefore, when obtaining a medical history, physicians should routinely ask, “Has anyone ever forced you to have sexual relations when you did not want to?”

Effects of Rape

Following sexual assault, women have many concerns, including pregnancy, STIs (including human immunodeficiency virus [HIV] infection), being blamed for the assault, having their name made public, and having their family and friends find out about the assault. The initial reactions to sexual assault may be shock, numbness, withdrawal, and possibly denial. It is difficult to predict how any assaulted individual will react. Despite their recent trauma, women presenting for medical care may appear calm and detached.

The rape trauma syndrome is a constellation of physical and psychological symptoms, including fear, helplessness, disbelief, shock, guilt, humiliation, embarrassment, anger, and self-blame. The acute, or disorganization, phase of the syndrome lasts from days to weeks. Survivors may experience intrusive memories of the assault, blunting of affect, and hypersensitivity to environmental stimuli. They are anxious, do not feel safe, have difficulty sleeping and eating, and experience nightmares and a variety of somatic symptoms (88,108,110). They may fear that their assailant will want to reapply to retaliate or rape them again.

In the weeks to months following the sexual assault, survivors often return to normal activities and routines. They may appear to have dealt successfully with the assault, but they may be repressing strong feelings of anger, fear, guilt, and embarrassment. In the months following the assault, survivors begin the process of integration and resolution. During this phase, they begin to accept the assault as part of their life experience, and somatic and emotional symptoms may decrease
progressively in severity. However, the sequelae of rape are often persistent and long-lasting (93). Over the long-term, survivors may have difficulty with work and with family relationships. Disruption of existing relationships is not uncommon. Nearly half of the survivors lose their jobs or are forced to quit in the year following the rape, and half change their place of residency (100).

**Examination and Treatment**

The responsibilities of physicians providing immediate treatment for sexual assault survivors are listed in Table 11.5. Because of the legal ramifications, consent must be obtained from the patient before obtaining the history, performing the physical examination, and collecting evidence. Documentation of the handling of specimens is especially important, and the "chain of evidence" for collected material must be carefully maintained. Everyone who handles the evidence must sign for it and hand it directly to the next person in the chain. The patient should be interviewed in a quiet and supportive environment by an examiner who is objective and nonjudgmental. Support personnel and patient advocates, such as family, friends, or, if available, a counselor from a rape crisis service, should be encouraged to accompany the patient. It is important not to leave the survivor alone and to give her as much control as possible over the examination. In order to provide useful forensic information, the examination should be performed as soon as possible after the incident occurred.

Table 11.5. Physician Responsibilities in Treating Sexual Assault Survivors

| 1. A general medical history and a gynecologic history, including last menstrual period, prior pregnancies, past gynecologic infections, tetanus status, history of liver disease, thrombosis or hypertension (possible contraindications to pregnancy prophylaxis with estrogens), contraceptive use, prior sexual assault, and last voluntary intercourse before the assault. |
| 2. It is important to ascertain whether the survivor bathed, doused, used a tampon, urinated, defecated, brushed her teeth, or changed her clothes after the assault. |
| 3. A detailed description of the sexual assault should be obtained, including the date and time of the assault, number of assailants, use of weapons, threats, and restraints, and any physical injuries that may have occurred. |
| 4. A detailed description of the type of sexual contact must be obtained, including whether vaginal, oral, or anal contact or penetration occurred, whether the assailant used a condom, and whether there were other possible sites of ejaculation, such as the hands, clothes, or hair of the survivor. |
| 5. The emotional state of the survivor should be observed and recorded. |

The survivor should undress while standing on clean examination table paper in order to catch any hair or fibers falling from her clothing. All of her clothing should be placed in individually labeled paper bags, sealed, and given to the proper authorities. Wet or damp clothing should be air dried before packaging. During the physical examination, the degree of injury to the survivor should be assessed, and any injuries should be documented for use as evidence. The nature, size, and location of all injuries should be carefully documented, using photographs or drawings if possible. Nongenital injuries occur in 20% to 50% of all rapes (111). The most common injuries are bruises and abrasions of the head, neck, and arms (98) and genital injuries accompanied by bleeding and pain. The most common genital findings are erythema and small tears of the vulva, perineum, and introitus. There may be bleeding, mucosal tears, erythema, or a hematoma noted around the rectum if penetration has occurred. Identification of small lacerations of the genitalia or rectum may be aided by colposcopy or by staining with toluidine blue (112). Bite marks are not uncommon and frequently are found on the breasts or genitalia. Foreign bodies may be found in the vagina, rectum, or urethra. If oral penetration has taken place, injuries of the mouth and pharynx may occur (113).

Evidence must be properly collected for legal purposes as follows:

1. Examination of the patient with a Wood light may help identify semen, which will fluoresce blue-green to orange. Areas of fluorescence should be swabbed with 86% fingernail scrapings from the survivor should be collected and evaluated for evidence of the assailant's blood, hair, or skin. This evidence may also be used for DNA fingerprinting.  
  2. A Pap test may also be useful to document the presence of sperm.  
  3. A sample of the vaginal secretions should be obtained for examination for motile sperm, semen, or pathogens. Motile sperm in the vagina indicate ejaculation within 6 hours. Nonmotile sperm can be found in the cervical mucus for as long as 1 week. If ejaculation has occurred in the mouth, seminal fluid will be rapidly destroyed by salivary enzymes (109).  
  4. Vaginal secretions should also be collected for test for the presence of seminal contents, including acid phosphatase, p30 protein (specific to the prostate), seminal vesicle–specific antigen, and ABO antigens, and for DNA fingerprinting (89).  
  5. The survivor's pubic hair should be combed over a sheet of paper in an attempt to obtain pubic hair from the assailant.  
  6. Fingernail scrapings from the survivor should be collected and evaluated for evidence of the assailant's blood, hair, or skin. This evidence may also be used for DNA fingerprinting.  
  7. Saliva should be collected from the survivor to document whether she is a secretor of major blood group antigens (80% of the population are secretors). If the patient is not a secretor and blood group antigens are found in vaginal washings, the antigens are probably from the semen of the assailant (88). Laboratory tests that should be performed on all sexual assault survivors are listed in Table 11.6.

| 1. A sample of saliva should be obtained before obtaining the history.  
  2. Saliva should be collected from the survivor to document whether she is a secretor of major blood group antigens (80% of the population are secretors).  
  3. A Pap test may also be useful to document the presence of sperm.  
  4. A sample of the vaginal secretions should be obtained for examination for motile sperm, semen, or pathogens. Motile sperm in the vagina indicate ejaculation within 6 hours. Nonmotile sperm can be found in the cervical mucus for as long as 1 week.  
  5. Vaginal secretions should also be collected for test for the presence of seminal contents, including acid phosphatase, p30 protein (specific to the prostate), seminal vesicle–specific antigen, and ABO antigens, and for DNA fingerprinting.  
  6. The survivor's pubic hair should be combed over a sheet of paper in an attempt to obtain pubic hair from the assailant.  
  7. Fingernail scrapings from the survivor should be collected and evaluated for evidence of the assailant's blood, hair, or skin. This evidence may also be used for DNA fingerprinting.  
  8. Saliva should be collected from the survivor to document whether she is a secretor of major blood group antigens (80% of the population are secretors).  
  9. A Pap test may also be useful to document the presence of sperm.  
  10. A sample of the vaginal secretions should be obtained for examination for motile sperm, semen, or pathogens. Motile sperm in the vagina indicate ejaculation within 6 hours. Nonmotile sperm can be found in the cervical mucus for as long as 1 week.  
  11. Vaginal secretions should also be collected for test for the presence of seminal contents, including acid phosphatase, p30 protein (specific to the prostate), seminal vesicle–specific antigen, and ABO antigens, and for DNA fingerprinting.  
  12. The survivor's pubic hair should be combed over a sheet of paper in an attempt to obtain pubic hair from the assailant.  
  13. Fingernail scrapings from the survivor should be collected and evaluated for evidence of the assailant's blood, hair, or skin. This evidence may also be used for DNA fingerprinting.  
  14. Saliva should be collected from the survivor to document whether she is a secretor of major blood group antigens (80% of the population are secretors). |

Table 11.6. Laboratory Studies in the Evaluation of Sexually Assaulted Adults

Treatment of sexual assault survivors should be directed to prevention of possible pregnancy and provision of prophylactic treatment for STIs. About 5% of fertile rape survivors will become pregnant as a result of the rape (114). Options include (a) awaiting the next expected menses; (b) repeating the serum pregnancy test in 1 to 2 weeks; and (c) using emergency (postcoital) contraception. If the patient desires emergency contraception, a preexisting pregnancy can usually be ruled
out by performing a sensitive human chorionic gonadotropin assay. Pregnancy prophylaxis can be provided by several different regimens (115) (see also Chapter 10):

1. Immediate administration of two tablets of a combination oral contraceptive (each containing 50 μg of ethinyl estradiol and 0.5 mg norgestrel, i.e., Ovral birth control pills) followed by two more tablets 12 hours later

2. Four tablets of a combination birth control pill containing 35 μg of ethinyl estradiol and a progestinere followed by four more tablets 12 hours later

3. Administration of one tablet containing 0.75 mg of levonorgestrel followed by a second tablet 12 hours later (Plan B)

4. Placement of a copper-containing intrauterine device

5. Mifepristone as a single 600-mg dose

These regimens are highly effective if administered within 72 hours after the sexual assault. Some investigators believe that emergency contraception can be effective up to 5 days after unprotected intercourse (88). However, the sooner the medications are taken, the more effective they are. Some patients experience nausea and vomiting when given postcoital contraception; these symptoms can be controlled with an antiemetic agent such as promethazine (12.5 mg every 4 to 6 mins). Emergency contraception has a small failure rate and potential teratogenicity, which should be discussed with the patient (116). Most women who take emergency contraception experience their next menstrual period within 3 days of the expected date.

The risk for acquiring an STI from a rape is difficult to assess because the prevalence of preexisting STIs is high (43%) in rape survivors (117, 119). However, it is estimated that the risk for acquiring STIs from a sexual assault is as follows: gonorrhea, 6% to 12%; trichomonas, 12%; chlamydia, 2% to 12%; syphilis, 5%.

1. Because it is difficult to differentiate between a preexisting STI and a newly contracted STI attributable to a sexual assault, prophylaxis for STIs should be offered to all survivors. This is especially important because most sexual assault patients do not return for follow-up appointments (110). STI prophylaxis should cover infections with Neisseria gonorrhoeae, Chlamydia trachomatis, trichomonas, and incubating syphilis. Current recommendations include (118, 119):
   a. Ceftriaxone, 250 mg intramuscularly (if the patient is allergic to cephalosporins, spectinomycin, 2 g intramuscularly, or ciprofloxacin, 500 mg orally, may be used), PLUS:
      b. A single dose of 2 g of metronidazole orally, PLUS:
      c. A single dose of 1 g of azithromycin orally or doxycycline orally twice a day for 7 days (if the patient is pregnant at the time of the assault, erythromycin may be substituted for doxycycline).

2. Hepatitis B should be offered to all the sexual assault survivor has experienced vaginal, oral, or anal penetration. Hepatitis B is 20 times more infectious than HIV during intercourse (88). Vaccination is recommended at the time of the initial evaluation. Subsequent doses are provided 1 month and 6 months after the first dose is administered. It is not necessary to treat the patient with hepatitis B immune globulin (HBIG) (119).

3. If a patient reports a recent intrauterine procedure, it should also be prophylactically treated if indicated.

4. If prophylactic treatment for gonorrhea, chlamydia, and trichomoniasis is not given, the patient should return for repeat testing in 2 weeks. If the initial test results were negative, repeat serologic tests for syphilis, hepatitis B, and HIV should be performed at 6, 12, and 24 weeks after the assault.

5. HIV conversion through sexual assault, although reported, is low and similar to conversion from occupational exposure (<0.1%). The probability of transmission depends on the type of assault, presence of trauma, site of ejaculation, HIV viral load in the ejaculate, and the presence of a concomitant STI in the patient (111). At present, no recommendations can be made regarding the use of antiretroviral prophylaxis for HIV in sexual assault survivors. Factors to consider when discussing HIV prophylaxis with patients include the likelihood of exposure to the virus, the risks and benefits of treatment, the interval between the sexual assault and therapy, and the patient's desire to be treated. Prophylactic therapy is known to be effective and that they will be carefully monitored if they initiate treatment with antiretroviral medication.

6. Ongoing supportive counseling for the patient should be arranged, and the patient should be referred to a sexual assault center or a therapist who specializes in the treatment of sexual assault survivors.

References

Psychiatric problems are a central or complicating factor in most outpatient visits (1,2). Psychiatric diagnoses are extremely common and account for considerable morbidity and mortality in the general population (3). Despite this, however, psychiatric disorders are often undiagnosed or misdiagnosed in the medical setting (4,5,6 and 7). Clinical depression affects up to one-fourth of women during their lives (8,9 and 10), but an estimated 80% of the cases are neither diagnosed nor treated (11). More than one-half of the patients who commit suicide have seen a nonpsychiatric physician during the previous 3 months (12).

Many gynecologists feel uncomfortable diagnosing and treating psychiatric illnesses for a variety of reasons. The practice of gynecology has many demands, and the care of these patients requires a commitment. Patients with psychological problems can evoke negative reactions in physicians (Table 12.1). In the past, gynecologists have found it difficult to use psychiatric diagnostic systems that were based on theories of unconscious motivation and conflict. New systems for the diagnosis of psychiatric disorders are reliable and valid and can be systematically applied, and treatments are specific and effective (8). By incorporating these management strategies into practice, gynecologists can play a major role in improving the health and well-being of their patients.

Table 12.1. Practitioners’ Negative Reactions Toward Patients with Psychiatric Problems

Psychiatric Assessment
In the past, psychiatric diagnosis was based partially on hypotheses about a patient's unconscious psychological conflicts (13). Current psychiatric diagnosis, as codified in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM IV), produced and published by the American Psychiatric Association, is based on empirical, valid, and reliable evidence (8). Use of the DSM IV yields reliability comparable to that of diagnostic systems in other areas of medicine. DSM IV diagnoses are also strongly correlated with response to treatment. The criteria in DSM IV are the basis for the diagnostic entities described in this chapter. A new edition, DSM IV TR, differs only in the text explaining some of the diagnoses, and not in the diagnostic criteria themselves (9). DSM IV PC is a special edition designed for the primary care provider. This volume is organized by initial signs and symptoms rather than psychiatric categories and uses algorithms and decision trees to facilitate the diagnostic process. Accurate diagnosis is absolutely critical to successful management, whether provided by the gynecologist or through referral to a mental health expert.

Approach to the Patient

Although diagnostic criteria list signs and symptoms, the interaction with a patient should not be reduced to a series of rapid-fire questions and answers. A wealth of valuable information can be obtained from the patient's spontaneous description of her concerns and from her responses to the physician's open-ended questions. A patient who is encouraged to speak for several minutes before being asked to respond to specific questions will reveal information that is useful, even vital, to her care: a thought disorder, a predominant mood, abnormally high anxiety, a personality style or disorder, and attitudes towards her diagnosis and treatment. Such information may emerge only much later, or not at all, in a question-and-answer format (15,15). It is critical that the gynecologist neither jumps to diagnostic conclusions nor proceeds directly to therapeutic interventions. One study revealed that many primary care physicians, feeling that they had too little time or training to assess psychological symptoms, tended to minimize verbal interactions with patients and to rely on the prescription of psychotropic medications (14). It is not necessary, however, for the physician and the other patients awaiting care to be held hostage by the overly talkative patient. The clinician can tell the patient with multiple, detailed complaints how much time is available for the current appointment, invite her to focus on her most pressing problem, and offer a future appointment to continue the account.

Psychiatric Referral

Many gynecologists consider referral to a mental health professional, particularly a psychiatrist, to be a delicate matter. The first question is when to refer. Most mild psychiatric disorders are treated by nonpsychiatric physicians (17). Many antidepressants and anxiolytics are prescribed by nonpsychiatric physicians. At the same time, however, most cases of psychiatric disorder are overlooked, misdiagnosed, or mistreated in primary care practice. The following factors determine the decision to refer:

- The nature and severity of the patient's disorder
- The expertise of the gynecologist
- The time available in the gynecologic practice
- The patient's preference
- The gynecologist's degree of comfort with the patient and the disorder
- The availability of mental health professionals.

Patients who are suicidal, homicidal, or acutely psychotic should be seen by a psychiatrist. Patients should also be referred for evaluation when the psychiatric diagnosis is not clear and when they fail to respond to initial treatment. For many patients, the gynecologist can resume the responsibility for ongoing care after an initial or periodic assessment by a psychiatrist.

How to Refer?

Some clinicians fear that patients will be insulted, alienated, or alarmed by a psychiatric referral. Techniques that decrease the discomfort of the gynecologist and patient and increase the likelihood of a successful referral are discussed below (19). The referral should be explained on the basis of the patient's own signs, symptoms, and distress. For a patient suffering from clinical depression, this might be her difficulty sleeping, her loss of appetite, or her lack of energy. For a patient with an anxiety disorder, it might be her palpitations, shortness of breath, or nervousness. For a patient with mild Alzheimer's disease, it might be forgetfulness or frightening episodes, in which she finds herself in a neighborhood she does not recognize. The advent of treatments that may slow the dementing process makes these referrals easier as well.

When somatizing (psychosomatic) disorder is suspected, the gynecologist should emphasize the difficulty of living with symptoms without definitive diagnosis and treatment, rather than the physician's hypothesis that the symptoms have a psychological basis:

1. "It is very stressful to be suffering while we can't pinpoint the problem. I would like you to see one of our staff who specializes in helping people cope with these difficult situations."
2. "It must be difficult to function when you have been so sickly all your life, have seen so many doctors, have had so many diagnostic tests and medical treatments, and still don't have an answer or feel well."

It is counterproductive to convey the idea that, because the diagnostic process has not revealed a specific disorder, the problem must be "in the patient's head." It is never possible to rule out an organic cause with absolute certainty.

Many physicians fear that questioning patients about suicide or homicide will provoke these behaviors. The opposite is the case (12). An open discussion of impulses to hurt oneself or someone else helps the patient to regain control, recognize the need for mental health care, or agree to emergency interventions such as psychiatric hospitalization, while avoiding the subject intensifies the patient's feelings of isolation. The management of suicidality is addressed in the section on mood disorders.

The possibility of psychosis need not be avoided, either. Most psychotic patients have had previous experience with psychiatric referral. Their psychotic symptoms are often distressing, and they can generally discuss hallucinations and delusions quite matter-of-factly. The rare patient who comes to a gynecologist with a first episode of acute psychosis is likely to be frightened by her symptoms and willing to accept expert consultation.

Despite increasing public sophistication about mental illnesses and psychiatric care, some patients believe that any mention of mental health intervention implies that they are "crazy" or that the referring physician is convinced that their physical symptoms are imaginary or feigned. The gynecologist may wish to state explicitly that this is not the case. Again, making the real reason for the referral clear and found in signs and symptoms obvious to the patient will nearly always allay anxiety over a psychiatric referral.

It is not acceptable to refer a patient to a psychiatrist without informing and asking her in advance unless she is acutely psychotic, functionally incompetent, or in the throes of a suicidal or homicidal emergency. Even under those circumstances, it is highly preferable to be straightforward. A referral that begins with an unexpected clinical encounter with a psychiatrist is unfair to the psychiatrist and the patient and is unlikely to result in a satisfactory collaboration. In order to address any concern a patient may have that a mental health referral is an indication of the gynecologist's disdain or disinterest, and in the interest of good patient care in general, the referring gynecologist should make it clear to the patient that he or she will remain involved in her care. The mental health professional should be introduced as an integral member of the health care team, and the gynecologist should ask the patient to call after the mental health appointment to report on how it went and to make a follow-up appointment with the gynecologist.

Where to Refer: Which Mental Health Professional?

Mental disorders are treated by social workers, psychologists, members of the clergy (often the first to be consulted), and various kinds of counselors as well as by psychiatrists. The distinctions among mental health professionals are not generally well known or understood by the lay public. The criteria for membership in each profession can vary from place to place and institution to institution. Social workers and psychologists can be educated at the bachelor's, master's, or doctoral level. In some states, licensure is required; generally, social workers require a master's degree and psychologists a doctoral degree, as well as supervised clinical experience, to qualify. The category of counselor includes a wide variety of practitioners, including marriage counselors, pastoral counselors, school counselors, family
counselors, and others. The training of social workers may focus on social policy, institutional work, the psychosocial aspects of medical illness, or individual psychotherapy.

Practitioners of all these disciplines may or may not be trained in psychotherapy. For symptoms not meeting criteria for a major psychiatric disorder, in a patient who is able to eat, sleep, and carry out her duties, supportive psychotherapy provided by an attended mental health professional may suffice. Doctoral-level psychologists and neuropsychologists can also perform testing that can be diagnostically helpful, especially in identifying and localizing brain pathology and in defining intelligence levels. Undiagnosed cognitive deficits may contribute to noncompliance with gynecologic care as well as other problems. Trained social workers are often knowledgeable about community resources for patients and their families and about the impact of gynecologic diseases and treatments on them. Self-help or professionally led therapy groups can be helpful for patients reacting to gynecologic problems such as infertility or malignancy. Participation in a supportive group lengthens the survival time and improves the quality of life for some patients with cancer (20,21,22,23,24 and 25).

Psychiatrists are the only medically trained mental health professionals. They are particularly important with diagnostic dilemmas, especially when there is a question of psychological or behavioral manifestations of medical illness and pharmacologic treatment, and when a medical understanding of the gynecologic condition and treatment is necessary for clinical care. Of all mental health professionals, only psychiatrists can prescribe psychoactive medications and other biologic interventions as well as psychotherapies. Psychiatrists treat the most seriously ill patients and take responsibility for psychiatric emergencies.

In light of frequent occurrence of psychiatric problems in gynecologic practice, it is worthwhile for the gynecologist to develop an ongoing relationship with one or more local mental health professionals. The state psychiatric society may have a list of subspecialists in “consultation liaison” psychiatry. The availability of familiar and trusted resources enhances the likelihood that problems will be identified and addressed. It is also important to keep up-to-date information on local suicide prevention and other kinds of hot lines and resources for battered women and for mothers who may pose a danger to their children.

Specific Disorders
Whenever a patient's thinking, emotions, or behaviors cause concern, the gynecologist should first consider a nonpsychiatric medical disorder and a reaction to prescribed or illicit drugs. Psychiatric disorders frequently coexist with these conditions as well.

Mood Disorders
Definitions and Diagnostic Criteria

Mood is the emotional coloration of a person’s experience. Mood may be pathologically elevated (mania) or lowered (depression) or may alternate between the two (bipolar or manic-depressive disorder) (26). Mood disorders are frequently confused with the inevitable ups and downs of everyday life, such as the reactions to difficult situations, including gynecologic conditions. Because of this confusion, both patients and their loved ones become frustrated when well-meaning attempts to reason with them, distract them, or do thoughtful things for them fail to influence their protractedly disturbed moods.

Mania
Mania is characterized by:

1. Elevated mood, with euphoria or without irritability
2. Grandiosity
3. Pressured, speeded-up speech, and physical activity
4. Increased energy
5. Decreased sleep
6. Reckless and potentially damaging behaviors, such as wild expenditures and promiscuity.

Mania can be acute or subacute (hymomania). Hypomania can produce self-confidence, ebullience, energy, and productivity that are the envy of others, and the patient is very reluctant to relinquish this mood for treatment and return to normal. It can therefore be particularly difficult to arrest the condition before it progresses to full-blown mania. Acute mania is a life-threatening condition; without treatment, patients literally exhaust themselves with frantic activity in the absence of adequate nutrition and rest.

Depression
The overall lifetime prevalence of affective disorders is 8.3%; the 6-month prevalence is 5.8%. During the reproductive years, depression is 2 to 3 times more common in women than in men (27,28 and 29). The highest incidence of depression is in the age group of 25 to 44 years, but depression occurs in every age group, from toddlers to the aged. Women have a lifetime risk of 10% to 25% and a point prevalence of 5% to 9% (30,31 and 32). Depression is the single most common reason for psychiatric hospitalization in the United States. As many as 15% of individuals with severe depressive disorders are successful in committing suicide. Depression is a recurrent disorder; of those who experience a major depressive episode, 50% have a second one. Of these, 70% have a third, and the incidence continues to increase with each subsequent episode. It is difficult to know whether the incidence of depression has increased over the years recently; diagnostic criteria in the past were vague and different from those used in DSM III and IV. There is no evidence that employment outside the home increases women's vulnerability to depression, although the need to carry out multiple roles in the absence of adequate social support can be stressful (33,34,35 and 36).

Depression is characterized by:

1. Sad mood or irritability
2. Hopelessness
3. Helplessness
4. Decreased ability to concentrate
5. Decreased energy
6. Interference with sleep, generally with early awakening, inability to return to sleep, and failure to feel rested; in atypical cases, with increased sleep
7. Decreased appetite and weight; in atypical cases, increased food intake
8. Withdrawal from social relationships
9. Inability to enjoy previously gratifying activities
10. Loss of libido
11. Guilt
12. Psychomotor retardation or agitation
13. Thoughts of death or suicide.

The patient who has five or more of the signs and symptoms of depression for most of each day for weeks or more has a clinical depression. Depression may be acute or chronic (dysthymic disorder). Depression can be caused by genetic, neurophysiologic, and environmental factors. Trauma in early life plays a role. Serotonin is a major mediator. Changes appear on magnetic resonance imaging, and are reversed with effective treatment or spontaneous recovery. The average duration of a major depressive episode is approximately 9 months.

Depression may be precipitated by an adverse life event such as an interpersonal loss, economic reversal, or serious illness (37,38). When there is an identifiable precipitant, there is a danger that the depression will be written off as the inevitable reaction to the event rather than considered properly as a complication, like infection or pneumonia, requiring active treatment. When a patient's symptoms meet criteria for the diagnosis, treating the depression will make her much more able to cope with the precipitating situation. Co-occurring gynecologic or other medical illness can cause signs and symptoms similar to those of depression—loss of energy, sleep, and appetite—but does not cause guilt, hopelessness, or helplessness (19).
Gynecologic Issues

The incidence of depression peaks, and the gender difference prevails, during the reproductive years, which has provoked study of both psychosocial and biologic factors. There may be a subgroup of women who are vulnerable, not to absolute circulating hormone levels, but to hormonal changes. These women experience severe premenstrual mood symptoms, postpartum depression and, possibly, depression in association with hormonal influences such as hormonal contraceptive methods, menopause, and hormone treatments.

Premenstrual Syndrome

Depending on the methodology used to gather the data, many women, perhaps a majority, experience mood and behavioral changes associated with the menstrual cycle, and many women seek care for self-diagnosed PMS, or premenstrual syndrome. Perhaps 3% to 5% of menstruating women suffer from symptoms so marked that they qualify for a diagnosis of premenstrual dysphoric disorder (PMDD). These categories have been the subject of many debates. In the United States, the prevalence of attitudes linking the menstrual cycle to adverse mood and behavioral changes is so high that it skews women's perceptions, the way they report symptoms to researchers, and the factors to which they attribute negative feelings. No specific hormone levels or markers are associated with premenstrual symptoms (39).

Most women who seek care for PMS have symptoms not related to the timing of the menstrual cycle (40,41). Therefore careful assessment is essential. Before the diagnosis of PMS or PMDD can be determined, a woman must record symptom ratings daily for at least two full cycles. Records of emotions and behaviors should be kept separate from menstrual records to avoid confounding patients' perceptions. At the same time, the patient must be screened for other psychiatric disorders, including depression, personality disorders, and domestic abuse.

While the evaluation proceeds, the clinician can recommend a number of lifestyle changes that have proved effective in milder cases. These include:

- Elimination of caffeine from the diet
- Smoking cessation
- Regular exercise
- Regular meals and a nutritious diet
- Adequate sleep
- Stress reduction.

Stress reduction can be accomplished by reducing or delegating responsibilities, insofar as that is possible, and devoting part of every day to relaxation techniques such as yoga. Still, many women experience stresses they cannot reduce: responsibility for the care of children and aging relatives, running a household, and employment often must be balanced.

The selective serotonin reuptake inhibitors (SSRIs) have proven effective for PMDD in clinical trials. As of this writing, fluoxetine has received U.S. Food and Drug Administration (FDA) approval for this indication, and other SSRIs are in the midst of the approval process (42,43,44 and 45). Although SSRIs and all other antidepressants require about 2 weeks of daily administration to achieve therapeutic effect, it appears that fluoxetine is effective for PMDD when taken in the usual daily doses for just the 1 to 2 weeks preceding menstruation. The medication has been packaged for this specific indication and dosage regimen. It is thought that the mode of action of SSRIs when used in this fashion is different from that which alleviates major depression. Other medications used for the treatment of PMS are shown in Table 12.2.

Other Reproductive Events

Infertility is described by most women undergoing treatment as the most stressful event of their lives. Each unsuccessful treatment is experienced as the loss of a hoped-for pregnancy. The loss of a fetus or newborn induces grief, which entails some of the same symptoms as depression. Patients should not be pressed to “put the loss behind them” or expected to be “over it” within several months. Some feelings of sadness may persist for years. However, their sleep, appetite, and other vital functions and behaviors should begin to improve after a few weeks (37). Depression can complicate grief and should be treated. There is no evidence that induced abortion increases the incidence of clinical depression.

Peripartum Depression

The incidence of depression does not decrease during pregnancy and increases to approximately 10% postpartum. It must be distinguished from the transitory, self-limited, and very common “baby blues.” Mild cases can be managed with psychotherapy. Moderate-to-severe cases may require antidepressant medications. Although no agent can be declared perfectly safe for use during pregnancy and lactation, the older SSRI agents have been well studied, yielding little or no evidence of adverse effects on the fetus or nursing infant (46,47). Medication should not be stopped arbitrarily, nor breast feeding prohibited.

Menopause

Although menopause was assumed for many years to be associated with an increased incidence of depression, this assumption has not been borne out in empirical studies. Whereas some patients are upset by their loss of fertility, others find menopause liberating (48,49). Patients who have suffered PMS or postpartum depression may, however, be vulnerable. Patients with depression at the time of menopause should be assessed for psychosocial precipitants and domestic abuse.

Depression in elderly patients can cause a pseudodementia, characterized by decreased activity and interest and what appears to be forgetfulness. Unlike patients with organically based dementia, these patients report memory loss rather than trying to compensate and cover up for it.

Approach to the Patient

The severity of depression is determined by the patient's emotional pain and the degree of interference with her normal functioning. Depression is an agonizingly painful but readily diagnosable and treatable disease (3). Nevertheless, it shares the stigma of all psychiatric disorders. Patients and their families often attribute the signs and symptoms of depression to life circumstances or to a medical condition, either diagnosed or undiagnosed. The persistence of symptoms in the face of a pleasant life situation or the failure of the patient to respond to attempts at cheering, such as changes of scene, often exacerbate suffering by provoking guilt.
in the patient and frustration in her significant others. Patients are more likely to report low energy and general malaise than depressed mood. Even patients with moderately severe depression can continue to function and can appear not only normal, but cheerful. The only way to rule out depression is by following the diagnostic criteria (26).

Management

Both antidepressant medication and psychotherapy are effective treatments for depression. There is evidence that a combination of the two produces the best outcomes. There are many forms of psychotherapy. Those that have been specifically studied for efficacy in the treatment of depression are cognitive-behavioral therapy and interpersonal therapy. These forms of therapy are focused on present thoughts, feelings, relationships, and behaviors. They proceed for a set number of sessions, usually no more than 16 weekly sessions, in a prescribed, predetermined direction (50). Supportive and psychodynamic psychotherapy are less clearly defined and studied modalities that also may be of help.

It is especially important for the patient to have ample opportunity to work out her feelings about having a psychiatric disorder, understand how it has affected her life, and feel comfortable about taking any medication prescribed. Patients often attribute depression to weakness or laziness, and they often confuse antidepressants with stimulants and other psychoactive drugs. It is useful to provide the patient with written material about depression so that she can review it and explain the diagnosis to her family and friends.

The types and characteristics of antidepressants are in Table 12.3. All of these agents have comparable therapeutic efficacy and all require at least 2 to 4 weeks to take full effect. It is not yet possible to identify which patients will respond best to which medications; responses vary on an individual basis, even within the same class of medications. The choice of antidepressant, therefore, is based on side effects, dosage schedule, cost, and familiarity of the physician (Table 12.4). Patients tend to respond to medications that have worked for them in the past and to those that have worked for depressed family members. It is essential to continue active management until the patient has not only responded but has returned to her premorbid level of mood and function. If she does not recover completely, she should be referred to a psychiatrist (51).

Monoamine oxidase (MAO) inhibitors are especially effective for atypical depression. They require dietary restrictions and can be used only in patients who are able to understand and comply with those restrictions in order to avoid hypertensive crises. SSRIs pose few risks of medical or suicidal complications. Side effects include anxiety, tremor, headache, and gastrointestinal upset (either diarrhea or constipation), and usually abate within a few days of the onset of treatment. A more serious side effect is loss of libido and interference with orgasm (52). Patients may be reluctant to report this side effect, but it may be the reason they discontinue treatment. Some women are willing to accept this side effect because it is an acceptable price to pay for recovery and because depression interferes with their sexual functioning anyway. Female patients are frequently concerned about weight gain. In one study, it appeared that a weight gain of 5 to 7 pounds may be expected. It is difficult to know, however, whether the weight gain is a result of the medication alone or whether it results from improved appetite associated with recovery from depression. This concern should be brought into the open; patients may be advised to watch their diets carefully while taking the medication.

SSRIs are administered in a once-a-day regimen, with little need for dosage adjustments in most cases. It is important to continue treatment until the patient is fully recovered. SSRIs have long half-lives, so occasional missed doses do not constitute a problem. There is an SSRI withdrawal syndrome, however, and patients should be cautioned not to discontinue their medication without consulting the physician, and only then by gradually decreasing the dose. SSRIs are considerably more expensive than tricyclic antidepressants. They were not initially tested in older women, but several are under consideration by the FDA for administration to this age group (59).

Atypical Agents

Medications considered atypical include venlafaxine (54,55 and 56), lithium salts, and anticonvulsants, which are effective mood stabilizers used for bipolar disorders (57,58), and bupropion.

Bupropion must be taken twice a day. It lowers the seizure threshold significantly more than other antidepressants. It is used, under a special trade name, for smoking cessation, and thus is particularly useful for depressed smokers. Bupropion seems to cause fewer sexual side effects than the SSRIs and may decrease these side effects when added to an SSRI regimen.

Suicide

SSRIs are considerably more expensive than tricyclic antidepressants. They were not initially tested in older women, but several are under consideration by the FDA for administration to this age group (59).

Atypical Agents

Medications considered atypical include venlafaxine (54,55 and 56), lithium salts, and anticonvulsants, which are effective mood stabilizers used for bipolar disorders (57,58), and bupropion.

Bupropion must be taken twice a day. It lowers the seizure threshold significantly more than other antidepressants. It is used, under a special trade name, for smoking cessation, and thus is particularly useful for depressed smokers. Bupropion seems to cause fewer sexual side effects than the SSRIs and may decrease these side effects when added to an SSRI regimen.
The most critical issue in the assessment and referral of depressed patients is the possibility of suicide. Risk factors for suicide include:

- Depression
- Recent losses
- Previous suicide attempts, even if seemingly not serious
- Impulsivity
- Concurrent alcohol or substance abuse
- Current or past physical or sexual abuse
- Family history of suicide
- A plan to commit suicide
- The means to carry out the plan.

Women attempt suicide more frequently than men, but men complete the act more frequently than women (59,60). This is probably due, at least in the past, to men's use of more drastic or irreversible means, such as firearms, while women tend to overdose and can be treated if discovered.

The association between unsuccessful past self-destructive behavior and successful suicide is counterintuitive. It would seem that someone who has repeatedly made suicidal gestures is more interested in the responses of others than in ending her life. However, past attempts or gestures increase the risk of completed suicide, and expressed suicidality in such patients cannot be dismissed. Most people who commit suicide have consulted a nonpsychiatric physician within the prior month. All clinicians must be prepared to discuss the possibility of suicide with their patients.

Inquiry about suicidal ideation and behavior is an inherent part of every mental status examination and is mandatory for every patient with past or current depression or evidence of self-destructive behavior. It follows from discussion of difficulties in the patient's life or mood, or the physician can open the subject by mentioning that almost everyone has thoughts of death at one time or another. Most patients will immediately volunteer that they have had such thoughts and that they have no intention of acting on them. They will often add the reasons: they have too much to look forward to, it is against their religion, it would hurt their family.

It is important to distinguish between the wish to be dead and the intention to kill oneself. In the context of a trusting doctor-patient relationship, patients will nearly always tell the truth about their feelings. A patient in a painful life situation—a chronic, painful, or terminal medical condition, the birth of a severely damaged child, or a grievous loss—may express a wish to die, and even refuse recommended medical care, but emphatically disavow any intention of actively harming herself.

If the patient has previously engaged in self-destructive behavior impulsively, without a plan or warning, it is wise to consult a psychiatrist. If a patient is actively contemplating suicide, she must see a psychiatrist immediately. Other mental health professionals may be helpful but are less likely to have dealt extensively with and assumed responsibility for suicidal patients, to be able to determine whether the patient should be hospitalized, and to have admitting privileges. Until she is in the physical presence of a psychiatrist, or in a safe environment such as a hospital emergency room, a suicidal patient should be observed and protected at all times—every second—whether she is in the consulting room or the bathroom. The staff member assigned to remain with her may not leave to make a telephone call, go to the bathroom, or get a cup of coffee. Family members may offer to monitor the patient, and can sometimes be effective, but the health care professional is responsible for ensuring that they understand these necessities. It is better to risk inconvenience and possible embarrassment to both the gynecologist and the patient than to risk a fatal outcome. Once suicide is a possibility, only a psychiatrist can make the decision that a patient is safe (61).

Psychiatric referral can also be useful in less dramatic cases: when the gynecologist lacks experience or is overloaded with other needy patients, when a first trial of treatment is unsuccessful or there is uncertainty about the diagnosis when domestic violence or substance abuse may be present, and when the depression is recurrent.

### Anxiety Disorders

#### Diagnosis

Anxiety is a sense of dread without objective cause for fear, accompanied by the usual physical concomitants of fear. Although every human being has anxious feelings from time to time, anxiety disorders are anxiety to the point of pathology: genuine painful, disabling diseases. The anxiety disorders include generalized anxiety disorder, panic disorder, agoraphobia, specific phobias, obsessive-compulsive disorder, and posttraumatic stress disorder (61,62).

Generalized anxiety disorder is a condition in which anxiety pervades every aspect of a patient's life. She suffers from restlessness, easy fatigability, difficulty concentrating, irritability, muscle tension, and sleep disturbances. Whereas depressed patients fall asleep more or less normally and then awaken earlier than intended, anxious patients have difficulty falling asleep.

Panic disorder is characterized by panic attacks: acute periods, generally lasting about 15 minutes, with intense fear and at least four of the following symptoms:

- Palpitations
- Diaphoresis
- Trembling
- Shortness of breath
- A choking sensation
- Chest discomfort
- Gastrointestinal distress
- Lightheadedness
- A sense of unreality
- Fear of going crazy or dying
- Paresthesias
- Chills or hot flushes.

The attacks can recur without specific precipitating events. The patient is preoccupied with them and makes behavioral changes she hopes will avert future attacks: avoiding specific situations, assuming there is an escape route from certain situations, or refusing to be alone.

The symptoms of panic attacks are often confused with the symptoms of cardiac or pulmonary disease. They lead to many fruitless trips to the emergency department and to costly, even invasive, medical investigations. A careful history can establish the correct diagnosis in most cases.

Agoraphobia is the avoidance of situations in which the patient fears she may be trapped, such as the center of a row in the theater or driving over a bridge. She fears that such a situation will trigger a panic attack. Agoraphobia and panic disorder can occur separately or together.

Specific phobias are irrational fears of certain objects or situations, although the patient recognizes that the object or situation poses no real danger. Of particular concern in gynecology are fears of needles and fear of vomiting. Social phobia causes the patient to fear and avoid situations in which the patient fears she will be observed by others in a humiliating light. Patients may alter their lives to avoid these anxieties, interfering with their interpersonal relationships and their ability to carry out their responsibilities, or they may manage to carry on despite considerable psychological pain.

Obsessive-compulsive disorder is characterized by obsessions: recurrent impulses, images, or thoughts that the patient recognizes as her own, dislikes, and cannot control, or compulsions: intrusive, repetitive behaviors that the patient feels she must perform in order to prevent some dire consequence. The disorder can be mild or totally crippling, in one-half of the cases it becomes chronic. This disorder is classified as an anxiety disorder because the obsessions are anxiety-provoking, and the compulsions are performed in order to avoid overwhelming anxiety.
Posttraumatic stress disorder (PTSD) is the result of exposure to an event that threatens the life or safety of the patient or others. At the time of the trauma, the patient experiences horror, terror, or a sense of helplessness. Afterward, the patient may lose conscious memory of all or part of the event, avoid situations reminiscent of it, and become acutely distressed when she cannot avoid them. She feels numb and detached, without a sense of the future. She is hyperarousable and irritable and experiences difficulty sleeping and concentrating. She reexperiences the events in nightmares, flashbacks, and intrusive thoughts.

Epidemiology

Panic disorder without agoraphobia is twice as common in women as it is in men; panic disorder with agoraphobia is 3 times more common in women. Onset is generally in young adulthood, often following a stressful event. The lifetime prevalence is 1.5% to 3.5%; the 1-year prevalence is 1% to 2%. A substantial percentage of patients experience depressive episodes as well. Phobias are somewhat more common in women, depending on the object of the phobia. The 1-year prevalence is 9%, and the lifetime prevalence is 10% to 11%. Obsessive-compulsive disorder is equally common in women and men, with evidence of familial transmission. Prevalences are 2.5% for lifetime and 1.5% to 2.1% for 1 year. Posttraumatic stress disorder has a lifetime prevalence of 1% to 14%; victims of violence (including child abuse and wife battering) and war are at increased risk.

Assessment

Given the relationship between anxiety disorders and traumatic experiences, the presence of signs and symptoms of anxiety disorders should trigger inquiries about abuse. It is important to know how long the patient has suffered from the disorder, what previous attempts have been made to diagnose and treat it, and the effect is has had on her psychological development, life choices, lifestyle, and relationships. In some cases, the entire family will have organized their schedules and activities around the patient's symptoms and limitations; they may not volunteer this information.

Management

Treatment should not be limited to antianxiety medications. Managing, even tolerating, patient anxiety is an anxiety-provoking process; anxiety is contagious, and raises the specter of unlimited demands on the gynecologist's time and energy. Prescribing medication is a familiar and comfortable, if not optimal, way to end a medical interview. The overprescription of benzodiazepines has become a cause for medical and media concern. It is useful to defer the administration of anxiolytics until the impact of the physician's support and interest can be assessed (63). Treatment should address the effects on the patient's life and family as well as the signs and symptoms of the specific disease (64).

Benzodiazepines are most useful in acute situations. Use can quickly become chronic, with escalating dosages, diminishing therapeutic effects, and increasing demands on the physician. So many women are taking benzodiazepines, and taking them for granted, that they forget to include them in their medical histories. Patients admitted to the hospital may suffer unrecognized withdrawal symptoms, complicating their treatment, or may continue to take medications from a personal supply without informing the medical staff. For chronic anxiety and many cases of acute anxiety, there are highly effective and safer approaches.

It is important to ascertain the source of anxiety or obsessiveness. Many patients and their families are anxious because of misinformation or misunderstanding about a medical problem or treatment. Few patients can absorb all the information about significant gynecologic conditions at a single visit, but most feel that asking questions will burden the physician or make them look stupid. Patients also suffer anxiety when there is disagreement among family members or medical staff about the diagnosis or recommended treatment. Many patients dread certain aspects of care, sometimes on the basis of past experience or outdated information. A simple explanation or alteration in procedure can alleviate the anxiety. For example, a reassuring family member or friend can be allowed to stay with the patient during a diagnostic test, sedation can be administered orally or by inhalation before an intravenous line is inserted, or the patient can be allowed control over her own analgesia.

Behavioral interventions are extremely useful in managing anxiety without problematic side effects. They include hypnosis, desensitization, and relaxation techniques (65,66,67,68 and 69). Whereas the use of prescribed medications fosters the patient's dependence, these techniques provide her with tools to cope with her own anxiety. Specialists in behavioral medicine, usually psychologists, are expert in these techniques. Interested gynecologists can master some of them as well.

It is easy to be trapped into a cat-and-mouse game with an anxious and needy patient. Faced with an obsessional or anxious, talkative, and needy patient in the midst of bedside rounds, clinic, or office hours, the clinician can develop a pattern of avoidance, sometimes alternating with overindulgence stemming from feelings of guilt. This kind of behavior results in sporadic, unpredictable reinforcement of the patient's symptoms and demands for attention and is very likely to increase them. Attempting to escape by appearing distracted or harassed, or yielding with despair to the destruction of the day's schedule and the care of other patients, simply heightens the patient's anxiety.

It is preferable to develop a prospecive approach. Gynecologists tend to underrate the power of their personal interactions with patients and their own ability to structure and limit those interactions appropriately. The patient should be informed of the time available and asked to focus on her most important problem, with other problems to be discussed at future, scheduled appointments. Instead of scheduling appointments and returning telephone calls grudgingly, in response to patient demands, the gynecologist should inform the patient that her condition requires regular, brief, scheduled visits. If she has been contacting the office more often than visits can reasonably be scheduled, she should be asked to call between visits, at rearranged times, to advise the staff of her progress. There are useful self-help groups for patients with various psychiatric conditions, and their families. Groups focused on victimization can validate patients' experiences and pain and help them build new lives, but they can also interfere with their motivation to find other ways to identify themselves and obtain gratification.

Medication does have a place in the management of anxiety disorders (70,71 and 72). Table 12.5 describes many of these agents. Sertraline recently received FDA approval for the treatment of PTSD, and other selective serotonin reuptake inhibitors are effective for other anxiety disorders as well. Benzodiazepines are effective when taken for acute anxiety or during relatively brief, time-limited (several days) stressful situations. The specific agent should be chosen on the basis of onset of action and half-life. The patient must be admonished to avoid concomitant use of alcohol and to exercise extreme care about driving or engaging in other activities requiring attention, concentration, and coordination.

Patients who fail to respond to a trial of office counseling or medication, who are unable to fulfill their responsibilities, who exhaust the patience and resources of significant others, who pose a diagnostic dilemma, who consume inordinate quantities of medical resources, or whose symptoms are becoming increasingly worse should be evaluated by a psychiatrist.
Definitions

Somatizing disorders are those in which psychological conflicts are expressed in the form of physical symptoms. There is a spectrum of somatizing disorders based on the degree to which the patient is consciously aware of or responsible for the onset of the symptoms. The spectrum ranges from the deliberate malingeringer to the so-called hysteric, who is completely unaware of the link between her psyche and her physical symptom (73).

Malingering

Malingering is the deliberate mimicking of signs and symptoms of physical or mental illness in order to achieve a tangible personal gain, such as exemption from dangerous military duties or exoneration from criminal responsibility. Factitious disorder, or Munchausen syndrome, is a related but poorly understood condition in which the patient actively causes physical damage to herself or feigns somatic symptoms that result in repeated hospital admissions and painful, dangerous, invasive diagnostic and therapeutic procedures. These patients introduce feces or purulent material into wounds or intravenous lines, inject themselves with insulin, or produce hemorrhages.

Significant iatrogenic conditions, such as adhesions from surgery or Cushing's syndrome from the administration of steroids, may develop. These patients are initially engaging but eventually frustrate the staff. When the staff becomes suspicious and calls for a psychiatric consultation, the patient generally flees, only to reappear in another medical facility. As a result, there are little data about the etiology, incidence, and management of this condition. Often these patients are medically sophisticated because they or their family members have had some kind of medical training, as well as knowledge gained during previous hospitalizations. Mothers may enact this disorder through their children, by deliberately making them ill; this is called Munchausen's by proxy. Declaring that the patient "only wants attention" is not helpful. Most people want attention, but very few are willing to go to these lengths to get it.

Somatization Disorder

Somatization disorder consists of multiple physical symptoms for which adequate medical bases cannot be established, with these symptoms leading either to numerous medical visits or to impairment in the patient's performance of her responsibilities. The disorder must begin before age 30 and continue for many years after. The diagnosis requires symptoms of pain related to at least four different anatomic or physiologic functions, two gastrointestinal symptoms, one sexual or reproductive symptom and one pseudoneurologic symptom or deficit other than pain (seizures, parasthesias). The patient's perception is that she is "sickly." She responds accurately to questions about her past symptoms and treatments but may not volunteer information about them unless she is asked.

Conversion Disorder

Conversion disorder is the condition formerly called hysteria. The patient loses a voluntary motor or sensory function that cannot be explained by medical illness, that is not deliberately produced by the patient, and that appears to be related to psychological stress or conflict. The prognosis is directly related to the length of time from onset to diagnosis and treatment (74,75,76 and 77).

Pain disorder is a conversion condition with pain as the only symptom.

Body dysmorphic disorder is preoccupation with a trivial or imagined defect in bodily appearance, a preoccupation that is not alleviated by the many medical and surgical treatments on which the patient insists. The gynecologist should hesitate to refer such a patient to a plastic surgeon, although plastic surgeons are quite familiar with the condition.

Hypochondriasis is not a matter of particular numbers or types of symptoms. It is a patient's (nonpsychotic) conviction or fear that she suffers from a serious disease.

Epidemiology

Somatization is believed to be the most common and most difficult set of psychological conditions in office practice. It has been estimated that 60% to 80% of the general population experiences one or more somatic symptoms in a given week. Somatization disorder occurs almost exclusively in women; menstrual complaints may be an early sign. Lifetime prevalence in women is 0.2% to 2.0%. Conversion disorder is 2 to 10 times more frequent in women than in men (there is no gender difference in children), and it is more common in rural and disadvantaged populations with little medical sophistication. Conversion disorder may develop into somatization disorder. Reported rates of somatization disorder range from 11 to 300 per 100,000. Pain disorder is extremely common in both genders. Hypochondriasis is equally distributed between men and women; prevalence in general medical practice is estimated to be 4% to 9%. There are few statistics about body dysmorphic disorder, but it seems to be equally distributed between men and women, with an average age of onset of about 30 years.

Assessment

Most somatizing disorders are chronic. The goal of treatment in primary care is not to eliminate all the somatic symptoms but to help the patient cope with them with as little effect on her relationships and responsibilities as possible. Because patients often seek care simultaneously or sequentially from several physicians, it is crucial to ask about all past and current diagnostic procedures, diagnoses, treatments, and responses. Her level of function over the years is also important; prognosis is inversely related to chronicity. The gynecologist needs to know what the patient believes is wrong with her and what she believes she needs in the way of diagnostic and therapeutic interventions.

Management

The management of somatizing disorders is focused on the avoidance of unnecessary medical interventions, iatrogenic medical or psychological complications, and disability. Unfortunately, it is never possible to definitively rule out all possible medical causes. The literature is full of case presentations of patients with multiple sclerosis, brain tumors, and intermittently flaring infections, labeled for years as neurotic before the condition was diagnosed correctly. Patients who for years have had benign gastrointestinal symptoms can get appendicitis.

Patients who have a somatizing disorder often approach each new clinician as the one who, unlike the incompetent and insensitive physicians she has consulted in the past, will finally get to the bottom of her troubles and allow her to live the perfect life that her symptoms have denied her. The gynecologist must not get caught up in these expectations but rather remind the patient that symptoms that have resisted diagnosis and treatment for many years are likely to be challenging ones. As with anxious patients, it is important not to structure the doctor-patient relationship so that the patient receives attention inconsistently and only in response to escalating symptoms and demands. It is best to schedule frequent, brief office visits during which the clinician alights a small amount of time to listen to and sympathize with the patient's somatic complaints and spends the bulk of the time reinforcing the patient's efforts to function despite her symptoms. Family members should be encouraged to facilitate function rather than invalidism.

It is often tempting to unmask patently psychologically based symptoms by tricking the patient: shouting "Fire!" in the vicinity of a "paralyzed" patient, searching the patient's hospital room or belongings for paraphernalia used to cause symptoms, documenting the patient's behavior when she does not realize she is being observed. Some of these attempts are useful diagnostically, but not therapeutically, and some (searches) are unethical and illegal. Humiliating a frustrating patient may be momentarily gratifying, and may force her to relinquish a symptom, at least temporarily. She may seek care elsewhere, relieving the original treatment team of her iatrogenic complications.

Patients with conversion, somatization, and hypochondriacal disorders often benefit from prescriptive behavioral regimens aimed at saving face and improving function. It was once believed that a patient so relieved of one symptom would soon substitute another, but this assumption has not been confirmed by empirical evidence. The behavioral regimen should consist of health-promoting activities relevant to the target symptoms, planned in a step-wise progression, and recommended with reasonable medical conviction and authority. For example, the patient with psychogenic difficulty swallowing should be advised to drink only clear
Personality disorders are pervasive, lifelong, maladaptive patterns of perception and behavior. Patients with personality disorders do not consider themselves symptomatic, but as treated unfairly by circumstances and other people. They view their own behaviors, which can wreak havoc in the health care setting as well as in patients’ lives, as normal, expectable, inevitable reactions to these perceived circumstances. To make matters worse, their behaviors tend to provoke in others the very responses that confirm their expectations. For example, a patient who is convinced that people always abandon her clings desperately to others, eventually driving them away.

Personality disorders are organized into clusters in DSM IV. Patients often manifest characteristics of several disorders within a cluster and between clusters.

Cluster A
- Paranoid personality disorder
- Schizoid personality disorder
- Schizotypal personality disorder

Cluster B
- Narcissistic personality disorder
- Histrionic personality disorder
- Borderline personality disorder
- Antisocial personality disorder

Cluster C
- Avoidant personality disorder
- Dependent personality disorder
- Obsessive-compulsive personality disorder

Individuals with Cluster A disorders are isolated, suspicious, detached, and odd. Narcissistic patients are grandiose, arrogant, envious, and entitled. Histrionic individuals are flamboyant and provocative. Antisocial patients disregard laws and rules of common decency toward others. Borderline personality disorder causes patients to have difficulty controlling their impulses and maintaining stable moods and relationships. They also engage in self-destructive behaviors. They fluctuate between overvaluation and castigation of the same person, or direct these feelings alternately between one person and another. When this happens on a gynecology service or in the office, it can precipitate significant tensions among the staff. Recent research reveals that many women who have been abused are diagnosed as borderline when posttraumatic stress disorder more accurately fits their symptoms. Posttraumatic stress disorder is a less stigmatizing and more treatable condition than abuse.

Epidemiology

Life-time prevalence of personality disorders as a group is 2.5%. Cluster A disorders are more common in males. Within Cluster B, 75% of cases are female; the prevalence in the general population is 2%. Personality disorders such as narcissistic personality are more common in the clinical population than in the general population. Among cluster C disorders, dependent personality is one of the most frequently diagnosed. Obsessive-compulsive personality is twice as common in males as in females. It is important to distinguish the personality disorder from the symptomatic obsessive-compulsive disorder. There is a strong association between personality disorders and a history of childhood abuse. The possibility of an ongoing abusive situation should be considered as well.

Assessment

The impact of personality disorders ranges widely. At one end of the spectrum, the disorder is an exaggerated personality style. At the other end of the spectrum, the individual suffers terrible emotional pain and is unable to function in work roles or relationships, spending significant periods of time in psychiatric hospitals. As the definition implies, the patient will not seek treatment for the signs and symptoms listed in the diagnostic criteria but instead will have complaints about her treatment by others, their responses to her, and the unfairness and difficulties of life in general. Taking the history, the clinician should frame questions in those same terms: how long have these troubles gone on, and how much do they interfere with her ability to work and relate to others? Personality disorders do not bring patients to gynecologists’ offices directly, but they greatly complicate things once patients arrive there.

Management

It generally requires intense and lengthy psychotherapy to effect significant improvement in patients who have personality disorders. The challenge in the gynecology setting is to minimize contention and drain on medical staff while maximizing the likelihood of effective diagnosis and treatment of the patient’s medical problems. The most helpful single step is the identification of the personality disorder. Diagnosis enables the gynecologist to recognize the reasons for a patient’s problem behaviors, to avoid becoming entangled in fruitless interactions with the patient, and to set limits on her demands that are neither withholding nor overindulgent.

There is increasing evidence that psychotropic medications are useful for personality disorders. Treatment should be provided in consultation with a psychiatrist. The patient’s ability to use the medication properly is compromised by impulsivity, self-destructive tendencies, and unstable relationships. Low doses of major tranquilizers are sometimes helpful, especially when the patient has brief psychotic episodes. Minor tranquilizers pose significant risk of habituation, overdose, and physical and psychological habituation. They can be prescribed for temporary stresses, but only in a quantity sufficient for several days and with no refill allowed. At the same time, some patients’ anxiety, demands, and power struggles are eased when they are given control over their own use of medication. Such an approach requires enough familiarity with the patient to ensure her safety.
Because the patient with a personality disorder attributes her problems to others, her symptoms cannot be adduced as reasons for psychiatric referral, but her suffering can be. If a diagnosis of a personality disorder is noted in the patient's chart or on insurance forms, it is essential that she be so informed. It is useful to review the DSM IV criteria with her so that she understands the basis for the diagnosis.

### Adjustment Disorders

#### Definitions

Adjustment disorders are temporary, self-limited responses to life stressors that are part of the normative range of human experience (unlike those that precipitate posttraumatic stress disorder). The patient has mood or anxiety symptoms that are sufficient to lead her to seek medical care but that do not meet criteria of sufficient quantity or quality to qualify for psychiatric diagnosis. The diagnosis requires an identifiable stressor, onset within 3 months after the stress begins, and spontaneous resolution within 6 months after the stressor ends. Obviously the latter cannot be determined until the symptoms resolve—but they do rule out the disorder if the symptoms persist beyond that time (81,82).

Adjustment disorders can be distinguished from normal grieving. Grieving produces symptoms similar to those of depression. Interference with function does not persist, but some degree of sadness and preoccupation with the lost loved one often goes on for months and years.

#### Epidemiology

Adjustment disorders affect males and females equally. Approximately 5% to 20% of patients in outpatient mental health treatment suffer from adjustment disorders. There is little literature on the subject; one study reported a 2.3% prevalence among a sample of patients receiving care in a walk-in general health clinic.

#### Management

Patients with adjustment disorders can be treated effectively with brief counseling in the primary care setting. The counseling can be provided by the gynecologist or by a nurse clinician, social worker, or psychologist, preferably a member of the office or hospital staff who is familiar with the gynecologist and the practice. The medical setting is sometimes the only one where the patient can vent her feelings and think through her situation. Counseling is aimed at facilitating the patient's own coping skills and helping her to make autonomous decisions about her situation. The gynecologist should follow the patient's progress and facilitate referral to a psychiatrist if symptoms do not resolve.

### Eating Disorders

#### Definitions

Preoccupation with thinness, sometimes to the point of pathology, is a major problem for women in North America. Only a small number of women profess to be satisfied with their weights and body shapes. Nearly all admit to current or recent attempts to limit food intake. Physicians often share social prejudices against overweight patients and can easily exacerbate patients' concerns by making chance comments.

*Anorexia nervosa* is characterized by severe restrictions on food intake, often accompanied by excessive physical exercise and the use of diuretics or laxatives. Clinical features include menstrual irregularities or amenorrhea, intense, irrational fear of becoming fat, preoccupation with body weight as an indicator of self-worth, and inability to acknowledge the realities and dangers of the condition. Some patients approach gynecologists for care of infertility (83).

*Bulimia* is characterized by eating binges followed by self-induced vomiting or purging. Patients' weights may be normal or somewhat more. Patients have drastically low self-esteem, and the condition is frequently comorbid with depression (83).

*Obesity* is an increasingly frequent health problem, with little evidence that any nonsurgical approach is effective over time. Sensible eating should be encouraged, and fat or crash diets are medically and psychologically counterproductive (85).

#### Epidemiology

More than 90% of cases of anorexia and bulimia occur in females. The prevalence is 0.5% to 1.0% in late adolescence and 1% to 3% in early adulthood. There is some evidence of familial transmission.

#### Assessment

The clinician treating the anorexic patient needs to know how much insight she has into her problem and to assess her mood, relationships, and general level of function. Anorexia poses significant risks of severe metabolic complications and death, often from cardiac consequences of electrolyte abnormalities. Thorough physical and laboratory examination is critical; immediate hospitalization may be necessary.

#### Management

Patients with anorexia or bulimia should be treated by mental health professionals, preferably subspecialists in this area. The conditions are highly refractory to treatment; patients can resort to elaborate subterfuges to conceal their failure to eat and gain weight. Antidepressant medication is sometimes helpful. Amenorrheic patients should not be treated with ovulation induction. Evaluation for osteopenia and osteoporosis is necessary.

### Psychotic Disorders

#### Definitions

Psychotic disorders are characterized by major distortions of thinking and behavior. They include schizophrenia, schizophreniform disorders, schizoaffective disorders, delusional disorders, and brief psychotic disorders. General medical and toxic conditions must be ruled out. Distinctions between the disorders are based on symptoms, time course, severity, and associated affective symptoms. The hallmark of psychosis is the presence of delusions or hallucinations. Hallucinations are sensory perceptions in the absence of external sensory stimuli. Delusions are bizarre beliefs about the nature of motivation of external events. Because there is no reliable definition of "bizarre," the diagnostician working with a patient from an unfamiliar culture must determine whether a given belief is normal in that culture. Delusions and hallucinations are the "positive symptoms" of schizophrenia. The "negative symptoms" include apathy and loss of connection to others and to interests. The negative symptoms may be more disabling than the positive.

#### Epidemiology

Schizophrenia occurs in approximately 1% of the population worldwide (85). Onset is in the late teens to mid-30s. Women succumb later and have more prominent mood symptoms and a better prognosis than men. The risk is 10 times greater for first-degree biologic relatives and for individuals of low socioeconomic status. It is unclear whether indigent status is a precipitating stress or a result of psychotic illness.

#### Assessment
There is wide variability in the functional impact of psychotic disorders. Patients must not be assumed to be incompetent to make medical decision or lead independent lives, especially if they comply with treatment. Patients must be asked specifically about their living situations and coping skills. When psychiatric women have responsibility for the care of children, their ability to do so should be assessed in consultation with a mental health professional. Motherhood and child custody are exceedingly sensitive matters for these vulnerable patients.

A relentlessly downhill course is not inevitable; remissions and recovery can occur. Therefore, the patient’s mental status must be examined. Under the pressure of a busy medical setting, psychotic illnesses can be overlooked, only to erupt in the labor room, operating room, or recovery room. Patients who believe that conspiracies or Martians are responsible for their symptoms can answer yes-or-no questions without revealing their delusions. Open-ended questions are more useful.

Sensationalized media accounts of violent crimes committed by psychotic patients exaggerate public misconceptions about these diseases. Statistically, individually with psychoses are more likely to be victims of perpetrators or crime. Patients under severe threat must be treated within an integrated system of social services, family support, rehabilitation, general medical care, psychotherapy, and psychopharmacology. In the process of referral to a mental health professional, the primary clinician should be clear, matter-of-fact, open, and confident of the possibility of successful treatment.

Management

Psychotic illnesses are nearly always managed by psychiatrists. However, a primary care practitioner can readily assume responsibility, in consultation with a psychiatrist or selected specialist who compiles the patient’s mental status. When a patient expresses delusions, the practitioner should not debate with the patient (88,89 and 90). It is important to concentrate on the patient’s strengths. She can easily be humiliated by thoughtless epithets or behaviors that betray the expectation of violence or incompetence. Patients with severe cases must be treated with an integrated system of social services, family support, rehabilitation, general medical care, psychotherapy, and psychopharmacology. In the process of referral to a mental health professional, the primary clinician should be clear, matter-of-fact, open, and confident of the possibility of successful treatment.

References

Benign conditions of the female genital tract include lesions of the uterine corpus and cervix, ovaries and fallopian tubes, and the vagina and vulva. A classification of the benign lesions of the vulva, vagina, and cervix appears in Table 13.1. Leiomyoma, polyps, and hyperplasia are the most common benign conditions of the uterus in adult women. Benign tumors of the ovaries are listed in Table 13.2.

Common gynecologic problems include abnormal bleeding, a pelvic mass, and vulvovaginal symptoms. The causes of vaginal bleeding and a pelvic mass vary by age group (Table 13.3). For each age group, the most common causes of these problems are described, along with techniques of diagnosis and principles of management. Malignant diseases are presented in Chapters 30 through 35.
Abnormal Bleeding

Prepubertal Age Group:

To appropriately evaluate a young girl with vaginal bleeding, the events of puberty must be understood. The hormonal changes that control the cyclic functioning of the hypothalamic–pituitary–ovarian axis are described in Chapter 7. An understanding of the normal sequence and timing of these events is critical to an appropriate assessment of a girl at the onset of bleeding (see Chapter 23).

Differential Diagnosis

Slight vaginal bleeding can occur within the first few days of life because of withdrawal from the high level of maternal estrogens. New mothers of female infants should be informed of this possibility in an effort to preclude unnecessary anxiety. After the neonatal period, a number of causes of bleeding should be considered in this age group (Table 13.4). Menses rarely occurs before breast budding. Vaginal bleeding in the absence of secondary sexual characteristics should be evaluated carefully.

The causes of bleeding in this age group range from the medically mundane to malignancies that may be life-threatening. The source of the bleeding is sometimes difficult to identify, and parents who observe blood in a child's diapers or panties may be unsure of the source. Pediatricians will usually look for urinary causes of bleeding, and gastrointestinal factors should also be considered.

Vulvar Lesions Vulvar irritation can lead to pruritus with excoriation, maceration of the vulvar skin, or fissures that can bleed. Other visible external causes of bleeding in this age group include urethral prolapse, condylomas, or molluscum contagiosum. Urethral prolapse can present acutely with a tender mass that may be friable or bleed slightly; it occurs more commonly in African American girls. It may be confused with a vaginal mass. The classic presentation is a mass symmetrically surrounding the urethra. This condition can be managed medically with the application of topical estrogens. The presence of a condyloma should prompt questioning about abuse, although it has been suggested that a condyloma that appears during the first 2 years of life may have been acquired perinatally from a mother with human papillomavirus infection. Excoriation and hemorrhage into the skin can cause external bleeding.

Foreign Body A foreign body in the vagina is a common cause of vaginal discharge, which may appear purulent or bloody. Young children explore all orifices and may place all varieties of small objects inside their vaginas. An object, such as a small plastic toy, can sometimes be palpated on rectal examination. The most common foreign bodies are small pieces of toilet paper that find their way into the vagina. One recent study suggests that the presence of vaginal foreign bodies may be a marker for sexual abuse; although this is by no means always the case, the possibility of abuse should be kept in mind in examining any child with vulvovaginal symptoms.

Precocious Puberty Precocious puberty (see Chapter 23) occasionally is marked by vaginal bleeding in the absence of other secondary sexual characteristics, although it is more common for the onset of breast budding or pubic hair growth to occur before vaginal bleeding. Although a large observational study suggests that the onset of pubertal changes—breast budding and pubic hair—may occur earlier than had originally been thought, the onset of menses before age 8 is sufficiently early to warrant evaluation for precocious puberty.

Trauma Trauma can be a cause of genital bleeding. A careful history should be obtained from one or both parents or caretakers and the child herself, because trauma caused by sexual abuse is often not recognized. Physical findings that are inconsistent with the description of the alleged accident should prompt consideration of abuse and appropriate consultation or referral to an experienced social worker or sexual abuse team. There is a mandatory legal obligation to report suspected child physical abuse in all states; most states specifically require reporting child sexual abuse as well, but even in those that do not, the laws
are broad enough to encompass sexual abuse implicitly (10). Even the suspicion of sexual abuse requires notification. In general, straddle injuries affect the vulvar area, whereas penetrating injuries with lesions of the fourchette or lesions that extend through the hymenal ring are less likely to occur as a result of accidental trauma (Fig. 13.2) (11).

Figure 13-2 Straddle injury—vulvar hematoma in a 13-year-old girl.

The medical evaluation of suspected child sexual abuse is best managed by individuals who have experience in assessing the physical findings, laboratory results, and the child’s statements and behaviors. Genital findings have been described as follows (12):

1. Normal or unrelated to abuse
2. Nonspecific for abuse
3. Concerning for abuse
4. Clear evidence of blunt force or penetrating trauma.

The overall classification of the likelihood for abuse can be categorized as follows (12):

1. No evidence of abuse
2. Possible abuse
3. Probable abuse
4. Definitive evidence of abuse or penetrating trauma.

Most cases of child sexual abuse do not come to light with an acute injury and instead are associated with normal or nonspecific genital findings (13,14). Forms of abuse such as fondling or digital penetration may not result in lasting visible genital lesions.

Other Causes Other serious but rare causes of true vaginal bleeding include vaginal tumors. The most common tumor in the prepubertal age group is a rhabdomyosarcoma (sarcoma botryoides), which is associated with bleeding and a grapelike clustered mass (Chapter 31). Other forms of vaginal tumor are also rare but should be ruled out if no other obvious source of bleeding is found externally.

Hormonally active ovarian tumors can lead to endometrial proliferation and bleeding. Exogenously administered estrogens can result in bleeding. This can be caused by the prolonged use of topical estrogens prescribed as therapy for vulvovaginitis or labial adhesions or can result from accidental ingestion of prescription estrogens.

HR color=#000000 noShade SIZE=1> Diagnosis

A careful examination is indicated when a child makes genital complaints. The technique of examining the prepubertal child is described in Chapter 1. If no obvious cause of bleeding is visible externally or within the distal vagina, an examination can be performed using anesthesia and an endoscope to completely visualize the vagina and cervix. This exam is best performed by a clinician with experience in pediatric and adolescent gynecology.

If an ovarian or vaginal mass is suspected, a pelvic ultrasonographic examination can provide useful information. The appearance of the ovaries (normal prepubertal size and volume, follicular development, cystic or solid) can be noted, as well as the size and configuration of the uterus. The prepubertal uterus has a distinctive appearance, with equal proportions of cervix and fundus and a size of approximately 2 to 3.5 cm in length and 0.5 to 1 cm in width (Fig. 13.3). The fundus enlarges with estrogen stimulation. An ultrasonographic examination should be the first imaging study performed; more sophisticated imaging techniques such as magnetic resonance imaging (MRI) or computed tomography (CT) scanning are rarely indicated.

Figure 13-3 Pelvic ultrasound (transabdominal) of a premenarchal 10-year-old girl. U, uterine corpus; C, cervix. Note that the body of the uterus is about the same size as the cervix.

Management

The management of bleeding in the prepubertal age group is directed toward the cause of bleeding. If bloody discharge believed to be due to nonspecific vulvovaginitis persists despite therapy, further evaluation to rule out the presence of a foreign body may be necessary. Skin lesions (chronic irritation) and lichen sclerosus may be difficult or frustrating to manage but can be treated with a course of topical steroids; lichen sclerosus often requires ongoing maintenance therapy. Vaginal and ovarian tumors should be managed in consultation with a gynecologic oncologist.

Adolescence

To assess vaginal bleeding during adolescence, it is necessary to have an understanding of the range of normal menstrual cycles (see Chapter 7). During the first 2 years after menarche, most cycles are anovulatory. Despite this, they are somewhat regular, within a range of approximately 21 to 40 days (15,16 and 17). In more than one-fourth of girls, a pattern of plus or minus 10 days and a cycle length of 21 to approximately 42 days are established within the first three cycles; in one-half of girls, the pattern is established by the seventh cycle; and in two-thirds of girls, such a pattern is established within 2 years of menarche (17).
Normal Menses

The mean duration of menses is 4.7 days; 89% of cycles last 7 days. The average blood loss per cycle is 35 ml (18), and the major component of menstrual discharge is endometrial tissue. Recurrent bleeding in excess of 80 ml/cycle results in anemia.

Quantitative information about the volume of menstrual blood loss is of little clinical use, however. The common clinical practice of asking how many pads or tampons are soaked on a heavy day or per cycle can give a rough approximation of blood loss (3 to 5 pads per day is typical). Individual variations in fastidiousness, lack of familiarity with the volume of blood loss other than one’s own, and errors in estimation or recollection result in inaccuracies in estimations of menstrual volume. One study found that one-third of individuals who estimated their cycles to be moderate or light had bleeding in excess of 80 ml/cycle, whereas nearly one-half of those who described the bleeding as heavy had flow less than 80 ml/cycle (19). In addition, the amount of menstrual blood contained in each tampon or pad may vary both within brands as well as from one brand to another (20).

The transition from anovulatory to ovulatory cycles takes place during the first several years after menarche. It results from the so-called maturation of the hypothalamic–pituitary–ovarian axis, characterized by positive feedback mechanisms in which a rising estrogen level triggers a surge of luteinizing hormone and ovulation. Most adolescents have ovulatory cycles by the end of their second year of menstruation, although most cycles (even anovulatory ones) remain within a rather narrow range of approximately 21 to 42 days.

Cycles that are longer than 42 days, cycles that are shorter than 21 days, and bleeding that lasts more than 7 days should be considered out of the ordinary, particularly after the first 2 years from the onset of menarche. The variability in cycle length is greater during adolescence than adulthood; thus, greater irregularity is acceptable if significant anemia or hemorrhage is not present. However, consideration should be given to an evaluation of possible causes of abnormal menses (particularly underlying causes of anovulation such as androgen excess syndromes) for girls whose cycles are consistently outside normal ranges (21) or whose cycles were previously regular and become irregular.

Differential Diagnosis

Anovulation Anovulatory bleeding can be too frequent, prolonged, or heavy, particularly after a long interval of amenorrhea. The physiology of this phenomenon relates to a failure of the feedback mechanism in which rising estrogen levels result in a decline in follicle-stimulating hormone (FSH) with subsequent decline of estrogen levels. In anovulatory cycles, estrogen secretion continues, resulting in endometrial proliferation with subsequent unstable growth and incomplete shedding. The clinical result is irregular, prolonged, and heavy bleeding. Conditions that are associated with anovulation are listed in Table 13.5 and more fully discussed in Chapter 24, Chapter 25, and Chapter 27.

Studies of adolescent menses show differences in rates of ovulation based on the number of months or years postmenarche. The younger the age at menarche, the sooner regular ovulation is established. In one study, the time from menarche until 50% of the cycles were ovulatory was 1 year for girls whose menarche occurred when they were younger than 12 years of age, 3 years for girls whose menarche occurred between 12 and 12.9 years of age, and 4.5 years for girls whose menarche occurred at 13 years of age or older (22).

Pregnancy-related bleeding The possibility of pregnancy must be considered when an adolescent seeks treatment for abnormal bleeding. Bleeding in pregnancy can be associated with a spontaneous abortion, ectopic pregnancy, or other pregnancy-related complications such as a molar pregnancy. In the United States, 50% of 17-year-old females have had sexual intercourse (23). Issues of confidentiality for adolescent health care are addressed in Chapter 1.

Exogenous Hormones The cause of abnormal bleeding that is experienced while an individual is taking exogenous hormones usually is very different from bleeding that occurs without hormonal manipulation (24). Oral contraceptive use is associated with breakthrough bleeding, which occurs in as many as 30% to 40% of individuals during the first cycle of combination pill use. In addition, irregular bleeding can result from missed pills (25,26). Strict compliance with correct and consistent pill taking is difficult for many individuals who take oral contraceptives; one study reported that only 40% of women took a pill every day (27). Other studies suggest that adolescents have an even more difficult time taking oral contraceptives, missing an average of three pills per month (28). With this many missed pills, it is not surprising that some individuals experience irregular bleeding. The solution is to emphasize consistent pill taking; if the individual is unable to comply with daily pill use, perhaps an alternative contraceptive method may be preferable.

Other methods of contraception can also produce irregular bleeding.

Irregular bleeding occurs frequently in users of depotmedroxyprogesterone acetate (DMPA), although at the end of 1 year, more than 50% of users will be amenorrheic (29). The implantable subdermal levonorgestrel implant also is associated with relatively high rates of irregular and unpredictable bleeding (30). Other contraceptive methods, including the monthly injectable combination contraceptive and the progestin-containing intrauterine system are associated with irregular bleeding in the first few months of use (31,32). Although the mechanism of bleeding associated with these hormonal methods is not well established, many believe that bleeding occurs from an atrophic endometrium, suggesting options for therapy (24). However, it should not be assumed that any bleeding occurring while an individual is using a hormonal method of contraception is caused by that method. Other local causes of bleeding, such as cervicitis or endometritis, also can occur during hormone therapy (33).

Hematologic Abnormalities In the adolescent age group, the possibility of a hematologic cause of abnormal bleeding must be considered. One classic study reviewed all patient visits of adolescents to an emergency room with the complaint of excessive or abnormal bleeding (Fig. 13.41 (34)). The most common coagulation abnormality diagnosed was idiopathic thrombocytopenic purpura, followed by von Willebrand’s disease. Adolescents who have severe menorrhagia, especially at menarche, should be screened for coagulation abnormalities, including von Willebrand’s disease.
Infections Irregular or postcoital bleeding can be associated with chlamydial cervicitis. Adolescents have the highest rates of chlamydial infections of any age group, and screening for chlamydia should be performed routinely among sexually active teens (35).

Menorrhagia can be the initial sign for patients infected with sexually transmissible organisms. Adolescents have the highest rates of pelvic inflammatory disease (PID) of any age group when only sexually experienced individuals are considered (36) (see Chapter 15).

Other Endocrine or Systemic Problems Abnormal bleeding can be associated with thyroid dysfunction. Signs and symptoms of thyroid disease can be somewhat subtle in teens (Chapter 25). Hepatic dysfunction should be considered, because it can lead to abnormalities in clotting factor production.

Polycystic ovarian syndrome (PCOS) can occur during adolescence, and manifestations of excess androgen effect (hirsutism, acne) should prompt evaluation (37). Androgen disorders occur in about 5% to 10% of women, making them the most common endocrine disorders in women (Chapter 25). Classic PCOS, functional ovarian hyperandrogenism, or partial late-onset congenital adrenal hyperplasia all can occur in adolescence (38). These disorders are often overlooked, unrecognized, or untreated. Women with even mild disorders are candidates for intervention. These disorders may be a harbinger of diabetes, endometrial cancer, and cerebrovascular disease.

Acne, hirsutism and menstrual irregularities are often dismissed as normal during adolescence but may be manifestations of hyperandrogenism (39). If an androgen abnormality is not treated, it is likely to persist beyond adolescence. Obesity, hirsutism, and acne should be evaluated to minimize the significant psychosocial costs (40). Androgenic changes are partially reversible if detected early and managed appropriately. Behavioral changes (diet and exercise) are desirable. Signs of insulin resistance (acanthosis nigricans) should also be evaluated and managed appropriately.

Anatomic Causes Obstructive or partially obstructive genital anomalies typically present during adolescence. müllerian abnormalities, such as obstructing longitudinal vaginal septa or uterus didelphys, can cause hematocolpos or hematometra. If these obstructing anomalies have or develop a small outlet, the sign may be of persistent dark brownish discharge (old blood) rather than or in addition to a pelvic mass. Many varieties of uterine and vaginal anomalies exist and should be managed by or in consultation with clinicians who have sufficient experience and expertise with these anomalies. Fig. 13.5 illustrates situations in which abnormal bleeding can occur as a result of obstructing septa.

Figure 13-5 The types of obstructive or partially obstructive genital anomalies that can occur during adolescence.

Diagnosis

Any adolescent with abnormal bleeding should undergo sensitive pregnancy testing, regardless of whether she states that she has had intercourse. The medical consequences of failing to diagnose a pregnancy are too severe to risk missing the diagnosis. Complications of pregnancy should then be managed accordingly.

Laboratory Testing In addition to a pregnancy test, laboratory testing should include a complete blood count with platelets, coagulation studies, and bleeding time. Thyroid studies also may be appropriate. A complete pelvic examination is appropriate if the patient has been sexually active, is having severe pain, or an anomaly is suspected. Cultures for gonorrhea and testing for chlamydia infection are appropriate if the patient has been sexually active. Some young teens who have a history that is classic for anovulation, who deny sexual activity, and who agree to return for follow-up evaluation may be managed with a limited gynecologic examination and pelvic ultrasonography.

Imaging Studies If the pregnancy test is positive, pelvic imaging using ultrasonography may be necessary to confirm a viable intrauterine pregnancy and rule out a spontaneous abortion or ectopic pregnancy. If a pelvic mass is suspected on examination, or if the examination is inadequate (more likely to be the case in an adolescent than an older woman) and additional information is required, pelvic ultrasonography may be helpful. Although transvaginal ultrasonographic examination can be more helpful than transabdominal ultrasonography in ascertaining details of pelvic anatomy, the use of the vaginal probe may not be possible in a young girl or one who has not used tampons or had intercourse. Direct communication between the clinician and the radiologist can be helpful in identifying candidates for transvaginal ultrasonographic examination.

Other imaging studies are not indicated as initial testing but may be helpful in selected instances. If a pelvic ultrasonographic examination does not lead to clarification of the anatomy when vaginal septa, uterine septa, uterine duplication, or vaginal agenesis are suspected, MRI can be helpful in delineating anatomic abnormalities. It has been suggested that this imaging technique may replace laparoscopy in the evaluation of uterine and vaginal developmental anomalies (41). CT scanning may be helpful in detecting nongenital intraabdominal abnormalities.

Management

Management of bleeding abnormalities related to pregnancy, thyroid dysfunction, hepatic abnormalities, hematologic abnormalities, or androgen excess syndromes should be directed to treating the underlying condition. Oral contraceptives can be extremely helpful in managing androgen excess syndromes. After specific diagnoses have been ruled out by appropriate laboratory testing, anovulation or dysfunctional bleeding becomes the diagnosis of exclusion.

Anovulation: Mild Bleeding

Adolescents who have mildly abnormal bleeding, as defined by adequate hemoglobin levels and minimal disruption of daily activities, are best treated with frequent reassurance, close follow-up, and supplemental iron. If the patient has been bleeding heavily or for a prolonged interval, however, an apparent decrease in the bleeding does not necessarily mean that therapy is not required. This type of on-again, off-again bleeding characterizes anovulatory bleeding and is likely to continue in the absence of therapy.

A patient who is mildly anemic will benefit from hormone therapy. If the patient is not bleeding at the time of evaluation, a combination low-dose oral contraceptive can be prescribed to be used in the manner in which it is used for contraception (21 days of hormonally active pills, followed by 7 days of placebo, during which time withdrawal bleeding is expected). If the patient is not sexually active, she should be reevaluated after three to six cycles to determine if she desires to continue this regimen. Parents may sometimes object to the use of oral contraceptives if their daughter is not sexually active (or if they believe her not
to be or even if they would like her not to be). These objections are frequently based on misconceptions about the potential risks of the pill and can be overcome by careful explanation of the pill’s role as medical therapy. If the medication is discontinued when the young woman is not sexually active and she subsequently becomes sexually active and requires contraception, it may be difficult to explain the reinstitution of oral contraceptives to the parents. Consideration can certainly be given to continuing the pill, and parents should be reassured that there are no medical risks associated with prolonged use.

Sometimes, providing parents with accurate information about the safety of oral contraceptives, emphasizing that currently available oral contraceptive preparations contain lower doses of estrogens and progestins than those used in the 1960s and 1970s, and emphasizing the hormonal rather than contraceptive function, may not be persuasive. In such cases, cyclic progestins are an alternative. medroxyprogesterone acetate, 5 to 10 mg/day for 10 to 13 days every 1 to 2 months, prevents excessive endometrial buildup and irregular shedding caused by unopposed estrogen stimulation. This therapy also should be reevaluated regularly and accompanied by oral administration of iron. Eventual maturation of the hypothalamic–pituitary–ovarian axis usually will result in the establishment of regular menses unless there are underlying conditions such as hyperandrogenism. Individuals may choose to continue oral contraceptives for contraception or their noncontraceptive benefits (improvement of acne, decreased dysmenorrhea, and lighter, more regular menstrual flow).

Acute Bleeding: Moderate

Patients who are bleeding acutely but who are stable and do not require hospital admission will require doses of hormones that are much higher than those in oral contraceptives. An effective regimen is the use of combination monophasic oral contraceptives (every 6 hours for 4 to 7 days). After that time, the dose should be tapered or stopped to allow withdrawal flow. With this therapy, the patient and her parents should be given specific written and verbal instructions warning them about the potential side effects of high-dose hormone therapy—nausea, breast tenderness, and breakthrough bleeding. The patient should be instructed to call with any concerns rather than discontinue the pills, and she must understand that stopping the prescribed regimen may result in a recurrence of heavy bleeding.

Both the patient and her mother should be warned to expect heavy withdrawal flow for the first period. It will be controlled by the institution of combination low-dose oral contraceptive therapy given once daily and continued for three to six cycles to allow regular withdrawal flow. If the patient is not sexually active, the pill may be discontinued and the menstrual cycles may be reassessed.

Acute Bleeding: Emergency Management

The decision to hospitalize a patient depends on the rate of current bleeding and the severity of any existing anemia. The actual acute blood loss may not be adequately reflected in the initial blood count but will be revealed with serial hemoglobin assessments. The cause of acute menorrhagia may be a primary coagulopathy or disorder (54), so measurements of coagulation and hemostasis, including bleeding time, should be performed for any adolescent patients with acute menorrhagia. Von Willebrand’s disease, platelet disorders, or hematologic malignancies can all cause menorrhagia. Depending on the patient’s level of hemodynamic stability or compromise, a blood sample can be analyzed for type and screen. The decision to transfuse must be considered carefully, and the benefits and risks should be discussed with the adolescent and her parents. Generally, there is no need for transfusion unless the patient is hemodynamically unstable.

In patients who, by exclusion, have been diagnosed as having dysfunctional bleeding, hormone therapy usually makes it possible to avoid surgical intervention (dilation and curettage [D & C], operative hysteroscopy, or laparoscopy). A patient who has been hospitalized for severe bleeding requires aggressive management as follows:

1. After stabilization, when appropriate laboratory assessment and an examination have established a working diagnosis of anovulation; hormonal management will usually control bleeding.
2. Conjugated estrogens, either 25 to 40 mg given intravenously every 6 hours or 2.5 mg given orally every 6 hours, will usually be effective.
3. If estrogens are not effective, the patient should be reevaluated, and the diagnosis should be reassessed. The failure of hormonal management suggests that a local cause of bleeding is more likely. In this event, consideration should be given to a pelvic ultrasonographic examination to determine any unusual cause for bleeding (such as uterine leiomyomas or endometrial hyperplasia) and to assess the presence of intrauterine clots that may impair uterine contractility and prolong the bleeding episode.
4. If intrauterine clots are detected, evacuation of the clots (suction curettage or D & C) is indicated. Although a D & C will provide effective immediate control of the bleeding, it is unusual to reach this step in adolescents.

More drastic forms of treatment other than a D & C (such as dilation of the endometrium by laser or rollerball devices) are considered inappropriate for adolescents because of concerns about future fertility. If intravenous or oral administration of estrogen controls the bleeding, oral progestin therapy should be instituted and continued for several days to stabilize the endometrium. This therapy can be accomplished by using a combination oral contraceptive, usually one with 30 to 35 μg of estrogen, or by using the tapering regimen previously described. The medication can be tapered and ultimately stopped to allow withdrawal bleeding. Low-dose combination oral contraception should be continued for three to six cycles, or longer if desired, to provide normal menstrual cycles.

In general, the prognosis for regular ovulatory cycles and subsequent normal fertility in young women who experience an episode of abnormal bleeding is good, particularly for patients who develop abnormal bleeding as a result of anovulation within the first year after menarche and in whom there are no signs of other specific conditions. Some girls, including those in whom there is an underlying medical cause, such as polycystic ovary syndrome, will continue to have abnormal bleeding into middle and late adolescence and adulthood and will benefit from the ongoing use of oral contraceptives to manage hirsutism, acne, and irregular periods. Ovulation induction may be necessary to achieve fertility in these individuals. Girls with coagulopathies may also benefit from ongoing oral contraceptive use.

Long-term Hormonal Suppression

For patients with underlying medical conditions, such as coagulopathies or a malignancy requiring chemotherapy, long-term therapeutic amenorrhea with menstrual suppression using the following regimens may be necessary:

1. Progestins, such as oral norethindrone, norethindrone acetate, or medroxyprogesterone acetate, on a continuous daily basis
2. Continuous (noncyclic) combination regimens of oral estrogen and progestins (birth control pills) that do not include a withdrawal bleeding–placebo week
3. Depot formulations of progestins (DMPA), with or without concurrent estrogen
4. Gonadotropin-releasing hormone (GnRH) analogs with or without estrogen add-back therapy

The choice of regimen depends on various contraindications (such as active liver disease precluding the use of estrogens) and the clinician’s experience. Although the goal of these long-term suppressive therapies is amenorrhea, all of these regimens may be accompanied by breakthrough bleeding. They require regular follow-up visits and continued patient participation. Occasional episodes of spotting and mild breakthrough bleeding that do not result in a lowered hemoglobin level may be managed expectantly. When breakthrough bleeding affects the hemoglobin level, it should be evaluated with respect to the underlying disease. For example, in a patient with underlying platelet dysfunction, breakthrough bleeding may reflect a lowered platelet count. Bleeding in a patient with hepatic disease may reflect worsening hepatic function. Supplemental low-dose estrogen can be helpful in the management of excessive breakthrough bleeding that has no specific cause other than the hormone therapy.

Reproductive Age Group:

Normal Menses

Beyond the first 2 to 2 years after menarche, menstrual cycles generally conform to a cycle length of 21 to 35 days, with a duration of less than 7 days of menstrual flow. As a woman approaches menopause, cycle length becomes more irregular as more cycles become anovulatory. Although the most frequent cause of irregular bleeding is hormonal, other causes occur more often during the adolescent years. Pregnancy-related bleeding (spontaneous abortion, ectopic pregnancy) should always be considered, and a pregnancy test should always be obtained as part of the evaluation of abnormal bleeding. Although a variety of terms have been used to describe abnormal menses (Table 13.6), accurate characterization of the bleeding based on recorded records (preferably charted prospectively)
Dysfunctional Uterine Bleeding  The term dysfunctional uterine bleeding has been used to describe abnormal bleeding for which no specific cause has been found. It most often implies a mechanism of anovulation, although not all bleeding that is outside the normal range (either in cycle length or duration) is anovulatory. The term is a diagnosis of exclusion, which is probably more confusing than enlightening.

Most anovulatory bleeding is a result of what has been termed estrogen breakthrough. In the absence of ovulation and the production of progesterone, the endometrium responds to estrogen stimulation with proliferation. This endometrial growth without periodic shedding results in eventual breakdown of the fragile endometrial tissue. Healing within the endometrium is irregular and dysynchronous. Relatively low levels of estrogen stimulation will result in irregular and prolonged bleeding, whereas higher sustained levels result in episodes of amenorrhea followed by acute, heavy bleeding.

Pregnancy-related Bleeding  Spontaneous abortion can be associated with excessive or prolonged bleeding. In the United States, more than 50% of pregnancies are unintended (42), and 10% of women are at risk for unintended pregnancy but use no method of contraception. About one-half of unintended pregnancies are a result of nonuse of contraception; however, the other one-half are contraceptive failures (43). Unintended pregnancies are most likely to occur among adolescents and women over 40 years of age (Chapter 10). A woman may be unaware that she has conceived and may seek care because of abnormal bleeding. If an ectopic pregnancy is ruled out, the management of spontaneous abortion may include either observation, if the bleeding is not excessive, or curettage or D & C, depending on the clinician’s judgment and the patient’s preference (44,45 and 46).

Exogenous Hormones  Irregular bleeding that occurs while a woman is using contraceptive hormones should be considered in a different context than bleeding that occurs in the absence of exogenous hormone use. Breakthrough bleeding during the first 1 to 3 months of oral contraceptive use occurs in up to 30% to 40% of users and should almost always be managed expectantly with reassurance, because the frequency of breakthrough bleeding decreases with each subsequent month of use (25). Irregular bleeding can also result from inconsistent pill taking (25,46 and 48).

Not all bleeding that occurs while an individual is taking oral contraceptives is a consequence of hormonal factors. In one study, women who experienced irregular bleeding while taking oral contraceptives were found to have a higher frequency of chlamydia infection (39).

Irregular bleeding is almost invariably present during the first year of use of both the subdermal implant levonorgestrel and DMPA (29,30). Because irregular bleeding is so often present with these two methods of contraception, counseling prior to their use is imperative. Women who do not believe that they can cope with irregular, unpredictable bleeding may not be good candidates for these methods. As with oral contraceptives, the possibility of nonhormonal causes of bleeding (e.g., chlamydial cervicitis) should be considered. When an individual is using one of these methods, reassurance and counseling should be provided. The exact mechanism of irregular bleeding associated with progestin-only methods is not well established but may be related to incomplete suppression of follicular activity with periodic elevations of estradiol (24). The additional oral use of estrogen has been reported to improve bleeding with both DMPA and the subdermal levonorgestrel (29,50,51). Combination oral contraceptives have also been used in patients with the subdermal levonorgestrel implants. For a patient who is considering removal of the implants because of irregular bleeding and who may choose an oral contraceptive as an alternative, the use of combination pills can allow both the clinician and the patient to assess the patient's tolerance of and compliance with oral contraceptive therapy. The use of nonsteroidal antiinflammatory drugs (NSAIDs) has been shown to result in decreased bleeding (50).

Endocrine Causes  Both hypothyroidism and hyperthyroidism can be associated with abnormal bleeding. With hypothyroidism, menstrual abnormalities including menorrhagia are common (Chapter 25). The most common cause of thyroid hyperfunctioning in premenopausal women is Graves' disease, which occurs 4 to 5 times more often in women than men. Hyperthyroidism can result in oligomenorrhea or amenorrhea, and it can also lead to elevated levels of plasma estrogen (52).

Diabetes mellitus can be associated with anovulation, obesity, insulin resistance, and androgen excess. Androgen disorders are very common among women of reproductive age and should be evaluated and managed. Because androgen disorders are associated with significant cardiovascular disease, the condition should be diagnosed promptly. This condition becomes more immediately of concern in older women of reproductive age. Management of bleeding disorders associated with androgen excess consists of an appropriate diagnostic evaluation followed by the use of oral contraceptives (in the absence of significant contraindications), coupled with dietary and exercise modification.

Anatomic Causes  Anatomic causes of abnormal bleeding in women of reproductive age occur more frequently than in women in other age groups. Uterine leiomyomas occur in as many as one-half of all women older than 35 years of age and are the most common tumors of the genital tract (53). Although they are asymptomatic in many or even most women, they have been estimated to be clinically significant in at least 25% of the American female population of reproductive age. They are more common in African American women and have been associated with obesity (54,55). The mechanism of abnormal bleeding related to leiomyomas is not well established. Several theories have been postulated, including dysregulation of a number of growth factors that regulate angiogenesis in a uterus in which leiomyomas are present.

Growth factors that are currently being investigated for their role in the process of abnormal bleeding associated with leiomyomas include basic fibroblast growth factor, vascular endothelial growth factor, heparin-binding epidermal growth factor, platelet-derived growth factor, transforming growth factor-β, parathyroid hormone-related protein, and prolactin (56).

Diagnosis is based on the characteristic finding of an irregularly enlarged uterus. The size and location of the usually multiple leiomyomas can be confirmed and documented with pelvic ultrasonography (Fig. 13.6). If the examination is adequate and symptoms are absent, ultrasonography is not always necessary unless an ovarian mass cannot be excluded.
Endometrial polyps are a cause of intermenstrual bleeding, irregular bleeding, and menorrhagia. The diagnosis is based on either visualization with hysteroscopy or sonohysterography, or on the microscopic assessment of tissue obtained by a biopsy done in the office or a curettage specimen.

Abnormal bleeding, either intermenstrual or postcoital, can be caused by cervical lesions. Bleeding can also result from endocervical polyps and infectious cervical lesions, such as condylomas, herpes simplex virus ulcerations, chlamydial cervicitis, or cervicitis caused by other organisms.

Other benign cervical lesions, such as wide erosion of endocervical columnar epithelium or Nabothon cysts, may be noted on examination but rarely cause symptoms.

Coagulopathies and Other Hematologic Causes The presence of excessively heavy menses should prompt an evaluation of hematologic status. A complete blood count will be helpful in detecting anemia, significant problems such as leukemia, or disorders associated with thrombocytopenia. Abnormal liver function, which can be seen with alcoholism or other chronic liver diseases, results in inadequate production of clotting factors and can lead to excessive menstrual bleeding. Coagulation abnormalities such as von Willebrand's disease can have a variable clinical picture and may escape diagnosis until the reproductive years (57,58). Oral contraceptives, which increase the level of factor VIII, can be helpful and newer therapies, including desmopressin acetate, may be necessary, particularly before surgical procedures are performed.

Infectious Causes Women with cervicitis, particularly chlamydial cervicitis, can experience irregular bleeding and postcoital spotting (see Chapter 15). Therefore, cervical testing for chlamydia should be considered, especially for sexually active adolescents, women in their twenties, and women who are not in a monogamous relationship. Endometritis can cause excessive menstrual flow. Thus, a woman who seeks treatment for menorrhagia and increased menstrual pain and has a history of light-to-moderate previous menstrual flow may have an upper genital tract infection or PID (endometritis, salpingitis, oophoritis). Occasionally, chronic endometritis will be diagnosed when an endometrial biopsy is obtained for evaluation of abnormal bleeding in a patient without specific risk factors for PID.

Neoplasia Abnormal bleeding is the most frequent symptom of women with invasive cervical cancer. An obvious cervical lesion should be evaluated by biopsy, because the results of a Papanicolaou (Pap) test may be falsely negative with invasive lesions as a result of tumor necrosis. Unopposed estrogen has been associated with a variety of abnormalities of the endometrium, from cystic hyperplasia to adenomatous hyperplasia, hyperplasia with atypia, and invasive carcinoma. Endometrial hyperplasia, hyperplasia with atypia, and invasive endometrial cancer can be diagnosed by endometrial sampling or D & C. Such sampling is mandatory in the evaluation of abnormal bleeding in women older than 35 to 40 years of age, obese women, and those with a history of anovulation. Although vaginal neoplasia is uncommon, the vagina should be evaluated carefully when there is abnormal bleeding. This includes attention to all surfaces of the vagina, including anterior and posterior areas that may be obscured by the vaginal speculum on examination.

Diagnosis

For all women, the evaluation of excessive and abnormal menses includes a thorough medical and gynecologic history, the exclusion of pregnancy, and a careful gynecologic examination. For women of normal weight between the ages of approximately 20 and 35 years who do not have clear risk factors for sexually transmitted diseases (STDs), who have no signs of androgen excess, who are not using exogenous hormones, and who have no other findings on examination, management may be based on a clinical diagnosis.

Laboratory Studies In any patients with excessive bleeding, an objective measurement of hematologic status should be performed with a complete blood count to detect anemia or thrombocytopenia. A pregnancy test should be performed to rule out pregnancy-related problems. In addition, because of the possibility of a primary coagulation problem, screening coagulation studies such as a prothrombin time and partial thromboplastin time should be considered; an assessment of bleeding time may help diagnose von Willebrand's disease, although if this diagnosis is strongly suspected further testing may be necessary (59).

Imaging Studies Women with abnormal bleeding who have a history consistent with chronic anovulation, who are obese, or who are older than 35 to 40 years of age require further evaluation. A pelvic ultrasonographic examination may be helpful in delineating anatomic abnormalities if the examination results are suboptimal or if an ovarian mass is suspected. A pelvic ultrasonographic examination is the best technique for evaluating the uterine contour, endometrial thickness, and ovarian structure. Ultrasonography is particularly valuable in determining whether a pelvic mass is cystic or solid. The use of a vaginal probe transducer allows assessment of endometrial and ovarian disorders, particularly in women who are obese.

Sonohysterography involves the infusion of saline into the uterine cavity during transvaginal ultrasonography. This technique has been reported to be especially helpful in visualizing intruterine problems such as polyps (60).

Transvaginal ultrasonography alone has also been reported to have value in differentiating benign polyps from malignant lesions. Although these techniques are helpful in visualizing intruterine pathology, histologic evaluation is required to rule out malignancy (61). Other techniques, such as CT scanning and MRI, are not as helpful in the initial evaluation and should be reserved for specific indications, such as exploring the possibility of other intraabdominal disorders or adenopathy. Contrast-enhanced MRI shows promise for staging endometrial cancer (62).

Endometrial Sampling Endometrial sampling should be performed to evaluate abnormal bleeding in women who are at risk for endometrial polyps, hyperplasia, or carcinoma. The technique of D & C, which in the past was used extensively for the evaluation of abnormal bleeding, has been replaced largely by endometrial biopsy in the office. The classic study in which a D & C was performed before hysterecotomy with the conclusion that less than one-half of the endometrium was sampled in more than one-half of the patients has led to questioning the use of D & C for endometrial diagnosis (63,64).

It has been argued that there is no longer a place for a “blind” D & C, because hysteroscopy can direct a biopsy to a specific area of the uterus (65). In most cases, however, endometrial biopsy done in the office can be performed instead of a D & C. Indications for a hysteroscopy with endometrial sampling include the following:

1. Cervical stenosis precluding adequate endometrial biopsy
2. Patient intolerance of endometrial biopsy
3. Anatomic factors (e.g., massive obesity) precluding adequate endometrial biopsy
4. The presence of abnormal bleeding in a patient who is undergoing another surgical procedure performed with general anesthesia.

A number of devices are designed for endometrial sampling (Fig. 13-7), including an inexpensive disposable flexible plastic sheath with an internal plunger that allows tissue aspiration, disposable plastic cannula of varying diameters that attach to a manually locking syringe that allows the establishment of a vacuum, and cannulae (both rigid metal and plastic) with tissue traps that attach to an electric vacuum pump. Several studies comparing the adequacy of sampling using these devices with D & C have shown a comparable ability to detect abnormalities. It should be noted that these devices are designed to obtain a tissue sample rather than a cytologic washing. Devices designed to obtain an endometrial sample for assessment of cytology are also available; they have been shown to detect invasive cancer as well as D & C but to have a lower sensitivity for detecting premalignant lesions.
One study reported a delay in withdrawal bleeding occurs beyond the expected time of withdrawal following cyclic progestin therapy. Modified this regimen to include continuous (every day) estrogen therapy. In addition, studies have assessed endometrial response to varying durations of progestin therapy. Because some women become symptomatic during the days when they are not taking estrogens, as in the previously described regimen, many clinicians have modified this regimen to include continuous (every day) estrogen therapy. Most women who take these hormones in this way will experience withdrawal bleeding, which is perceived by the patient as a menstrual period. Although the incidence of withdrawal bleeding does decline somewhat with age and duration of therapy, more than 50% of women continue to experience bleeding after 65 years of age.

In Europe, the intrauterine device containing norgestrel has long been used therapeutically to deliver progestin locally to the endometrium in women with abnormal bleeding. This device was approved for use in the United States in 2000, and its use has been suggested as a cost-effective alternative to hysterectomy for excessive bleeding.

The surgical options range from hysteroscopy with resection of submucous leiomyomas to laparoscopic techniques of myomectomy to uterine artery embolization to hysterectomy. Although this effect was first demonstrated with oral contraceptive formulations that contained higher doses of both estrogens and progestins than the agents used today, low-dose combined oral contraceptives have been shown to have a similar effect. Low-dose oral contraceptives may be used during the perimenopausal years in healthy nonsmoking women who have no major cardiovascular risk factors. The benefits of menstrual regulation in such women often override the potential risks.

Differential Diagnosis

The causes of postmenopausal bleeding and the percentage of patients who seek treatment for different conditions are presented in Table 13.7. The surgical management of abnormal bleeding should be reserved for situations in which medical therapy has been unsuccessful or is contraindicated. The D & C, although sometimes appropriate as a diagnostic technique, is questionable as a therapeutic modality. One study reported a measured reduction in menstrual blood loss for the first menstrual period only. Other studies have suggested a longer-lasting benefit. Much has been written about the psychologic sequelae of hysterectomy, and some of the aforementioned surgical techniques have been developed in an effort to provide less drastic management options. Most well-controlled recent studies have suggested that, in the absence of preexisting psychopathology, indicated but elective surgical procedures for hysterectomy have few, if any, significant psychologic sequelae (including depression) (Chapter 12).

**Benign Disorders**

Women who are taking hormone replacement therapy during menopause may be using a variety of hormonal regimens that can result in bleeding (see Chapter 29). In the classic sequential method of administration, estrogens are given for the first 25 days of each month. A progestin, often 5 to 10 mg/day of medroxyprogesterone acetate, is added to the last 10 to 13 days of this regimen in an effort to reduce the risk of endometrial hyperplasia and neoplasia. Most women who take these hormones in this way will experience withdrawal bleeding, which is perceived by the patient as a menstrual period. Although the incidence of withdrawal bleeding does decline somewhat with age and duration of therapy, more than 50% of women continue to experience bleeding after 65 years of age.

Because some women become symptomatic during the days when they are not taking estrogens, as in the previously described regimen, many clinicians have modified this regimen to include continuous (every day) estrogen therapy. In addition, studies have assessed endometrial response to varying durations of progestin regimens; longer duration of therapy is associated with a lower risk of hyperplasia. It has been suggested that endometrial sampling is indicated for any bleeding that occurs beyond the expected time of withdrawal following cyclic progestin therapy. A significant change in withdrawal bleeding (e.g., absence of withdrawal
bleeding for several months followed by resumption of bleeding or a marked increase in the amount of bleeding) should prompt endometrial sampling.

Patient compliance has been a significant issue with hormone replacement therapy. Missed doses of medication and failure to take the medication in the prescribed fashion can lead to irregular bleeding or spotting that is benign in origin but that can result in patient dissatisfaction (83).

The primary problems that women report with hormone replacement therapy include vaginal bleeding and weight gain. The use of a continuous low-dose combined regimen has the advantage that, for many women, bleeding will ultimately cease after a period of several months during which irregular and unpredictable bleeding may occur (84). Some women are unable to tolerate these initial months of irregular bleeding. The risk of endometrial hyperplasia or neoplasia with this regimen appears to be low.

Other benign causes of bleeding include atrophic vaginitis and cervical polyps, which may become apparent as postcoital bleeding or spotting. Women who experience bleeding after menopause may attempt to minimize the extent of the problem; they may describe only “spotting” or “pink or brownish discharge.” However, any indication of bleeding or spotting should be evaluated. In the absence of hormone therapy, any bleeding after menopause (classically defined as absence of menses for 1 year) should prompt evaluation with endometrial sampling. At least one-fourth of postmenopausal women with bleeding have a neoplastic lesion.

Endometrial polyps and other abnormalities can be seen in women who are taking tamoxifen. These polyps can be benign, although they must be distinguished from endometrial malignancies, which may also occur with this medication.

Neoplasia Endometrial, cervical, and ovarian malignancies must be ruled out in cases of postmenopausal bleeding. A Pap test is essential when postmenopausal bleeding is noted, although the Pap test is an insensitive diagnostic test for detecting endometrial cancer. The Pap test results are negative in some cases of invasive cervical carcinoma because of tumor necrosis.

Cervical malignancy is diagnosed by cervical biopsy of grossly visible lesions and colposcopically directed biopsy for women with abnormal Pap test results (Chapter 18). Functional ovarian tumors may produce estrogen and lead to endometrial hyperplasia or carcinoma, which may cause bleeding.

Diagnosis

Pelvic examination to detect local lesions and a Pap test to assess cytology are essential first steps in finding the cause of postmenopausal bleeding. Endometrial sampling, through office biopsy, hysteroscopy, or D & C, is usually considered essential. Pelvic ultrasonographic examination and, in particular, vaginal ultrasonography or sonohysterography can suggest the cause of bleeding. Initial biopsy done in the office is more cost effective than D & C, surgery, or observation alone (85). The cost effectiveness of other screening strategies, including transvaginal ultrasonography or sonohysterography, has not been well studied. It has been suggested that an endometrial thickness of less than 6 mm (4 to 5 mm in some reports) measured by transvaginal ultrasonography is unlikely to indicate endometrial cancer.

Management

The management of atrophic vaginitis includes topical or systemic use of estrogens after other causes of abnormal bleeding have been excluded. Cervical polyps can easily be removed in the office.

Endometrial Hyperplasia The terminology that has been used to describe endometrial hyperplasia is confusing, and the clinician must consult with the pathologist to ensure an understanding of the diagnosis. The following lesions are considered to be benign: anovulatory, proliferative, cystic glandular hyperplasia, simple cystic hyperplasia (Fig. 13.8), simple hyperplasia, and adenomatous hyperplasia without atypia. These terms reflect and describe an exaggerated proliferative response of the endometrium. In most cases, benign endometrial hyperplasia is resolved with D & C or progesterin therapy. Repeat surveillance with endometrial biopsy may be warranted.

![Figure 13-8 Simple cystic hyperplasia of the endometrium. The normal tabular pattern is replaced by cystically dilated proliferative endometrial glands. (From Berek JS, Hacker NF. Practical gynecologic oncology, 2nd ed. Baltimore: Lippincott Williams & Wilkins, 1994:126, with permission.)](image)

The presence of atypia with abnormal proliferation, including features of back-to-back crowding of the glands, with epithelial activity demonstrated by papillary projections into the glands, is associated with an increased risk of progression to endometrial carcinoma (Fig. 13.9). These architectural abnormalities may be associated with individual cellular atypia (enlarged, irregular nuclei, chromatin clumping, and prominent nucleoli). The presence of mitotic activity also can be variable.

![Figure 13-9 Atypical hyperplasia (complex hyperplasia with severe nuclear atypia). The proliferative endometrial glands reveal considerable crowding and papillary infoldings. The endometrial stroma, although markedly diminished, can still be recognized between the glands. (From Berek JS, Hacker NF. Practical gynecologic oncology, 2nd ed. Baltimore: Lippincott Williams & Wilkins, 1994:127, with permission.)](image)

The management of endometrial hyperplasia rests on an understanding of the natural history of the lesion involved. In one study, only 2% of 122 patients with hyperplasia without cytologic atypia progressed to carcinoma, whereas 23% of those with atypical hyperplasia subsequently developed carcinoma (86). Architectural complexity and crowding appears to place patients at greater risk for progression than does the presence of cytologic atypia alone.
These data suggest that most women with endometrial hyperplasia will respond to progestin therapy and are not at increased risk of developing cancer. Patients who do not respond are at a significantly increased risk of progressing to invasive cancer and should be advised to have a hysterectomy. Patients who are unlikely to respond can be identified on the basis of cytologic atypia. A suggested scheme of management is outlined in Fig. 13.10. This treatment is discussed in more detail in Chapter 30.

Pelvic Mass

The probable causes of a pelvic mass found on physical examination or through radiologic studies are vastly different in a prepubertal child than they are during adolescence or during the postmenopausal years (Table 13.3). A pelvic mass may be gynecologic in origin or it may arise from the urinary tract or bowel. The gynecologic causes of a pelvic mass may be uterine, adnexal, or more specifically ovarian.

Prepubertal Age Group

Differential Diagnosis

Fewer than 5% of ovarian malignancies occur in children and adolescents. Ovarian tumors account for approximately 1% of all tumors in these age groups. Germ cell tumors make up one-half to two-thirds of ovarian neoplasms in individuals younger than 20 years of age. A review of studies conducted from 1940 until 1975 concluded that 35% of all ovarian neoplasms occurring during childhood and adolescence were malignant (87). In girls younger than 9 years of age, approximately 60% of the ovarian neoplasms were found to be malignant (88,89). Germ cell tumors account for approximately 60% of ovarian neoplasms in children and adolescents compared with 20% of these tumors in adults (87). Epithelial neoplasms are rare in the prepubertal age group; thus, data usually are reported from referral centers. However, some reports include only neoplastic masses, whereas others include nonneoplastic masses; some series combine data from prepubertal and adolescent girls. One community survey of ovarian masses revealed that the frequency of malignancy was much lower than previously reported; of all ovarian masses confirmed surgically in childhood and adolescence, only 6% of masses were malignant neoplasms, and only 10% of neoplasms were malignant (90). Surgical decision making clearly influences the statistics on incidence; the surgical excision of functional masses that would resolve in time inflates the percentage of benign masses. In one series, nonneoplastic masses in young women and girls younger than 20 years of age constituted two-thirds of the total (91). Even in girls younger than 10 years of age, 60% of the masses were nonneoplastic, and two-thirds of the neoplastic masses were benign. Functional, follicular cysts can occur in fetuses, newborns, and prepubertal children. They may be associated with sexual precocity.

Abdominal or pelvic pain is one of the most frequent initial symptoms. In a prepubertal child, a pelvic mass very quickly becomes abdominal in location as it enlarges because of the small size of the pelvic cavity. The diagnosis of ovarian masses in the prepubertal age group is difficult because of the rarity of the condition (and therefore a low index of suspicion), because many symptoms are nonspecific, and acute symptoms are more likely to be attributed to more common entities such as appendicitis. Abdominal palpation and bimanual rectoabdominal examination are important in any child who has nonspecific abdominal or pelvic complaints. An ovarian mass that is abdominal in location can be confused with other abdominal masses occurring in children, such as Wilms’ tumor or neuroblastoma. Acute pain is often associated with torsion. The ovarian ligament becomes elongated as a result of the abdominal location of these tumors, thus creating a predisposition to torsion.

Diagnosis and Management

In recent years, ultrasonography has become an excellent tool for predicting the presence of a simple ovarian cyst. Figure 13.11 outlines a plan of management for pelvic masses in the prepubertal age group. Unilocular cysts are virtually always benign and will regress in 3 to 6 months; thus, they do not require surgical management with oophorectomy or oophorocystectomy. Close observation is recommended, although there is a risk of ovarian torsion that must be discussed with the child’s parents. Recurrence rates after cyst aspiration (either ultrasonographically guided or with laparoscopy) may be as high as 50%. Attention must be paid to long-term effects on endocrine functioning as well as future fertility; preservation of ovarian tissue is a priority for patients with benign tumors. Premature surgical therapy for a functional ovarian mass can result in ovarian and tubal adhesions that can affect future fertility.

Figure 13-11 Management of pelvic masses in premenarchal and adolescent girls.

Additional imaging studies, such as CT scanning, MRI, or Doppler flow studies, may be helpful in establishing the diagnosis (92). Because the risk of a germ cell tumor is high, the finding of a solid component mandates surgical assessment (93).

Adolescent Age Group

Differential Diagnosis

Ovarian Masses

Many series report ovarian tumors occurring in both children and adolescents. Some reports divide their findings by age group, although this is less helpful than a division by pubertal development. The clinician’s response to a pelvic or abdominal mass varies in relation to the patient’s pubertal status, because the likelihood of...
functional masses increases after menarche. The risk of malignant neoplasms is lower among adolescents than among younger children. Epithelial neoplasms occur with increasing frequency with age. Germ cell tumors are the most common tumors of the first decade of life but occur less frequently during adolescence (Chapter 32). Mature cystic teratoma is the most frequent neoplastic tumor of children and adolescents, accounting for more than one-half of ovarian neoplasms in women younger than 20 years of age (84).

It is well established that neoplasia can arise in dysgenetic gonads. Malignant tumors have been found in about 25% of dysgenetic gonads of patients with a Y chromosome (85). Gonadectomy is recommended for patients with XY gonadal dysgenesis or its mosaic variations (95).

Functional ovarian cysts occur frequently in adolescence. They may be an incidental finding on examination or may be associated with pain caused by torsion, leakage, or rupture. Endometriosis is less common during adolescence than in adulthood, although it can occur during adolescence. In series of adolescents referred with chronic pain, 50% to 65% have been found to have endometriosis (96). Although endometriosis can occur in young women with obstructive genital anomalies (presumably as a result of retrograde menstruation), most adolescents with endometriosis do not have associated obstructive anomalies (98). In young women, endometriosis may have an atypical appearance, with nonpigmented or vesicular lesions, peritoneal windows, and puckering.

**Uterine Masses**

Other causes of pelvic masses, such as uterine abnormalities, are rare in adolescence. Uterine leiomyomas are not commonly seen in this age group. Obstructive uterovaginal anomalies occur during adolescence, at the time of menarche, or shortly thereafter. The diagnosis is frequently neither suspected nor delayed, particularly when the patient is seen by a general surgeon (99). A wide range of anomalies can be seen, from imperforate hymen to transverse vaginal septa, to vaginal agenesis with a normal uterus and functional endometrium, vaginal duplications with obstructing longitudinal septa, and obstructed uterine horns. Patients may seek treatment for cyclic pain, amenorrhea, vaginal discharge, or an abdominal, pelvic, or vaginal mass (Fig. 13.5). A hematocolpos, hematometra, or both frequently will be present, and the resulting mass can be quite large.

**Inflammatory Masses**

Adolescents have the highest rates of PID of any age group, if one considers only individuals at risk for STD (i.e., those who have had sexual intercourse) (100). Thus, an adolescent who has pelvic pain may be found to have an inflammatory mass. The diagnosis of PID is primarily a clinical one based on the presence of lower abdominal, pelvic, and adnexal tenderness; cervical motion tenderness; a mucopurulent discharge; and the signs of elevated temperature, white blood cell count, or sedimentation rate (Chapter 15). PID is clearly associated with the risks of acquiring STD, and methods of contraception may either decrease the risk (oral contraceptives, male latex condoms) or increase it (the intrauterine device in the interval immediately after insertion) (101,102). As infection of the lower genital tract is commonly accompanied by infection of the urinary tract, simultaneous cultures should be obtained. Treatment of PID with antibiotics is accompanied by the following complications: infertility, chronic pelvic pain, and ectopic pregnancy. Inflammatory masses may consist of a tuboovarian complex (a mass consisting of matted bowel, tube, and ovary), tuboovarian abscess (a mass consisting primarily of an abscess cavity within an anatomically defined structure such as the ovary), pyosalpinx or, chronically, hydrosalpinx.

**Pregnancy**

In adolescents, pregnancy should always be considered as a cause of a pelvic mass. In the United States, more than 50% of adolescent young women have experienced sexual intercourse by 17 years of age (23). Most pregnancies in adolescents are unintended; 82% of pregnancies in adolescents under age 15, 83% in women aged 15 to 17, and 75% of pregnancies in women aged 18 to 19 are unintended (102). Adolescents may be more likely than adults to deny the possibility of pregnancy because of wishful thinking, anxiety about discovery by parents or peers, or unfamiliarity with menstrual cycles and information about fertility. Ectopic pregnancies may cause pelvic pain and an adnexal mass. With the availability of quantitative measurements of b-human chorionic gonadotropin (hCG), more ectopic pregnancies are being discovered before rupture, allowing conservative management with laparoscopic surgery or medical therapy with methotrexate (Chapter 17). The risk of ectopic pregnancy varies by method of contraception; users of no contraception have the highest risk, whereas oral contraceptive users have the lowest risk (103). As in older patients, parovarian cysts and nongynecologic masses can appear as a pelvic or abdominal mass in adolescents.

**Diagnosis**

A history and pelvic examination are critical in the diagnosis of a pelvic mass. Considerations in adolescents include the anxiety associated with a first pelvic examination, as well as issues of confidentiality related to questions of sexual activity. Techniques for history taking and the performance of the first examination are discussed in Chapter 1.

Laboratory studies should always include a pregnancy test (regardless of stated sexual activity), and a complete blood count may be helpful in diagnosing inflammatory masses. Tumor markers, including a-fetoprotein and hCG, may be elaborated by germ cell tumors and can be useful in preoperative diagnosis as well as follow-up (Chapter 32).

As in all age groups, the primary diagnostic technique for evaluating pelvic masses in adolescents is ultrasonography. Although transvaginal ultrasonographic examinations may provide more detail than transabdominal ultrasonography, particularly for inflammatory masses, a transvaginal examination may not be well tolerated by adolescents (104). For cases in which the ultrasonographic examination is inconclusive, CT or MRI may be helpful. An accurate preoperative assessment of anatomy is critical, particularly in cases of uterovaginal malformations. MRI can be useful for evaluating this group of rare anomalies (105,106). Some sort of imaging technique should be used in evaluating adolescents who come in with abdominal pain, because an unexpected finding of a complex uterine or vaginal anomaly requires careful surgical planning and decision making.

**Management**

The management of masses in adolescents depends on the suspected diagnosis as well as the initial complaint. Figure 13.11 outlines a plan of management for pelvic masses in adolescents. Asymptomatic unilocular cystic masses are best managed conservatively, because the likelihood of malignancy is low. If surgical management is required based on symptoms or uncertainty of diagnosis, attention should be paid to minimizing the risks of subsequent infertility resulting from pelvic adhesions. In addition, every effort should be made to conserve ovarian tissue. In the presence of a malignant unilateral ovarian mass, management may include unilateral oophorectomy rather than more radical surgery, even if the ovarian tumor has metastasized (Chapter 32). Analysis of frozen sections may not be reliable. In general, conservative surgery is appropriate; further surgery can be performed, if necessary, after an adequate histologic evaluation of the ovarian tumor.

Some surgeons advocate the use of laparoscopy in the management of suspected acute PID to confirm the diagnosis, and to perform irrigation, lysis of adhesions, drainage and irrigation of unilateral or bilateral pyosalpinx or tuboovarian abscess, or extirpation of significant disease (106,107). While symptoms persist in a patient with the clinical diagnosis of PID or tuboovarian abscess, laparoscopy should be considered to confirm the diagnosis. A clinical diagnosis may be incorrect in up to one-third of patients (108). The surgical management of inflammatory masses is rarely necessary in adolescents, except to treat rupture of tuboovarian abscess or failure of medical management with broad-spectrum antibiotics (Chapter 15). Conservative, unilateral adnexitomy usually can be performed in these situations, rather than a pelvic clean-out, maintaining reproductive potential. Percutaneous drainage, transvaginal ultrasonographic drainage, and laparoscopic management of tuboovarian abscesses are becoming more popular, although, as with the laparoscopic management of ovarian masses, the surgeon's skill and experience are critical and prospective studies are lacking (109). Laparoscopic management has been associated with a risk of major complications, including bowel obstruction and bowel or vessel injury (110).

**Reproductive Age Group**

Conditions diagnosed as a pelvic mass in women of reproductive age are presented in Table 13.8.
Differential Diagnosis

It is difficult to determine the frequency of diagnoses of pelvic mass in women of reproductive age, because many pelvic masses are not ultimately treated with surgery. Nonovarian or nongynecologic conditions may be confused with an ovarian or uterine mass (Table 13.8). There are series in which the frequency of masses found at laparotomy is reviewed, although the varying indications for surgery, indications for referral, type of practice (gynecologic oncology versus general gynecology), and patient populations (a higher percentage of African Americans with uterine leiomyomas, for example) will affect the percentages. Benign masses, such as functional ovarian cysts, will often not require surgery.

Age is an important determinant of the likelihood of malignancy. In one series of women who underwent laparotomy for pelvic mass, malignancy was seen in only 10% of those younger than 30 years of age, and most of these tumors had low malignant potential (111). The most common tumors found during laparotomy for pelvic mass are mature cystic teratomas or dermoids (seen in one-third of women younger than 30 years of age) and endometriomas (approximately one-fourth of women 31 to 49 years of age) (111).

Uterine Masses

Uterine leiomyomas, also known as myomas or fibroids, are by far the most common benign uterine tumors. Other benign uterine growths, such as uterine vascular tumors, are rare. Uterine leiomyomas are usually diagnosed on physical examination. They may be subserosal, intramucosal, or submucosal in location within the uterus or located in the cervix, in the broad ligament, or on a pedicle (Fig. 13.12). They are estimated to be present in at least 20% of all women of reproductive age and may be discovered incidentally during routine annual examination. Leiomyomas are more common in African American than in white women. Asymptomatic fibroids may be present in 40% to 50% of women older than 35 years of age (55). They may occur singly but often are multiple. They may cause a range of symptoms, from abnormal bleeding to pelvic pressure, which may lead to the diagnosis. Fewer than one-half of uterine leiomyomas are estimated to produce symptoms, however (112).

The cause of uterine leiomyomas is unknown. Several studies have suggested that each leiomyoma arises from a single neoplastic cell within the smooth muscle of the myometrium (113). There appears to be an increased familial incidence (55). Hormonal responsiveness and binding has been demonstrated in vitro. Fibroids have the potential to enlarge during pregnancy as well as to regress after menopause.

Grossly, fibroids are discrete nodular tumors that vary in size and number (Fig. 13.13). They may be microscopic or huge (a uterine weight of 74 lb has been reported). They may cause symmetric uterine enlargement or they may distort the uterine contour significantly. The consistency of an individual leiomyoma varies from hard and stony (as with a calcified leiomyoma) to soft (as with cystic degeneration), although the usual consistency is described as firm or rubbery. Although they do not have a true capsule, the margins of the tumor are blunt, noninfiltrating, and pushing, and are usually separated from the myometrium by a pseudocapsule of connective tissue, which allows easy enucleation at the time of surgery. There is usually one major blood vessel supplying each tumor. The cut surface is characteristically whorled.

Degenerative changes are reported in approximately two-thirds of all specimens (114). Leiomyomas, with an increased number of mitotic figures, may occur in various forms: (a) during pregnancy or in women taking gestational agents, (b) with necrosis, and (c) as a smooth muscle tumor of uncertain malignant potential (defined as having 5 to 9 mitoses per 10 high-power fields [hpf] that do not demonstrate nuclear atypia or giant cells, or with a lower mitotic count [2 to 4 mitoses/10 hpf] that does demonstrate atypical nuclear features or giant cells). Studies suggest that malignant degeneration of a preexisting leiomyoma is extremely uncommon, occurring in less than 0.5% (115).
Leiomyosarcoma is a rare malignant neoplasm composed of cells that have smooth muscle differentiation (Chapter 30). The typical patient with leiomyosarcoma is in her mid-50s and seeks treatment for abnormal bleeding. In most cases, diagnoses are determined (postoperatively) after microscopic examination of a uterus removed because of leiomyomas. Sarcomas that have a malignant behavior have >10 mitoses/hpf.

Uterine fibroids are frequently diagnosed on the basis of clinical findings of an enlarged, irregular uterus on pelvic examination. They are also frequently noted on ultrasonography obtained for a variety of indications and may be an incidental finding. However, any pelvic tumor potentially can be confused with an enlarged uterus.

The most common initial symptom associated with fibroids, and the one that most frequently leads to surgical intervention, is menorrhagia. Chronic pelvic pain may also be present. Pain may be characterized as dysmenorrhea, dyspareunia, or pelvic pressure (Chapter 14). Acute pain may result from torsion of a pedunculated leiomyoma or infarction and degeneration. The following urinary symptoms may be present:

1. Frequency, which may result from extrinsic pressure on the bladder.
2. Partial ureteral obstruction may be caused by pressure from large tumors at the pelvic brim. Reports suggest some degree of ureteral obstruction in 30% to 70% of tumors above the pelvic brim. Ureteral compression is 3 to 4 times more common on the right, because the left ureter is protected by the sigmoid colon.
3. Rarely, complete urethral obstruction, resulting from elevation of the base of the bladder by the cervical or lower uterine leiomyoma with impingement on the region of the internal sphincter, may occur.

Leiomyomas are an infrequent primary cause of infertility and have been reported as a sole cause in only a small percentage of infertile patients (116). One review of myomectomies performed for all indications noted a history of infertility in 27% of women (112). Pregnancy loss or complications can occur in women with leiomyomas, although most patients have uncomplicated pregnancies and deliveries. One study calculated a 10% rate of pregnancy complications in women with fibroids (117). Although growth of leiomyomas may occur with pregnancy, no demonstrable change in size (based on serial ultrasonographic examination) has been noted in 70% to 80% of patients (118, 119). The risk of pregnancy complications is influenced by both myoma location and size (120).

The following symptoms may infrequently be associated with leiomyomas:

1. Rectosigmoid compression, with constipation or intestinal obstruction
2. Prolapse of a pedunculated submucous tumor through the cervix, with associated symptoms of severe cramping and subsequent ulceration and infection (uterine inversion has also been reported)
3. Venous stasis of the lower extremities and possible thrombophlebitis secondary to pelvic compression
4. Polycythemia
5. Ascites.

Ovarian Masses

During the reproductive years, the most common ovarian masses are benign. About two-thirds of ovarian tumors are encountered during the reproductive years. Most ovarian tumors (80% to 85%) are benign, and two-thirds of these occur in women between 20 and 44 years of age. The chance that a primary ovarian tumor is malignant in a patient younger than 45 years of age is less than 1 in 15. Most tumors produce few or only mild, nonspecific symptoms. The most common symptoms include abdominal distension, abdominal pain or discomfort, lower abdominal pressure sensation, and urinary or gastrointestinal symptoms. If the tumor is hormonally active, symptoms of hormonal imbalance, such as vaginal bleeding related to estrogen production, may be present. Acute pain may occur with adnexal torsion, cyst rupture, or bleeding into a cyst. Pelvic findings in patients with benign and malignant tumors differ. Masses that are unilateral, cystic, mobile, and smooth are most likely to be benign, whereas those that are bilateral, solid, fixed, irregular, and associated with ascites, cul-de-sac nodules, and a rapid rate of growth are more likely to be malignant.

In terms of assessing ovarian masses, the distribution of primary ovarian neoplasms by decade of life can be helpful (121). Ovarian masses in women of reproductive age are most likely to be benign, but the possibility of malignancy must be considered (Fig. 13.14).

![Figure 13-14 Preoperative evaluation of the patient with an adnexal mass. (From Berek JS, Hacker NF. Practical gynecologic oncology, 3rd ed. Baltimore: Lippincott Williams & Wilkins, 2000:465.)](image)

Nonneoplastic Ovarian Masses Functional ovarian cysts include follicular cysts, corpus luteum cysts, and theca lutein cysts. All are benign and usually do not cause symptoms or require surgical management. The annual rate of hospitalization for functional ovarian cysts has been estimated to be as high as 500 per 100,000 woman-years in the United States, although little is known about the epidemiology of the condition (122). The most common functional cyst is the follicular cyst, which is rarely larger than 8 cm. A cystic follicle can be defined as a follicular cyst when its diameter is greater than 3 cm. These cysts are usually found incidental to pelvic examination, although they may rupture, causing pain and peritoneal signs (Fig. 13.15). They usually resolve in 4 to 8 weeks.

![Figure 13-15 Follicular cysts of the ovary.](image)

Corpus luteum cysts are less common than follicular cysts. Corpus luteum cysts may rupture, leading to a hemoperitoneum and requiring surgical management (Fig. 13.16). Patients taking anticoagulant therapy are at particular risk for rupture. Rupture of these cysts occurs more often on the right side and may occur during...
intercourse. Most ruptures occur on cycle days 20 to 26 (123).

Figure 13-16 Corpus luteum cyst of the ovary. The left ovary is normal and the right ovary has a ruptured hemorrhagic corpus luteum cyst.

Theca lutein cysts are the least common of functional ovarian cysts. They are usually bilateral and occur with pregnancy, including molar pregnancies. They may be associated with multiple gestations, molar pregnancies, choriocarcinoma, diabetes, Rh sensitization, clomiphene citrate use, human menopausal gonadotropin–human chorionic gonadotropin ovulation induction, and the use of GnRH analogs. Theca lutein cysts may be quite large (up to 30 cm), are multicystic, and regress spontaneously (124,125).

Combination monophasic oral contraceptive therapy has been reported to markedly reduce the risk of functional ovarian cysts (126). It appears that, in comparison with previously available higher-dose pills, the effect of cyst suppression with current low-dose oral contraceptives is attenuated (127,128). Most studies have suggested that the use of triphasic oral contraceptives is not associated with an appreciable increased risk of functional ovarian cysts (129). It has been suggested that smokers have as much as a twofold increased risk of developing ovarian cysts, although other studies have not found smoking to be a risk factor (130,131).

Other Benign Masses Women with endometriosis may develop ovarian endometriomas ("chocolate" cysts), which can enlarge to 6 to 8 cm in size. A mass that does not resolve with observation may be an endometrioma (Chapter 26).

Although enlarged, polycystic ovaries were originally considered the sine qua non of PCOS, polycystic ovaries probably represent a final common phenotype of a wide variety of causes; they are not always present with other features of the syndrome. The prevalence of PCOS among the general population depends on the diagnostic criteria used. In one study, 257 volunteers were examined with ultrasonography; 22% were found to have polycystic ovaries (132). The finding of bilateral generously sized ovaries on examination or polycystic ovaries on ultrasonographic examination should prompt evaluation for the full-blown syndrome which includes hyperandrogenism and chronic anovulation as well as polycystic ovaries. Therapy for PCOS is medical and generally not surgical.

Neoplastic Masses More than 80% of benign cystic teratomas (dermoid cysts) occur during the reproductive years, although dermoid cysts have a wider age distribution than other ovarian germ cell tumors (133). Histologically, benign cystic teratomas have an admixture of elements (Fig. 13.17). In one study of ovarian masses that were surgically excised, dermoid cysts represented 62% of all ovarian neoplasms in women younger than 40 years of age (121). Malignant transformation occurs in less than 2% of dermoid cysts in women of all ages; most cases occur in women older than 40 years of age. The risk of torsion with dermoid cysts is approximately 15%, and it occurs more frequently than with ovarian tumors in general, perhaps because the high-fat content of most dermoid cysts, allowing them to float within the abdominal and pelvic cavity (Fig. 13.18). As a result of this fat content, on pelvic examination, a dermoid cyst frequently is described as anterior in location. They are bilateral in approximately 10% of cases, although many have advanced the argument against bivalving a normal-appearing contralateral ovary because of the risk of adhesions, which may result in infertility. An ovarian cystectomy is almost always possible, even if it appears that only a small amount of ovarian tissue remains. Preserving a small amount of ovarian cortex in a young patient with a benign lesion is preferable to the loss of the entire ovary (134). Laparoscopic cystectomy is often possible, and intraoperative spill of tumor contents is rarely a cause of complications (135,136).

Figure 13-17 Histologic appearance of a mature cystic teratoma of the ovary.

The risk of epithelial tumors increases with age. Although serous cystadenomas are often considered the more common benign neoplasm, in one study, benign cystic teratomas represented 66% of benign tumors in women younger than 50 years of age; serous tumors accounted for only 20% (121). Serous tumors are generally benign; 5% to 10% have borderline malignant potential and 20% to 25% are malignant. Serous cystadenomas are often multilocular, sometimes with papillary components (Fig. 13.19). The surface epithelial cells secrete serous fluid, resulting in a watery cyst content. Psammoma bodies, which are areas of fine calcific granulation, may be scattered within the tumor and are visible on radiograph. A frozen section is necessary to distinguish between benign (Fig. 13.20), borderline, and malignant serous tumors, because gross examination alone cannot make this distinction. Mucinous ovarian tumors may grow to large dimensions (Fig. 13.21). Benign mucinous tumors typically have a lobulated, smooth surface, are multilocular, and may be bilateral in up to 10% of cases. Mucoid material is present within the cystic loculations (Fig. 13.22). Five to ten percent of mucinous ovarian tumors are malignant. They may be difficult to distinguish histologically from metastatic gastrointestinal malignancies. Other benign ovarian tumors include fibromas (Fig. 13.23) (a focus of stromal cells), Brenner tumors (Fig. 13.24) (which appear grossly...
similar to fibromas and which are frequently found incidentally), and mixed forms of tumors such as the cystadenofibroma.

Other Adnexal Masses

Masses that include the fallopian tube are related primarily to inflammatory causes in this age group. A tuboovarian abscess can be present in association with PID (Chapter 15). In addition, a complex inflammatory mass consisting of bowel, tube, and ovary may be present without a large abscess cavity. Ectopic pregnancies can occur in the reproductive age group and must be excluded when a patient presents with pain, a positive pregnancy test, and an adnexal mass (Chapter 17). Paraovarian cysts may be noted either on examination or on imaging studies. In many instances, a normal ipsilateral ovary can be visualized using ultrasonography. The frequency of malignancy in paraovarian tumors is quite low, although one review reported malignancy in 2% of patients (137).

Diagnosis

A complete pelvic examination, including rectovaginal examination and Pap test, should be performed. Estimations of the size of a mass should be presented in centimeters rather than in comparison to common objects or fruit (e.g., orange, grapefruit, tennis ball, golf ball). After pregnancy has been excluded, one simple office technique that can help determine whether a mass is uterine or adnexal includes sounding and measuring the depth of the uterine cavity.

Other Studies Endometrial sampling with an endometrial biopsy or D & C is mandatory when both a pelvic mass and abnormal bleeding are present. An endometrial lesion—carcinoma or hyperplasia—may coexist with a benign mass such as a leiomyoma. In a woman with leiomyomas, abnormal bleeding cannot be assumed to be caused solely by the fibroids. Clinicians differ in recommendations about the need for endometrial biopsy when the diagnosis is leiomyomas with regular menses.

Studies of the urinary tract may be necessary if urinary symptoms are prominent, including cystometric measurements if incontinence or pressure is a prominent symptom. Cystoscopy may sometimes be necessary or appropriate to rule out intrinsic bladder lesions. Ultrasonography or an intravenous pyelogram may be appropriate to demonstrate ureteral deviation, compression, or dilation in the presence of moderately large and laterally located fibroids or other pelvic mass. Such findings rarely provide an indication for surgical intervention for otherwise asymptomatic leiomyomas.

Laboratory Studies Laboratory studies that are indicated for women of reproductive age with a pelvic mass include pregnancy test, cervical cytology, complete blood count, erythrocyte sedimentation rate, and testing of stool for occult blood. The value of tumor markers, such as CA125 in a premenopausal woman with a pelvic mass, has been widely debated. A number of benign conditions, including uterine leiomyomas, PID, pregnancy, and endometriosis can cause elevated CA125 levels, and thus may lead to unnecessary surgical intervention.

Imaging Studies Other studies may be necessary or appropriate. The most commonly indicated study is pelvic ultrasonography, which will help document the origin of the mass to determine whether it is uterine, adnexal, bowel, or gastrointestinal. The ultrasonographic examination also provides information about the size of the mass and its consistency—unilocular cyst, mixed echogenicity (Fig. 13.25), multiloculated cyst, solid cyst (Fig. 13.26)—which can help determine management.

Figure 13-25 Transvaginal ultrasonogram of a unilocular ovarian cyst. This is characteristic of a benign process or corpus luteum cyst.

Figure 13-26 Transvaginal ultrasonogram of a complex, predominantly solid mass.

The value of transvaginal and transabdominal ultrasonography in the diagnosis of pelvic masses has been compared. Transvaginal scanning has the advantage of providing additional information about the internal architecture or anatomy of the mass. Heterogeneous pelvic masses, described as tuboovarian abscesses on transabdominal ultrasonography, can be separated on transvaginal scans into pyosalpinx, hydrosalpinx, tuboovarian complex, and tuboovarian abscess (103) (Fig. 13.27).
The diagnostic accuracy of transvaginal ultrasonography in diagnosing endometrioma can be quite high (Fig. 13.28). Endometriomas can have a variety of ultrasonographic appearances, from purely cystic to varying degrees of complexity with septation or debris, to a solid appearance. A scoring system that can help predict benign versus malignant adnexal masses is presented in Table 13.9. Other ultrasonographic indices have been developed in an attempt to predict the risk of malignancy in ovarian masses (138,139). The indices have included not only characterizations of morphology such as septations, solid components, and ovarian size, but also demographic factors (i.e., age) as well as color flow imaging and Doppler waveform analysis (140,141). Although an analysis of such features may be helpful, histologic confirmation of surgically removed persistent masses remains the standard of care (142).

Table 13.9. Ultrasonographic Scoring System for Adnexal Masses

CT is seldom indicated as a primary diagnostic procedure, although it may be helpful in planning treatment when a malignancy is strongly suspected or when a nongynecologic disorder may be present. An abdominal flat plate radiograph is not a primary diagnostic procedure, although taken for other indications it may reveal calcifications that can assist in the discovery or diagnosis of a mass. Pelvic calcifications (teeth) consistent with a benign cystic teratoma (Fig. 13.29), a calcified uterine fibroid, or scattered calcifications consistent with psammoma bodies of a papillary serous cystadenoma can be seen on abdominal radiograph.

Hysteroscopy provides direct evidence of intrauterine pathology or submucous leiomyomas that distort the uterine cavity (see Chapter 21). Hysterosalphingography will demonstrate indirectly the contour of the endometrial cavity and any distortion or obstruction of the uterolutal junction secondary to leiomyomas, an extrinsic mass, or peritubal adhesions. The techniques combining hysterosalphingography, in which fluid is instilled into the uterine cavity, with transvaginal ultrasonography have been helpful in the diagnosis of intrauterine pathology.

MRI may be most useful in the diagnosis of uterine anomalies, although its value rarely justifies the increased cost of the procedure over ultrasonography for the diagnosis of other pelvic masses (143,144 and 145).

Management

The management of a pelvic mass is based on an accurate diagnosis. An explanation of this diagnosis should be conveyed to the patient, along with a discussion of the likely course of the disease (e.g., growth of uterine leiomyomas, regression of fibroids at menopause, regression of a follicular cyst, the uncertain malignant potential of an ovarian mass). All options for management should be presented and discussed, although it is appropriate for the physician to state a recommended
Management of Leiomyomas

Nonsurgical Management  Judicial patient observation and follow-up are indicated primarily for uterine leiomyomas; intervention is reserved for specific indications and symptoms (146). Periodic examinations are indicated to ensure that the tumors are not growing rapidly. Uterine size should be recorded on the patient’s chart, and the location of palpable and ultrasonographically localized leiomyomas should be described and diagrammed.

The use of GnRH agonists results in a 40% to 60% decrease in uterine volume and can be of value in some clinical situations. Treatment results in hypoestrogenism, which has been associated with reversible bone loss and symptoms such as hot flashes. Thus, treatment has been limited to short-term use, although low-dose hormonal replacement may be effective in minimizing the hypoestrogenic effects. Regrowth of leiomyomas is experienced within a few months after stopping therapy in about one-half of women treated. Some indications for the use of GnRH agonists in women with leiomyomas are as follows:

1. Preservation of fertility in women with large leiomyomas before attempting conception, or preoperative treatment before myomectomy
2. Treatment of anemia to allow recovery of normal hemoglobin levels before surgical management, minimizing the need for transfusion or allowing autologous blood donation
3. Treatment of women approaching menopause in an effort to avoid surgery
4. Preoperative treatment of large leiomyomas to make vaginal hysterectomy, hysteroscopic resection or ablation, or laparoscopic destruction more feasible
5. Treatment of women with medical contraindications to surgery
6. Treatment of women with personal or medical indications for delaying surgery.

Newer therapies combining GnRH agonists with estrogen add-back therapy have been promising in reducing side effects of agonist therapy alone, although this is a costly alternative (147). Tibolone, a synthetic steroid with estrogenic, progestational, and androgenic activity, has been widely used outside the United States for treatment of menopausal symptoms; its use with GnRH agonists as add-back therapy holds promise for longer-term therapy of leiomyoma (148). The use of GnRH antagonists holds promise, because it appears to be less likely than agonist therapy to result in bleeding early in therapy; it also causes rapid uterine shrinkage (149,150).

RU486, a progesterone antagonist, also has been shown to decrease the size of uterine leiomyoma (151). As the role of growth factors in leiomyoma-associated bleeding is better elucidated, treatment targeted at the growth factor or its receptor may prove useful. In addition, as the molecular biology and genetics of leiomyoma are better understood, newer nonsurgical therapies may be developed.

Surgical Therapy  Determining potential indications for surgical treatment requires careful judgment and assessment of the degree of associated symptoms. Asymptomatic leiomyomas do not usually require surgery. Some indications for surgery include the following:

1. Abnormal uterine bleeding with resultant anemia, unresponsive to hormonal management
2. Chronic pain with severe dysmenorrhea, dyspareunia, or lower abdominal pressure or pain
3. Acute pain, as in torsion of a pedunculated leiomyoma, or prolapsing submucous fibroid
4. Urinary symptoms or signs such as dysuria or increased frequency after complete evaluation
5. Infertility, with leiomyomas as the only abnormal finding
6. Markedly enlarged uterine size with compression symptoms or discomfort

Rapid enlargement of the uterus during the premenopausal years or any increase in uterine size in a postmenopausal woman have been suggested as indications for surgery because of the inability to exclude uterine sarcoma.

Although the absolute risk of uterine sarcomas developing in a fibroid uterus has been reported to be less that 2 to 3 per 1,000, one study found sarcomas to be no more common in women with rapid uterine growth than those without such growth (152). However, rapid enlargement has not been well defined, and serial measurements may be hampered by variations in the interpretation of size by the examiner or series of examiners.

Hysterectomy has long been viewed as the definitive management of symptomatic uterine leiomyomas (Chapter 22). Myomectomy is an alternative to hysterectomy for patients who desire childbearing, who are young, or who prefer that the uterus be retained. Recent studies suggest that the morbidity of abdominal myomectomy and hysterectomy are similar, although previous reports had suggested higher risks for myomectomy, including the risks of hemorrhage and transfusion requirements (153,154). Blood loss and risk of transfusion are greater for women with larger uteri (155). Laparoscopic myomectomy minimizes the size of the abdominal incision, although several small incisions are required. The biggest concerns with laparoscopic myomectomy include the removal of large myomas through small incisions and the repair of the uterus (146). Instruments that efficiently morcellate the myomas have been developed, although skilled surgical techniques are required. There is controversy as to whether laparoscopic suturing provides strength and healing equivalent to that achieved with laparotomy. Risks include the need to convert to a laparotomy and the risk of uterine rupture with subsequent pregnancy (148). Vaginal myomectomy is indicated in the case of a prolapsed pedunculated submucous fibroid. Hysteroscopic resection of small submucous leiomyomas is a technique that may offer benefits for a selected group of patients (Chapter 21). The recurrence risk for leiomyomas has been reported to be as high as 50% after myomectomy, with up to one-third requiring repeat surgery (112,156). Endometrial ablation can decrease bleeding for women with primary intramural fibroids and can be performed using a variety of techniques, including laser ablation, thermal ablation, resection, or chemical destruction (148).

The preoperative use of GnRH agonists for both hysterectomy and myomectomy result in a decrease in uterine size. The expense, side effects, and time required to achieve a significant decrease in size are limitations to their use. The use of GnRH agonists may make surgical plans less distinct and thus myomectomy technically more difficult.

Noninvasive approaches to the management of leiomyomas include myolysis and uterine artery embolization, although long-term safety and efficacy have not yet been demonstrated. Uterine artery embolization has been reported to have serious consequences, including infection, massive bleeding, and necrosis requiring emergency surgery (157). Pain is frequently a consequence. The procedure has been characterized as investigational (146). Myolysis involves the use of lasers to coagulate or needle electrodes to deliver an electrical current to individual leiomyoma (158).

Ovarian Masses

The now-routine application of ultrasound technology to gynecologic examinations has led to the more frequent detection of ovarian cysts. Ultrasoundography is a relatively easy diagnostic study to perform, but this ease has led to the labeling of physiologic ovarian morphology, cystic follicles, as pathologic and the referral of patients for surgical excision, which is often unnecessary. Treatment of ovarian masses that are suspicious to be functional tumors is expectant. A classic study popularized the use of oral contraceptives as suppressive therapy, although the results of this study have been misinterpreted (159). In this study, 286 patients (aged 16 to 48 years) with adnexal masses were treated with combination oral contraceptives. Eighty-one women had a persistent mass after this therapy; surgery was performed on these women, none of whom was found to have a physiologic cyst. This study has been interpreted to indicate that suspected functional cysts should be treated with oral contraceptives, although there are no data to indicate a more rapid resolution with oral contraceptives than with time alone. If a woman needs contraception and wishes to use oral contraceptives for birth control or for noncontraceptive indications, it is perfectly acceptable to prescribe them in this setting. However, a number of randomized prospective studies have shown no acceleration of the resolution of functional ovarian cysts (which were associated with the use of domperidone citrate or human menopausal gonadotropin) with oral contraceptives compared with observation alone (160,161 and 162). However, oral contraceptives are effective in reducing the risk of subsequent ovarian cysts.

Symptomatic cysts should be evaluated promptly, although mildly symptomatic masses suspected to be functional should be managed with analgesics rather than surgery to avoid the development of adhesions that may impair subsequent fertility. Surgical intervention is warranted in the presence of severe pain or the suspicion of malignancy or torsion. On ultrasonography, large cysts and those that have multiloculations, septa, papillae, and increased blood flow should be suspected of neoplasia. If a malignant cyst is suspected at any age, exploratory laparotomy should be performed promptly.

Ovarian or adnexal torsion is suspected on the basis of peritoneal signs and the acute of onset. Doppler flow studies suggesting abnormal flow are highly predictive.
of torsion (153). The absence of internal ovarian flow is not specific to torsion, and may be seen with cystic lesions, although in these situations peripheral flow is typically visualized (164). Visualization of a twisted vascular pedicle has also been shown to be highly predictive (165). Normal flow does not exclude torsion, and in one study 60% of surgically confirmed cases of torsion had normal Doppler flow (163). The management of suspected ovarian torsion, which can occur at any age, from prepubertal to postmenopausal, is surgical. Previous studies have suggested that ovarian torsion requires oophorectomy on the basis that the untwisting (detorsion) of the ovarian pedicle would lead to embol. Recent studies have suggested that the primary management should be detorsion with ovarian cystectomy, if a cyst is present; normal ovarian function frequently results even in ovaries that do not initially appear to be viable (166,167 and 168). This management is particularly important in prepubertal and young women (169). Oophorexy may be helpful in preventing recurrent torsion (169,170).

Ultrasonographic or CT-directed aspiration procedures should not be used in women in whom there is a suspicion of malignancy. In the past, laparoscopic surgery for ovarian masses has been reserved for diagnostic or therapeutic purposes in patients at very low risk for malignancy. One survey of gynecologic oncologists' experiences with patients who had originally undergone laparoscopic management of malignant or borderline tumors suggested that so-called benign characteristics do not preclude malignancy and that laparoscopic management can be associated with partial or complete excision, delays in definitive surgery, or seeding and spread of disease (171,172 and 173). Even with frozen section, there is a possibility of a missed diagnosis of malignancy, which would necessitate reexploration. Whether this practice results in long-term compromise of outcome is unclear; thus, the laparoscopic management of complex masses that may be malignant remains controversial (171,174). More recently, the laparoscopic management of masses without selection for benign characteristics has been advocated provided the surgeon has expertise in operative laparoscopy, the capability for immediate and accurate pathologic examination is available, and appropriate further treatment can be instituted if indicated (including laporotomy for malignancy) (175).

The management of presumptive benign ovarian masses with operative laparoscopy has become increasingly common. The choice of surgical approach (laparotomy or laparoscopy) should be based on the surgical indications, the patient's condition, the surgeon's expertise and training, informed patient preference, and the most recent data supporting the chosen approach (176). The clear advantage of this technique is the shorter hospital stay, shorter recovery time, and lessened postoperative pain. Few controlled trials have been performed to compare the laparoscopic approach with laparotomy (129) (Chapter 21). Surgical complications include bowel injury, ureteral or other urinary tract injury, cannula site vessel injury, or incisional hernia (177). In one series the overall complication rate was 13.3% (177). Randomized clinical trials evaluating laparoscopy versus laparotomy in the treatment of ovarian masses have been performed and typically demonstrate a shorter hospitalization time with less postoperative pain and a shorter recovery period (159,178,179).

The role of laparoscopy has been even more controversial in the removal of dermoid cysts than with other benign masses. Concern centers around prevention of spill of the cyst contents. Randomized clinical trials have been reported with variable findings regarding spill; some studies suggest that cyst contents are more likely to spill with laparoscopy, whereas others do not find a difference or note no increase in morbidity when spillage occurred (180,181 and 182). Cystotomy and the use of an endoscopic specimen bag have been associated with lower rates of tumor spillage (182,183).

### Postmenopausal Age Group

#### Differential Diagnosis

**Ovarian Masses**

**During the postmenopausal years, the ovaries become smaller (129):**

1. **Before menopause**, the dimensions are approximately $3.5 \times 2 \times 1.5$ cm.
2. **In early menopause**, the ovaries are approximately $2 \times 1.5 \times 0.5$ cm.
3. **In late menopause**, they are even smaller: $1.5 \times 0.75 \times 0.5$ cm.

Barber has described the postmenopausal palpable ovary (PMPO) syndrome, suggesting that any ovary that is palpable on examination beyond the menopause is abnormal and deserves evaluation (184); however, this has not been shown to be a reliable predictor of malignancy (Chapter 32). Clearly, body habitus makes a difference in the ease of examination, but a postmenopausal ovary that, on palpation, is comparable in size to a premenopausal ovary is abnormally large. Ovarian cancer is predominantly a disease of postmenopausal women; the incidence increases with age, and the average patient age is about 56 to 60 years (Chapter 32).

With increased use of pelvic ultrasonographic evaluation, a new problem has arisen in postmenopausal women: the discovery of a small ovarian cyst. This is particularly troublesome in a woman who is entirely asymptomatic and whose ultrasonographic examination was performed for indications unrelated to pelvic pathology. It has been suggested that *when the cyst is asymptomatic, small (<5 cm in diameter), unilocular, and thin-walled, with a normal CA125 level, the cyst contents should be aspirated (185).* Even with frozen section, there is a possibility of a missed diagnosis of malignancy, which would necessitate reexploration. Whether this practice results in long-term compromise of outcome is unclear; thus, the laparoscopic management of complex masses that may be malignant remains controversial (171,174). The clear advantage of this technique is the shorter hospital stay, shorter recovery time, and lessened postoperative pain. Few controlled trials have been performed to compare the laparoscopic approach with laparotomy (129) (Chapter 21). Surgical complications include bowel injury, ureteral or other urinary tract injury, cannula site vessel injury, or incisional hernia (177). In one series the overall complication rate was 13.3% (177). Randomized clinical trials evaluating laparoscopy versus laparotomy in the treatment of ovarian masses have been performed and typically demonstrate a shorter hospitalization time with less postoperative pain and a shorter recovery period (159,178,179).

**Uterine and Other Masses**

In women who have been receiving regular gynecologic care, the discovery of a new pelvic mass after menopause is worrisome because the likelihood of malignant neoplasm is high if it is an ovarian tumor. Many postmenopausal women have not had regular gynecologic care, however, so the discovery of a mass may reflect the persistence of uterine fibroids that had not previously been discovered. Some women may not remember having been told they had a pelvic mass. Thus, a review of medical records may be helpful in determining the preexistence of a benign pelvic mass. Other benign masses can occur in this age group, including paraovarian cysts and unusual tumors, such as benign retroperitoneal cysts of müllerian type (192).

**Diagnosis**

A personal and family medical history is helpful in detecting individuals at increased risk for the development of ovarian cancer. Several hereditary family cancer syndromes involve ovarian neoplasms (see Chapter 32). However, patients with hereditary forms of epithelial ovarian cancer account for only a small percentage of all cases; 90% to 95% of cases of ovarian cancer are sporadic and without identifiable heritable risk (193).

In one multicenter prospective study, the individual accuracy of pelvic examination, ultrasonography, and serum CA125 assessments in discriminating between benign and malignant pelvic masses was approximately the same (approximately 75%) (194). When the results of all three examinations were negative, no malignancy was found.

**Management**

The use of improved imaging techniques may allow the nonoperative management of ovarian masses that are probably benign (Table 13.9). When surgery is believed to be indicated, based on characteristics of the mass, a family or personal medical history, or the patient's desire for definitive diagnosis, selection of the appropriate surgical procedure is critical for effective therapy. The standard of care continues to be laparotomy, with appropriate staging procedures performed as necessary (Chapter 32), although laparoscopy has shown promise as a technique that offers the potential for lower morbidity. Ovarian cystectomy or oophorectomy may be indicated.

### Vulvar Conditions

Vulvar and vaginal symptoms are a common initial complaint to gynecologists. The presence of vulvar symptoms may prompt a patient to seek care; however, this anatomic site is not one that is easily inspected by the patient. Thus, vulvar lesions may be noted on examination and may not have been noticed by the patient. Vulvar self-examination should be encouraged and could potentially result in the earlier diagnosis of vulvar lesions such as melanoma (195).

### Neonatal
In the neonatal age group, various developmental and congenital abnormalities may be noted. Whereas an extensive discussion of these abnormalities is beyond the scope of this text, obstetricians will recognize that they must be prepared to deal with the parents and family when an infant is born with ambiguous genitalia. The etiology of these problems, as well as intersex disorders that may be discovered in an older child, can be complex. Chromosomal abnormalities, enzyme deficiencies (including 17- or 21-hydroxylase deficiency as causes of congenital adrenal hyperplasia), or prenatal masculinization of a female fetus resulting from maternal androgen-secreting ovarian tumors or, rarely, drug exposures can all result in genital abnormalities that are noted at birth. These abnormalities are addressed in Chapter 23.

Ambiguous genitalia represents a social and potential medical emergency that is best handled by a team of specialists, which may include urologists, neonatologists, endocrinologists, and pediatric gynecologists. The first questions parents ask after a baby is born include "Is it a boy or a girl?" In the case of ambiguous genitalia, the parents should be informed that the baby's genitals are not fully developed and, therefore, a simple examination of the external genitalia cannot determine the actual sex. The parents should be told that data will be collected but that it may take several days or longer to determine the baby's intended sex. In some situations, it may be best to state simply that the baby has some serious medical complications. The issues of gender assignment and timing of surgical therapy are controversial and should be managed by clinicians with extensive experience in the field (196,197).

Other genital abnormalities may be noted at birth, although few obstetricians or pediatricians carefully examine the external genitalia of female neonates. It has been argued that careful inspection of the external genitalia of all female infants should be performed, with gentle probing of the introitus and anus to determine the patency of the hymen or a possible imperforate anus. If patency is in doubt, a rectal thermometer may be used to gently test the patency. It has been suggested that this examination should be performed on all female infants in the delivery room (198). Various types of hymenal configurations in the newborn have been described, ranging from imperforate to microperforate, to cribiform, to hymenal bands, and hymens with central anterior, posterior, or eccentric orifices (199). An examination during the neonatal period would prevent the discovery of an imperforate hymen or vaginal septum only after a young woman experiences periodic pelvic and abdominal pain with the development of a large hematometra or hematocolpos.

Congenital vulvar tumors may include strawberry hemangiomas, which are relatively superficial vascular lesions, and large cavernous hemangiomas. Treatment is controversial; many lesions will spontaneously regress. Some clinicians have advocated cryotherapy, argon laser therapy, or sclerosing solutions (200).

**Childhood**

It may be difficult for a young child to describe vulvar sensations. Parents may notice the child crying during urination, scratching herself repeatedly, or complaining of vague symptoms. Often, the child's pediatrician will have evaluated the child for urinary tract infection. Evaluation for pinworms is also warranted, because pinworms can cause severe itching in the vulvar as well as perianal area. Vulvovaginitis is the most common gynecologic problem of childhood. Prepubertally, the vulva, vestibule, and vagina are anatomically and histologically vulnerable to infection with the bacteria typically present in the perianal area. The physical proximity of the vagina and vestibule to the anus can result in overgrowth of bacteria that can cause primary vulvitis and secondary vaginitis (see Chapter 15). Yeast infections are uncommon in prepubertal children who are toilet trained.

The clinician should be familiar with normal prepubertal genital anatomy and hymenal configuration (201,202). The unestrogenized vulvar vestibule is mildly erythematous and can be confused with infection. In addition, smegma around and beneath the prepuce may resemble patches of candida vulvitis. In prepubertal girls, the vulvar area is quite susceptible to chemical irritants.

Chronic skin conditions such as lichen sclerosus, psoriasis, seborrheic dermatitis, and atopic vulvitis may occur in children (203). Lichen sclerosus, the cause of which is not well established, has a characteristic "cigarette paper" appearance in a keyhole distribution (around the vulva and anus) (Fig. 13.30). Lichen sclerosus should be treated in pediatric patients as it is in adults; there is some suggestion that the condition may regress as the child progresses through adrenarche and menarche. The use of ultrapotent steroids topically has been successful in children as well as adults (204).

![Figure 13-30 A: Lichen sclerosus in a 7-year-old girl. (From Novak ER, Woodruff JB, eds. Novak's gynecologic and obstetric pathology, 7th ed. Philadelphia: WB Saunders, 1974:21, with permission.) B: Histologic appearance of lichen sclerosus.](image)

Labial agglutination may occur as a result of chronic vulvar inflammation from any cause (Fig. 13.31). The treatment of labial agglutination consists of a brief course (2 to 4 weeks) of externally applied estrogen cream. The area of agglutination (adhesion) will become thin as a result, and separation can often be performed in the office with the use of a topical anesthetic (e.g., lidocaine jelly) (Fig. 13.32). Urethral prolapse may cause acute pain or bleeding, or the presence of a mass may be noted.

![Figure 13-31 Posterior labial agglutination in a 9-year-old girl.](image)
Vulvovaginal complaints of any sort in a young child should prompt the consideration of possible sexual abuse. Sexually transmitted infections may occur in prepubertal children (205). Sensitive but direct questioning of the parent or caretaker and the child should be a part of the evaluation; if sexual abuse is suspected, reporting to the appropriate social services agency is required.

Adolescence

Adolescents with gonadal dysgenesis or androgen insensitivity may have abnormal pubertal development and primary amenorrhea (Chapter 23). Various developmental abnormalities—vaginal agenesis, imperforate hymen, transverse and longitudinal vaginal septa, vaginal and uterine duplications, hymenal bands, and septa—most commonly occur in early adolescence with amenorrhea (for the obstructing abnormalities) or with concerns such as inability to use tampons (for hymenal and vaginal bands and septa). These developmental abnormalities must be evaluated carefully to determine both external and internal anatomy.

A tight hymenal ring may be discovered because of concerns about the inability to use tampons or initiate intercourse. Manual dilation can be successful, as can small relaxing incisions at 6 o'clock and 8 o'clock in the hymenal ring. This can sometimes be done in the office using local anesthesia but may require conduction or general anesthesia in the operating room. Hymenal bands are not rare and also lead to difficulty in using tampons; they usually can be incised in the office using local anesthetic.

The condition of hypertrophy of the labia minora has been described, along with surgical procedures to correct this developmental abnormality (206). This condition is more appropriately considered a variant of normal, with reassurance rather than a cosmetic surgical reduction as the primary therapy. Genital ulcerations may be noted in girls with leukemia or other cancers requiring chemotherapy (207). The possibility of sexual abuse, incest, or involuntary intercourse should be considered for young adolescents with vulvovaginal complaints, STDs, or pregnancy.

Reproductive Age Women

In postmenarchal individuals, vulvar symptoms are most often related to a primary vaginitis and a secondary vulvitis. The presence of vaginal discharge can lead to vulvar irritative symptoms, or candidal vulvitis may be present. The causes of vaginitis and cervicitis are covered in Chapter 15. As noted, young children may have a difficult time describing vulvar symptoms; adult women describe vulvar symptoms using a variety of terms (itching, pain, discharge, discomfort, burning, external dysuria, soreness, pain with intercourse or sexual activity). Burning with urination from noninfectious causes may be difficult to distinguish from a urinary tract infection, although some women can distinguish pain when the urine hits the vulvar area (an external dysuria) from burning pain (often suprapubic in location) during urination. A urine culture may be necessary to help make the distinction. Itching is a very common vulvar symptom. A variety of vulvar conditions and lesions can present with pruritus.

A number of skin conditions that occur on other areas of the body may occur on the vulvar area. Table 13.10 contains a list of these conditions classified by either infectious or noninfectious causes. Whereas the diagnosis of some of these conditions is apparent from inspection alone (e.g., a skin tag) (Fig. 13.33), any lesions that appear atypical or in which the diagnosis is not clear should be analyzed by biopsy.

| Table 13.10. Subacute and Chronic Recurrent Conditions of the Vulva |

Pigmented vulvar lesions include benign nevi, lentigines, melanosis, seborrhoeic keratosis, and some vulvar intraepithelial neoplasias (VIN), especially multifocal VIN 3. Suspicious pigmented vulvar lesions, in particular, should warrant biopsy to rule out VIN or malignant melanoma (208). Approximately 10% of white women have a pigmented vulvar lesion; some of these lesions may be malignant (Chapter 33) or have the potential for progression (VIN) (Chapter 16). The behavior of some nevocellular lesions (representing about 2% of nevi) is not well established but has been linked to melanoma (209). Multiple hyperpigmented lesions of typical lentigo simplex and melanosis are common, and any areas with irregular borders should be evaluated by biopsy (Fig. 13.34).
**Vulvar Biopsy**

A vulvar biopsy is essential in distinguishing benign from premalignant or malignant vulvar lesions, especially because many types of lesions may have a somewhat similar appearance. Vulvar biopsies should be performed liberally to ensure that these lesions are diagnosed and treated appropriately. A prospective study of vulvar lesions evaluated by biopsy in a gynecologic clinic found lesions occurring in the following order of frequency: epidermal inclusion cyst (Fig. 13.35), lentigo, Bartholin duct obstruction, carcinoma in situ, melanocytic nevi, acrochordon, mucous cyst, hemangiomas, postrheumatoid hyperpigmentation, seborrheic keratoses, varicosities, hidradenomas, verruca, basal cell carcinoma, and unusual tumors such as neurofibromas, ectopic tissue, syringomas, and abscesses (210). Clearly, the frequency with which a lesion would be reported after a tissue biopsy is related to the frequency with which all lesions of a given pathology are evaluated in this manner. Thus, this listing probably underrepresents such common lesions as condylomata.

Biopsy is easily performed in the office using a local anesthetic. Typically, 1% lidocaine is infiltrated beneath the lesion using a small (25- to 27-gauge) needle. Disposable punch biopsy instruments come in a variety of sizes from 2- to 6-mm in diameter. They have the advantage of being sharp and thus facilitate obtaining a good specimen. Sterilizable instruments are also available and may be a more ecologically sound choice if they can be maintained and sharpened periodically. These skin biopsy instruments, along with fine forceps, scissors, and a scalpel, should be available in all outpatient gynecologic settings. For the smaller biopsies, it is usually unnecessary to place a suture. Topical silver nitrate can be used for hemostasis. Multiple tissue samples may be appropriate to obtain representative areas of a lesion if the lesion has a variable appearance or is multifocal. Although the vulvar biopsy procedure involves minimal discomfort, the biopsy sites will be painful for several days after the procedure. The prescription of a topical anesthetic such as 2% lidocaine jelly, to be applied periodically and before urinating, is appreciated by patients who require this procedure. Infection of the site can occur, and patients should be cautioned to report excessive erythema or purulent drainage.

**Other Vulvar Conditions**

Pseudofolliculitis, similar to what has been described as pseudofolliculitis barbae (razor bumps), may occur in women who follow the increasingly popular practice of shaving pubic hair to conform to a swimsuit (210). It consists of an inflammatory reaction surrounding an ingrown hair and occurs most commonly among individuals with curly hair, particularly African Americans.

Fox-Fordyce disease is characterized by a chronic, pruritic eruption of small papules or cysts formed by keratin-plugged apocrine glands. It is commonly present over the lower abdomen, mons pubis, labia majora, and inner portions of the thighs. Hidradenitis suppurativa is a chronic condition involving the apocrine glands with the formation of multiple deep nodules, scars, pits, and sinuses that occur in the axilla, vulva, and perineum (Fig. 13.36). Hyperpigmentation and secondary infection are often seen. Hidradenitis suppurativa can be extremely painful and debilitating. It is often treated with antibiotics (with coverage of both aerobic and anaerobic bacteria). Estrogens or antiandrogen therapy has been attempted; surgical therapy with wide local excision may be necessary. Therapy with isotretinoin and steroids has been reported to be successful (211,212).

Acanthosis nigricans involves widespread velvety pigmentation in skin folds, particularly the axillae, neck, thighs, submammary area, and vulva and surrounding skin. It is of particular interest to gynecologists because of its association with hyperandrogenism and PCOS as such, it is associated with obesity, chronic anovulation, acne, glucose intolerance, and cardiovascular disease (37,213).

**Intraepithelial Neoplasia**
A classification of intraepithelial lesions of the vulva is presented in Table 16.13.

Extramammary Paget's disease of the vulva is an intraepithelial neoplasia containing vacuolated Paget's cells (Chapter 16). Clinically, it may have an appearance varying from moist, oozing ulcerations to an eczematoid lesion with scaling and crusting, to a grayish lesion (209). A biopsy to confirm the diagnosis is mandatory.

Vulvar intraepithelial neoplasia is associated with human papillomavirus infection and is increasing in frequency, particularly among young women (Chapter 16) (214). Diagnosis requires biopsy of any suspicious vulvar lesions, particularly those that are pigmented or discolored. The increasing frequency of this entity makes a careful vulvar inspection mandatory during annual gynecologic examinations.

**Vulvar Tumors, Cysts, and Masses**

Condyloma acuminata are very common vulvar lesions and are usually easily recognized and treated with topical therapies such as tri- and bichloracetic acid. Other sexually transmitted organisms, such as the virus responsible for molluscum contagiosum and the lesions of syphilis and condyloma lata, may occasionally be mistaken for vulvar condyloma acuminata caused by the human papillomavirus (see Chapter 15). A summary of benign vulvar tumors is listed in Table 13.11. There is argument regarding whether sebaceous cysts exist on the vulva or whether these lesions are histopathologically epidermal or epidermal inclusion cysts (219). These cysts may result from the burial of fragments of skin after the trauma of childbirth or episiotomy.

It has been argued that the commonly cited concept of milk lines extending into the vulva and accounting for lesions of mammary-like anogenital glands (e.g., fibroadenoma, lactating glands) is not supported by observations in human embryos; such studies show that primordia of the mammary glands do not extend beyond the axillary-pectoral area (216). Eccrine or apocrine glands have been suggested as the probable source of these unusual lesions. Bartholin duct cysts are common vulvar lesions. They result from occlusion of the duct with accumulation of mucus and are frequently asymptomatic. Infection of the gland may result in the accumulation of purulent material, with the formation of a rapidly enlarging, painful, inflammatory mass (a Bartholin abscess). An inflatatable bulb-tipped catheter has been described by Word and is quite easy to use (217). The small catheter is inserted through a small stab wound into the abscess after infiltration of the skin with local anesthesia; the balloon of the catheter is inflated with 2 to 3 ml of saline and the catheter remains in place for 4 to 6 weeks, allowing epithelialization of a tract and the creation of a permanent gland opening.

Skene duct cysts are cystic dilations of the Skene glands, typically located adjacent to the urethral meatus within the vulvar vestibule (Fig. 13.37). Although most are small and often asymptomatic, they may enlarge and cause urinary obstruction, requiring excision.

**Vulvar Ulcers**

A number of STDs can cause vulvar ulcers, including herpes simplex virus, syphilis, lymphogranuloma venereum, and granuloma inguinale (Chapter 15). Crohn's disease can include vulvar involvement with abscesses, fistula, sinus tracts, fenestrations, and other scarring. Although medical treatment with systemic steroids and other systemic agents is the mainstay of therapy, surgical therapy of both intestinal and vulvar disease may be required.

Behçet's disease is characterized by genital and oral ulcerations with ocular inflammation. The cause and the most effective therapy are not well established. Lichen planus also causes oral and genital ulcerations. Typically, there is desquamative vaginitis with erosion of the vestibule. Treatment is based on the use of both topical and systemic steroids. Plasma cell mucositis appears as erosions in the vulvar area, particularly the vestibule. Biopsy is essential in making the diagnosis.

The symptom of painful intercourse (dyspareunia) may be caused by many different vulvovaginal conditions, including common vaginal infections and vaginismus (Chapter 14). A careful sexual history is essential, as is a careful examination of the vulvar area and vagina. Vulvodynia is the term used to describe unexplained vulvar pain, sexual dysfunction, and the resultant psychological disability (218). The term vulvar vestibulitis has been used to describe a situation in which there is pain during intercourse, primarily during entry (219,220). The condition is characterized by tender areas surrounding the vulvar vestibule and hymenal ring (see Chapter 14). A number of recent studies have failed to demonstrate a consistent relationship with any genital infectious organism, including chlamydia, gonorrhea, Trichomonas, mycoplasma, Ureaplasma, Gardnerella, candida, or human papillomavirus (221,222 and 223). Although the symptoms of dyspareunia with insertion can be disabling, no curative therapies have been found. Surgical therapies have been suggested, and both medical and behavioral therapies are of some benefit (224,225). The visible lesion of vestibular papillomatosis may be a nonspecific response to discharge or inflammation.

**Vulvar Ulcers**

A number of STDs can cause vulvar ulcers, including herpes simplex virus, syphilis, lymphogranuloma venereum, and granuloma inguinale (Chapter 15). Crohn's disease can include vulvar involvement with abscesses, fistula, sinus tracts, fenestrations, and other scarring. Although medical treatment with systemic steroids and other systemic agents is the mainstay of therapy, surgical therapy of both intestinal and vulvar disease may be required.

Behçet's disease is characterized by genital and oral ulcerations with ocular inflammation. The cause and the most effective therapy are not well established. Lichen planus also causes oral and genital ulcerations. Typically, there is desquamative vaginitis with erosion of the vestibule. Treatment is based on the use of both topical and systemic steroids. Plasma cell mucositis appears as erosions in the vulvar area, particularly the vestibule. Biopsy is essential in making the diagnosis.

**Postmenopausal Women**

**Vulvar Dystrophies**
Several vulvar conditions occur most commonly in postmenopausal women. Symptoms are primarily itching and vulvar soreness, in addition to dyspareunia.

In the past, numerous terms have been used to describe disorders of vulvar epithelial growth that produce a number of nonspecific gross changes. These terms have included leukoplakia, lichen sclerosus et atrophicus, atrophic and hyperplastic vulvitis, and kraurosis vulvae. The malignant potential of the vulvar dystrophies is less than 5%; at particular risk is the patient with cellular atypia on initial biopsy. The International Society for the Study of Vulvar Diseases (ISSVD) has recommended a classification of vulvar dystrophies, which is presented in Table 16.13.

Squamous Hyperplasia Squamous hyperplasia is seen most often in postmenopausal women but may occur during the reproductive years. Pruritus is the most common symptom. The lesion appears thickened and hyperkeratotic, and there may be excoriation. Squamous hyperplasia tends to be discrete but may be symmetric and multiple. Biopsies are necessary to make the diagnosis and to evaluate the presence of atypia and exclude malignancy.

The treatment is local application of a fluorinated corticosteroid ointment 2 times a day for 6 weeks. Typically, the lesion totally regresses. If a new lesion recurs, another biopsy should be performed and an additional 6 weeks of treatment with topical steroids should be given (224).

Lichen Sclerosus Lichen sclerosus is the most common white lesion of the vulva (Fig. 13.38). Lichen sclerosus can occur at any age, although it is most common among postmenopausal women and prepubertal girls (224). The symptoms are pruritus, dyspareunia, and burning. Lichen sclerosus characteristically is associated with decreased subcutaneous fat such that the vulva is atrophic, with small or absent labia minora, thin labia majora, and sometimes phimosis of the prepuce. The surface is pale with a shiny, crinkled pattern, often with fissures and excoriation. The lesion tends to be symmetric and often extends to the perineal and perianal areas. The diagnosis is confirmed by biopsy. Invasive cancer is only rarely associated with lichen sclerosus.

![Lichen Sclerosus of the Vulva](image)

**Figure 13.38 Lichen sclerosus of the vulva in a postmenopausal patient. (From Wilkinson EJ, Stone IK. Atlas of vulvar disease. Baltimore: Lippincott Williams & Wilkins, 1995:36, with permission.)**

Treatment is with an ultrapotent topical steroid such as 0.05% clobetasol. Approximately 80% of patients have a satisfactory response (226). Maintenance therapy is important and may include the use of a lower potency steroid or the use of a topical emollient (227).

**Urethral Lesions**

Vulvar lesions that may be seen in other age groups, but that occur more commonly among older women, include urethral caruncles and prolapse of the urethral mucosa. Both conditions can be treated with topical or systemic estrogen preparations. Various vulvar skin lesions, including seborrheic keratoses and cherry hemangiomas (senile hemangiomas), occur more commonly on aging skin.

**Vaginal Conditions**

Vaginal discharge is one of the most common vaginal symptoms. Conditions ranging from vaginal candidiasis to chlamydia cervicitis to bacterial vaginosis to cervical carcinoma may cause vaginal discharge. Infectious vaginal conditions are addressed more completely in Chapter 15. Vaginal lesions may occasionally be palpable to a woman. More commonly, vaginal lesions are discovered on examination by a clinician. They may contribute to symptoms (such as bleeding or discharge) or they may be entirely asymptomatic. Vaginitis, cervicitis, and vaginal or cervical lesions (including malignancies) can be causes of vaginal discharge. Other noninfectious causes of discharge are as follows:

1. Retained foreign body—tampon, pessary
2. Ulcerations—tampon-induced, lichen planus
3. Malignancy—cervical, vaginal
4. Postmenopausal atrophic vaginitis, postradiation vulvovaginitis

**Pediatric**

Sexual abuse should always be considered in prepubertal children with vaginal discharge. Although the use of routine STD cultures in girls with a history of sexual abuse has been questioned, vaginal culture for gonorrhea and chlamydia should be performed in girls with vaginal discharge (228). In prepubertal girls, vulvovaginitis is usually caused by multiple organisms that are present in the perineal area, although a single organism such as streptococcus or even, rarely, Shigella may be causative. Treatment should be initiated with a focus on hygienic and cleansing measures. A short-term (<4 weeks) course of topical estrogens and broad-spectrum antibiotics may be necessary. The problem can be recurrent.

A technique for obtaining vaginal cultures and for performing vaginal irrigation has been described by Pokorny (229). A catheter within a catheter can be fashioned using the tubing from an intravenous butterfly setup within a sterile urethral catheter. Nonbacteriostatic saline (1 ml) can be injected, aspirated, and sent for culture.

Cultures taken in this manner are almost always better tolerated than cultures obtained using a cotton-tipped applicator. A larger quantity of saline can then be used to irrigate the vagina while the catheter is still within the vagina. Small foreign bodies can often be flushed from the vagina in this manner.

**Adolescence and Older**

Vaginal tampons have been associated with both microscopic and macroscopic ulcerations. Healing of the macroscopic ulcerations occurs within several weeks without specific therapy if tampon use is suspended. A follow-up examination to demonstrate healing is appropriate, with biopsy of any persistent ulcerations to rule out other lesions.

Toxic shock syndrome (TSS) has been associated with tampon use and vaginal Staphylococcus aureus–produced exotoxins. TSS consists of fever, hypotension, a diffuse erythema with desquamation of the palms and soles, plus involvement of at least three major organ systems (230). Vaginal involvement includes mucous membrane inflammation. TSS appears to be declining in frequency, and an increasing percentage of cases are not associated with menses (231).

Some vaginal lesions are asymptomatic and are noted incidentally on examination. Fibroepithelial polyps consist of polyoid folds of connective tissue, capillaries, and stroma covered by vaginal epithelium. Although they can be excised easily in the office, their vascularity can be troublesome, and excision is not necessary unless the diagnosis is in question. Cysts of embryonic origin can arise from mesonephric, paramesonephric, and urogenital sinus epithelium. Gardner’s duct cysts are of mesonephric origin and are usually present on the lateral vaginal wall. They rarely cause symptoms and, therefore, do not require treatment. Other embryonic cysts
can arise to the anterior and beneath the bladder. Cysts that arise from the uterine sinuses epithelium are located in the area of the vulva vestibule. Vaginal adenosia, the presence of epithelial-lined glands within the vagina, has been associated with in utero exposure to diethylstilbestrol. No therapy is necessary, but close observation is required to detect nodules that may need to be removed by biopsy to rule out vaginal clear cell adenocarcinoma (Chapter 31).

Women will sometimes describe a bulging lesion of the vagina and vulvar area, variously associated with symptoms of pressure or discomfort. The most common cause of such a lesion is one of the disorders of vaginal support: cystocele, rectocele, or urethrocele. Management of these conditions is discussed in Chapter 20. Other genital lesions, such as urethral diverticula or occasionally embryonic cysts, may cause similar symptoms.

References

Pelvic pain is the most challenging symptom confronting the practitioner. The problems of acute, cyclic, and chronic pelvic pain encompass a large proportion of gynecologic complaints. The etiology of pelvic pain is diverse. Dysmenorrhea is one of the most common medical issues in gynecology.

Acute pain is intense and characterized by sudden onset, sharp rise, and short course. Cyclic pain refers to pain that occurs with a definite association to the menstrual cycle. Dysmenorrhea, or painful menstruation, is the most common cyclic pain phenomenon and is classified as primary or secondary on the basis of associated anatomic pathology. Chronic pelvic pain has been defined as pain of greater than 6 months' duration. Whereas acute pain is often associated with profound autonomic reflex responses, such as nausea, emesis, diaphoresis, and apprehension, obvious autonomic reflex responses are not present in chronic pelvic pain. In addition, acute pelvic pain often is associated with signs of inflammation or infection, such as fever and leukocytosis, which are absent in chronic pain states. The pathophysiology of acute pelvic pain involves mediators of inflammation present in high concentration as a result of infection, ischemia, or chemical irritation. By contrast, the etiology of chronic pelvic pain often is obscure. Additionally, chronic pain is characterized by physiologic, affective, and behavioral responses that are quite different from those associated with acute pain.

Acute Pain

The differential diagnosis of acute pelvic pain is outlined in Table 14.1. Assessing the character of the pain is helpful in creating a differential diagnosis. Rapid onset of pain is most consistent with perforation of a hollow viscus or ischemia. Colic or severe cramping pain is commonly associated with muscular contraction or obstruction of a hollow viscus, such as intestine or uterus, whereas pain perceived over the entire abdomen suggests a generalized reaction to an irritating fluid within the peritoneal cavity.

Table 14.1. Differential Diagnosis of Acute Pelvic Pain

The viscera are relatively insensitive to pain. The first perception of visceral pain is a vague, deep, poorly localizable sensation associated with autonomic reflex responses; however, once the pain becomes localized, the pain is called referred pain. Referred pain is well localized and superficial. It is appreciated within the nerve distribution or dermatome of the spinal cord segment innervating the involved viscus. The location of the referred pain provides insight into the location of the primary disease process. The innervation of the pelvic organs is outlined in Table 14.2.
In the evaluation of acute pelvic pain, early diagnosis is critical because significant delay increases morbidity and mortality. Central to correct diagnosis is an accurate history (Fig. 14.1). The date and character of the last and previous menstrual periods and the presence of abnormal bleeding or discharge should be ascertained. Menstrual, sexual, and contraceptive history and the past history of sexually transmitted conditions and previous gynecologic disorders are important. The patient should be questioned about her medical history and any previous surgery. Pain history should be obtained, including how and when the pain started; the presence of gastrointestinal symptoms (e.g., anorexia, nausea, vomiting, constipation, obstipation, flatus pattern); urinary symptoms (e.g., urgency, frequency, hematuria, or dysuria); and signs of infection (e.g., fevers, chills).

Pathology

Abnormal Pregnancy

An ectopic pregnancy is defined as implantation of the fetus in the site other than the uterine cavity (see Chapter 17). Ninety-five percent of ectopic pregnancies develop in the fallopian tube. With the advent of sensitive pregnancy tests, misdiagnosis of ectopic pregnancy is less common. However, a substantial proportion of maternal mortality is still attributable to ectopic gestation.

Symptoms

Implantation of the fetus in the fallopian tube produces pain only with acute dilation of the tube. If tubal rupture occurs, localized abdominal pain tends to be temporarily relieved and is replaced by generalized pelvic and abdominal pain as the hemoperitoneum develops. Typically, there has been amenorrhea for 6 to 8 weeks and irregular bleeding or spotting related to fluctuating levels of human chorionic gonadotropin (hCG) and low progesterone concentrations. A mass in the cul-de-sac may produce an urge to defecate. Referred pain to the right shoulder often develops if the intraabdominal blood collection transverses the right colic gutter and irritates the diaphragm (C-3 to C-5 innervation). Dizziness or syncope can ensue if blood loss is significant.

Diagnosis

The diagnosis of ectopic pregnancy is discussed in Chapter 17. In women of reproductive age, serum or urine pregnancy test with sensitivity of greater than 20 IU/mL of hCG should be obtained; if positive, ectopic pregnancy must be excluded before the patient can be discharged or treated for another diagnosis. Acute pelvic pain during pregnancy can also result from other types of pathology. Once ultrasound has confirmed an intrauterine pregnancy, one must consider adnexal torsion, leakage or rupture of an ovarian cyst, degeneration of leiomyoma, or gastrointestinal or urinary pathology. Coexistent intrauterine and ectopic pregnancy is rare (1 in 30,000).

Leaking or Ruptured Ovarian Cyst

Functional cysts (e.g., follicle, corpus luteum) are the most common ovarian cysts and rupture more readily than do benign or malignant neoplasms. The pain associated with rupture of the ovarian follicle at the time of ovulation is called mittelschmerz. The small amount of blood leaking into the peritoneal cavity and high concentration of follicular fluid prostaglandins could cause this midcycle pelvic pain. However, the pain is mild or moderate and self-limited, and with an intact coagulation system, hemoperitoneum is unlikely. A hemorrhagic corpus luteum cyst can develop in luteal phase of the menstrual cycle. Rupture of this cyst can produce either a small amount of intraabdominal bleeding or frank hemorrhage resulting in significant blood loss and hemoperitoneum.

Nonmalignant neoplasms, most commonly cystic teratomas (dermoid cysts) or cystadenomas, as well as inflammatory ovarian masses, such as endometriomas, can also leak or rupture. A history of a dermoid cyst or endometrioma that has not yet undergone surgical extirpation is not uncommon. Surgical exploration is indicated if rupture of the cyst leads to hemoperitoneum (corpus luteum) or chemical peritonitis (endometrioma, benign cyst teratoma), which could impair future fertility.

Symptoms

An ovarian cyst that is not torsing, rapidly expanding, infected, or leaking does not cause acute pain. A corpus luteum cyst is the most common cyst to rupture and lead to hemoperitoneum. Symptoms of a ruptured corpus luteum cyst are similar to those of a ruptured ectopic pregnancy. The onset of pain is usually sudden and is associated with increasing generalized abdominal pain and occasionally dizziness or syncope if a hemoperitoneum develops. A ruptured endometrioma or benign cystic teratoma (dermoid cyst) produces similar symptoms, however, dizziness and signs of hypovolemia are not present because blood loss is minimal.

Signs

Hypovolemia is present only when there is a hemoperitoneum. The most important sign is the presence of significant abdominal tenderness, often associated with rebound tenderness because of peritoneal irritation. The abdomen can be moderately distended with decreased bowel sounds. On pelvic examination, a mass is often present if the cyst is leaking and not completely ruptured. Fever and leukocytosis are rare. The hematocrit is decreased only if active bleeding is present.
Tuboovarian abscesses can be palpated on bimanual examination as very firm, exquisitely tender, bilateral fixed masses. The abscesses can be palpated or “point” in the presence of acute salpingitis, although pain and fever have often been present for longer than 1 week before presentation to the emergency room. A ruptured tuboovarian abscess is a life-threatening surgical emergency because gram-negative endotoxic shock can develop rapidly.

Tuboovarian abscesses, a sequela of acute salpingitis, are usually bilateral, but unilateral abscess formation is not rare. The symptoms and signs are similar to those of acute salpingitis, although pain and fever have often been present for longer than 1 week before presentation to the emergency room. A ruptured tuboovarian abscess is a life-threatening surgical emergency because gram-negative endotoxic shock can develop rapidly.

Signs
Tuboovarian abscesses can be palpated on bimanual examination as very firm, exquisitely tender, bilateral fixed masses. The abscesses can be palpated or “point” in the presence of acute salpingitis, although pain and fever have often been present for longer than 1 week before presentation to the emergency room. A ruptured tuboovarian abscess is a life-threatening surgical emergency because gram-negative endotoxic shock can develop rapidly.

Tuboovarian abscesses can be palpated on bimanual examination as very firm, exquisitely tender, bilateral fixed masses. The abscesses can be palpated or “point” in the presence of acute salpingitis, although pain and fever have often been present for longer than 1 week before presentation to the emergency room. A ruptured tuboovarian abscess is a life-threatening surgical emergency because gram-negative endotoxic shock can develop rapidly.
Diagnosis

The clinical diagnosis can be substantiated by ultrasonography. The differential diagnosis of a unilateral mass includes not only tuboovarian abscess but also adnexal torsion, endometrioma, leaking ovarian cyst, and periappendiceal abscesses. If physical and ultrasound examination results are not definitive, laparoscopy or laparotomy must be performed.

Management

Unruptured tuboovarian abscesses may be treated medically with appropriate intravenous antibiotics and close monitoring to detect leakage or impending rupture. A ruptured tuboovarian abscess rapidly leads to diffuse peritonitis evidenced by tachycardia, rebound tenderness in all four quadrants of the abdomen, and, if progressive, hypotension and oliguria. Exploratory laparotomy with resection of infected tissue is mandatory.

Uterine Leiomyomas

Leiomyomas are uterine smooth muscle tumors. Discomfort may be present when myomas encroach on adjacent bladder, rectum, or supporting ligaments of the uterus, although acute pelvic pain attributable to uterine leiomyomas is rare. Acute pelvic pain can develop if the myoma undergoes degeneration or torsion. Degeneration of myomas occurs secondary to loss of blood supply, usually attributable to rapid growth associated with pregnancy. In a nonpregnant woman, degenerating uterine leiomyoma often is misdiagnosed, frequently being confused with subacute salpingo-oophoritis. A pedunculated subserosal leiomyoma can undergo torsion ischemic necrosis; when this situation occurs, it is associated with pain similar to that of adnexal torsion. When a submucous leiomyoma becomes pedunculated, the uterus contracts forcefully as if to expel a foreign body, and the resulting pain is similar to that of labor. The cramping pain is usually associated with hemorrhage.

Signs

Abdominal examination reveals an irregular solid mass or masses arising from the uterus. If degeneration occurs, the inflammation can cause abdominal tenderness in response to palpation and mild localized rebound tenderness. Elevation of temperature and leukocytosis also can occur.

Diagnosis and Management

Ultrasound is useful in distinguishing adnexal from uterine etiology of an eccentric mass. Degeneration of a leiomyoma is treated with observation and pain medication. A pedunculated, torsed, subserosal leiomyoma can easily be excised laparoscopically; however, surgery is not mandatory. A submucous leiomyoma with pain and hemorrhage should be excised transcervically, with hysteroscopic guidance if needed.

Endometriosis

A thorough discussion of endometriosis is presented in Chapter 26. Endometriosis is characterized by the presence and proliferation of endometrial tissue in sites outside the endometrial cavity. Women with endometriosis often experience dysmenorrhea (painful menses), dyspareunia (painful intercourse), and dyschezia (pain with bowel movements). There often is a history of luteal phase bleeding or infertility. Acute pain attributable to endometriosis is usually premenstrual and menstrual (dysmenorrhea); however, if nonmenstrual acute generalized pain occurs, a ruptured endometrioma (chocolate endometriotic cyst within the ovary) should be considered. In this situation, hemoperitoneum is absent, although the fluid from the chocolate cyst can cause chemical peritonitis.

Signs

The abdomen is often tender in the lower quadrants. Significant distention or rebound tenderness is usually not present. Pelvic examination often reveals a fixed, retroverted uterus with tender nodules in the uterosacral region or thickening of the cul-de-sac. An adnexal mass, if present, usually is fixed to the broad ligament and cul-de-sac.

Diagnosis

If a culdocentesis is performed, it will reveal the cyst contents of the ruptured endometrioma. If the diagnosis is unclear, ultrasound is helpful, and laparoscopy findings are definitive. In a patient who has an established diagnosis of endometriosis or who has recently been treated surgically for the disease, a trial of ovarian hormonal suppression (pseudomenopause) can be used to treat the condition and to confirm the correlation between the current pain and the underlying diagnosis of endometriosis.

Management

A ruptured endometrioma is an indication for laparoscopy or laparotomy with ovarian cystectomy or oophorectomy. If a small endometrioma (less than 3 cm) is suspected and there are no signs of rupture, medical management may proceed (see Chapter 26). Diagnostic laparoscopy can be performed if endometriosis or unruptured endometrioma is suspected but not confirmed.

Gastrointestinal Tract

Appendicitis is the most common intestinal source of acute pelvic pain in women. The symptoms and signs of appendicitis can be similar to those of PID.

The first symptom of appendicitis is typically diffuse abdominal pain, especially epigastric pain, associated with anorexia and nausea. Within a matter of hours, the pain generally shifts to the right lower quadrant. Fever, chills, emesis, and obstipation may ensue. However, this classic symptom pattern is often lacking. Abnormal abdominal pain can occur when the appendix is retrocecal or entirely within the true pelvis. In this setting, tenesmus and diffuse suprapubic pain may result. The patient with appendicitis is more likely to have pronounced and persistent gastrointestinal symptoms than the patient with salpingo-oophoritis.

Signs

Local tenderness is usually elicited on palpation of the right lower quadrant (McBurney point). The appearance of severe generalized muscle guarding; abdominal rigidity; rebound tenderness, right-sided mass, or tenderness on rectal examination; positive psoas sign (pain with forced hip flexion or passive extension of hip); and obturator signs (pain with passive internal rotation of flexed thigh) indicates appendicitis. A low-grade temperature is generally present, but the temperature may be normal. The pelvic examination is usually without cervical motion or bilateral adnexal tenderness, but right-sided unilateral adnexal tenderness can be present.

Diagnosis

Many patients with acute appendicitis have a normal total leukocyte count; however, the differential usually reveals a left shift. Ultrasound examination of the pelvic organs generally has normal findings, whereas the appendix may be abnormal on ultrasound or computed tomography scan. Gastrografin or barium enema with normal filling of the appendix rules out appendicitis. Diagnostic laparoscopy can be useful to rule out other sources of pelvic pathology, but it is occasionally difficult to visualize the appendix sufficiently to rule out early appendiceal inflammation.

Management

Laparotomy, with a false-positive rate of 20%, is an acceptable approach and is preferable to continued observation with rupture and peritonitis. Not only is a ruptured appendix life-threatening but it also may have profound sequelae for the fertility of a young woman of reproductive age.
Acute Diverticulitis

Acute diverticulitis is a condition in which there is inflammation of a diverticulum or outpouching of the wall of the colon, usually involving the sigmoid. Diverticulitis typically affects postmenopausal women but can occur in women in their 30s and 40s.

Symptoms

The severe, left lower quadrant pain of diverticulitis can follow a long history of symptoms of irritable bowel (bloating, constipation, and diarrhea), although diverticulitis usually is asymptomatic. Diverticulitis is less likely to lead to perforation and peritonitis than is appendicitis. Fever, chills, and constipation typically are present, but anorexia and vomiting are uncommon.

Signs

Abdominal examination reveals distention with left lower quadrant tenderness on direct palpation and localized rebound tenderness. Abdominal and pelvic examination may reveal a poorly mobile, doughy inflammatory mass in the left lower quadrant. Bowel sounds are hypoactive and, if peritonitis is present, absent. Leukocytosis frequently is observed.

Diagnosis and Management

Computed axial tomography scan is a useful adjunct to history and physical examination. A barium enema is contraindicated. Diverticulitis is initially managed medically with broad-spectrum intravenous antibiotics. A diverticular abscess often requires surgical intervention.

Urinary Tract

Ureteral colic due to ureteral lithiasis is caused by a sudden increase in intraluminal pressure and associated inflammation. Urinary tract infections producing acute pain include cystitis and pyelonephritis.

Symptoms and Signs

The pain of lithiasis is typically severe and crampy; it can radiate from the costovertebral angle to the groin. Hematuria is often present. Cystitis is associated with dull suprapubic pain, urinary frequency, urgency, dysuria, and occasionally hematuria. Because urethritis can occur secondary to chlamydia or gonorrhea and has similar symptoms, these infections must be ruled out, if appropriate. Pyelonephritis is associated with flank and costovertebral angle pain, although lateralizing lower abdominal pain occasionally is present. There is pain with firm pressure over the costovertebral angle in the case of lithiasis or pyelonephritis. Peritoneal signs are absent. Suprapubic tenderness may accompany cystitis.

Diagnosis

Diagnosis of stone is afforded by urinalysis revealing red blood cells and ultrasound or CT urogram or intravenous pyelogram outlining the stone. In the case of urinary tract infection, the diagnosis is based on urinalysis revealing bacteria and leukocytes and subsequently confirmed by culture.

Management

Expectant medical and surgical management are both options for renal lithiasis. Nonpregnant women with pyelonephritis and all women with cystitis can be treated on an outpatient basis.

Diagnostic Tools

All women of reproductive age with acute pelvic pain should have a complete blood count with differential, ESR, urinalysis, and a sensitive qualitative urine or serum pregnancy test. The sedimentation rate is nonspecific but often is the only abnormal laboratory finding in women with subacute PID. Other studies that may be helpful include culdocentesis with hematocrit, if bloody fluid is obtained, and Gram stain and culture, if the fluid is purulent. The presence of cul-de-sac mass precludes culdocentesis. Pelvic ultrasound is useful to rule out ectopic gestation or to assess the adnexae if the results of the examination are confusing or difficult to interpret because of obesity or guarding. Abdominal x-ray series or upper or lower Gastrografin studies are helpful to rule out gastrointestinal obstruction. Computed tomography scan is useful for evaluation of retroperitoneal masses or abscesses related to the gastrointestinal tract. Diagnostic laparoscopy is reserved for establishing the diagnosis in patients who have acute abdomen of uncertain cause, for elucidating the nature of an ambiguous adnexal mass, or for delineating whether a pregnancy is intrauterine or extrauterine (if ultrasound results are negative or equivocal). If there is a clinical evidence of salpingo-oophoritis, diagnostic laparoscopy can be used to confirm the diagnosis. Visualization is hampered if diagnostic laparoscopy is performed for a large pelvic mass (>12 cm) and is relatively contraindicated in patients with peritonitis, severe ileus, or bowel obstruction. In these settings, laparotomy is preferable.

Cyclic Pain: Primary and Secondary Dysmenorrhea

Dysmenorrhea is a common gynecologic disorder affecting up to 50% of menstruating women. Primary dysmenorrhea refers to menstrual pain without pelvic pathology, whereas secondary dysmenorrhea is defined as painful menses associated with underlying pathology. Primary dysmenorrhea usually appears within 1 to 2 years of menarche, when ovulatory cycles are established. The disorder affects younger women but may persist into the 40s. Secondary dysmenorrhea usually develops years after menarche and can occur with anovulatory cycles. The differential diagnosis of secondary dysmenorrhea is outlined in
Primary Dysmenorrhea

The cause of primary dysmenorrhea is increased endometrial prostaglandin production (12, 13, 14 and 15). These compounds are found in higher concentration in secretory endometrium than in proliferative endometrium. The decline of progesterone levels in the late luteal phase triggers lytic enzymatic action, resulting in a release of phospholipids with the generation of arachidonic acid and activation of the cyclooxygenase pathway. The biosynthesis and metabolism of prostaglandins and thromboxane derived from arachidonic acid are depicted in Fig. 14.2 (14). Women with primary dysmenorrhea have higher uterine tone with high-amplitude contractions resulting in decreased uterine blood flow (16). Vasopressin concentrations are also higher in women with dysmenorrhea (17).

The pain of primary dysmenorrhea usually begins a few hours before or just after the onset of a menstrual period and may last up to 48 to 72 hours. The pain is similar to labor, with suprapubic cramping, and may be accompanied by lumbosacral backache, pain radiating down the anterior thigh, nausea, vomiting, diarrhea, and rarely syncopal episodes. The pain of dysmenorrhea is colicky in nature and is improved with abdominal massage, counterpressure, or movement of the body, unlike abdominal pain due to chemical or infectious peritonitis.

Secondary Dysmenorrhea

The pain of secondary dysmenorrhea often begins 1 to 2 weeks before menstrual flow and persists until a few days after the cessation of bleeding. The mechanisms underlying secondary dysmenorrhea are diverse and not fully elucidated, although most involve either excess prostaglandin production or hypertonic uterine contractions secondary to cervical obstruction, intrauterine mass, or the presence of a foreign body. However,
nonsteroidal antiinflammatory agents and oral contraceptive pills are less likely to provide pain relief in women with secondary dysmenorrhea than in those with primary dysmenorrhea. The most common cause of secondary dysmenorrhea is endometriosis, followed by adenomyosis and intrauterine device (for a discussion of endometriosis, see diagnosis of acute and chronic pain, this chapter and Chapter 26). The differential diagnosis of secondary dysmenorrhea is outlined in Table 14.3. The management of secondary dysmenorrhea is treatment of the underlying disorder.

Adenomyosis

Dysmenorrhea associated with adenomyosis often begins up to a week before menses and may not resolve until after the cessation of menses. Associated dyspareunia, dyschezia, and metrorrhagia increase the probability of the diagnosis. Whereas endometriosis is characterized by ectopic endometrium appearing within the peritoneal cavity, adenomyosis is defined as presence of endometrial tissue within the myometrium, at least one high-power field from the basis of the endometrium. Adenomyosis, endometriosis, and uterine leiomyomas frequently coexist. Although occasionally noted in women in the younger reproductive years, the average age of symptomatic women is usually older than 40 years.

Symptoms

Adenomyosis often is asymptomatic. Symptoms typically associated with adenomyosis include excessively heavy or prolonged menstrual bleeding and dysmenorrhea, often beginning up to a week before the onset of a menstrual flow.

Signs

The uterus is diffusely enlarged, although usually less than 14 cm in size, and is often soft and tender, particularly at the time of menses. Mobility of the uterus is not restricted, and there is no associated adnexal pathology.

Diagnosis

Adenomyosis is a clinical diagnosis, and imaging studies, although helpful, are not definitive. Because of their cost and negligible improvement in diagnostic accuracy, these studies are not recommended routinely. In women with diffuse uterine enlargement and a negative pregnancy test, secondary dysmenorrhea may be attributed to adenomyosis; however, the pathologic confirmation of suspected adenomyosis can be made only at the time of hysterectomy. In one study to confirm preoperative diagnosis of adenomyosis before hysterectomy, the clinical diagnosis of adenomyosis was confirmed in only 46% of the cases (28).

Management

The management of adenomyosis clearly depends on the patient's age and desire for future fertility. Relief of secondary dysmenorrhea due to adenomyosis can be ensured after hysterectomy, but less invasive approaches can be tried initially. Nonsteroidal antiinflammatory agents, oral contraceptives, and menstrual suppression using progestins have all been found to be useful.

Chronic Pelvic Pain

Chronic pelvic pain remains an inclusive, general diagnosis that encompasses many more specific causes from endometriosis to nerve entrapment syndrome. Various forms of chronic pelvic pain affect 12% to 15% of women in the United States (27). The differential diagnosis of chronic pelvic pain is outlined in Table 14.3. Patients with chronic pelvic pain are frequently anxious and depressed. Their marital, social, and occupational lives have usually been disrupted. These patients have often had poor treatment outcomes after traditionally effective gynecologic and medical therapy and may have undergone multiple unsuccessful surgical procedures for pain. About 12% of hysterectomies are performed for pelvic pain, and 30% of patients who present to pain clinics have already had a hysterectomy (28,29). Anywhere from 20% to 80% of patients undergoing laparoscopy for chronic pelvic pain have no intraperitoneal pathology or have tissue distortion that does not correlate with the pain (2). Additionally, the relationship can be inconsistent between the pain response and certain types of prevalent intraperitoneal pathology, such as endometriosis, adhesions, or venous congestion (2). Nongynecologic causes of pain, such as irritable bowel syndrome, interstitial cystitis, abdominal wall or pelvic floor myofascial syndrome, or nerve entrapment, are frequently overlooked but common causes of chronic pelvic pain.

Recent investigations have suggested that “plasticity” of the nervous system or alterations in signal processing may be involved in the maintenance of painful states (2,4,30). Various neurohumoral modulators, such as prostaglandins, vasoactive intestinal peptide, substance P, and endorphins, can modulate peripheral neurotransmission and also affect neurotransmission at the level of the spinal cord (31). The spinal cord is not a simple conduit between the periphery and the brain. It is an important site of “gating” mechanisms, such as excitation, inhibition, convergence, and summation of neural stimuli (32). The pain sensation is also modified by neurotransmitters within the brain, such as norepinephrine, serotonin, and g-aminobutyric acid (GABA), as well as by endogenous endorphin and nonendorphin algesic systems. Different regions of the brain are also important in altering the sensory and affective components of the pain response. Evidence from animal studies indicates that supraspinal factors can interact at the level of the dorsal horn to modulate the sensory perception of pain from the pelvic viscera (33). The sensory and affective component of pain is affected by early experience, conditioning, fear, arousal, depression, and anxiety (34).

Evaluation of Chronic Pelvic Pain

Table 14.3 outlines an approach to the patient with chronic pelvic pain. On the first visit, a thorough pain history should be performed, addressing the nature of each pain complaint: location, radiation, severity, aggravating and alleviating factors; effect of menstrual cycle, stress, work, exercise, intercourse, and orgasm; the context in which pain arose; and the social and occupational toll of the pain.

The patient should be questioned about symptoms specific to the types of pathology (see Table 14.3):

1. Genital (abnormal vaginal bleeding, discharge, dysmenorrhea, dyspareunia, infertility)
2. Enterococcal (constipation, diarrhea, flatulence, hematochezia, and relationship of pain to bowel movements)
3. Musculoskeletal (trauma, exacerbation with exercise, or postural changes)
4. Urologic (urgency, frequency, nocturia, dysuria, incontinence, hematuria)

The history should include gynecologic, medical, and surgical factors; medication intake; prior evaluations for pain; and operative and pathology reports (2). Symptoms
of an acute process (fever, anorexia, nausea, emesis, significant diarrhea, obstipation, abdominal distention, undiagnosed uterine bleeding, pregnancy, or recent abortion) should alert the physician to the possibility of an acute condition requiring immediate medical or surgical intervention. This occurrence is especially important if symptoms are accompanied by elevated temperature, orthostasis, peritoneal signs, pelvic or abdominal mass, abnormal complete blood count, positive genital or urinary tract cultures, or a positive pregnancy test.

A complete physical examination should be performed, with particular attention directed to the abdominal, lumbosacral, external genital, vaginal, bimanual, and rectovaginal examination. The examination should include evaluation of the abdomen with muscles tensed (head raised off the table or with straight leg raising) to differentiate abdominal wall and visceral sources of pain. Abdominal wall pain is augmented and visceral pain is diminished with these maneuvers (35,36). The patient should be examined while standing for hernias, both abdominal (inguinal and femoral) and pelvic (cystocele and enterocele). An attempt should be made to locate by palpation the tissues that reproduce the patient's pain. If abdominal wall sources of pain are noted, it is useful to block these areas with local anesthetics and then perform the pelvic examination (35,36).

The Psychological Component

A pain history includes the current and past psychological history addressing psychosocial factors; history of past (or current) physical, sexual, or emotional abuse; history of psychiatric hospitalization; suicide attempts; and chemical dependency (2). The attitude of the patient and her family toward the pain, resultant behavior of the patient and family, and current upheavals in the patient's life should be discussed. The part of the history addressing sensitive issues may have to be reobtained after establishing rapport with the patient.

It is vital to appreciate the various influences that can distort pain perception and expression. A distinction can be drawn between factors leading to a painful condition and those now maintaining it. Whatever the original cause of the pain, when pain has persisted for any length of time, it is likely that other facts are now maintaining or at least contributing to it. The full physical examination, outlined previously, should be accompanied by a review of psychosocial factors. Pain is commonly accompanied by anxiety and depression, and these conditions need to be carefully assessed and treated (2). In a typical gynecologic setting, referral to a psychologist for parallel evaluation can evoke resistance. The inference is drawn that the referring physician is ascribing the pain to psychological causes. The patient needs to understand the reason for this referral and to be reassured that it is a routine and necessary part of the evaluation.

Gynecologic Causes

The most common gynecologic pathologies noted at the time of laparoscopy performed for chronic pelvic pain are endometriosis and adhesions. For a thorough discussion of endometriosis and treatment, see Chapter 26.

Other Gynecologic Pathology: Leiomyomas, Ovarian Tumors, Pelvic Relaxation

Patients with obvious gynecologic pathology, such as benign or malignant ovarian cysts, uterine leiomyomas of sufficient size to encroach on surrounding ligaments or other somatic structures, or significant pelvic relaxation should be evaluated and managed as is appropriate for the underlying condition (see Chapter 13 and Chapter 20).

Endometriosis

Endometriosis can be demonstrated in 15% to 40% of patients undergoing laparoscopy for chronic pelvic pain (37). Endometriosis produces a low-grade inflammatory reaction (38). However, the cause of the pain is not well established. There is no correlation between the location of disease and pain symptoms (39,40). There also appears to be no relationship between the incidence or severity of pain and the stage of the endometriotic lesion, and as many as 30% to 50% of patients have no pain regardless of stage. Similarly, 40% to 60% of patients have no tenderness on examination regardless of stage (40). However, deeply infiltrating rectovaginal septum lesions are strongly associated with pain (41,42), and vaginal and uterosacral endometrioses are associated with complaints of deep dyspareunia (43). Prostaglandin E and F₂α production from explants of petechial lesions present in mild, low-stage disease was found to be significantly greater than from the explants of powder-burn or black lesions, which are more common in patients with higher-stage endometriosis (44). Therefore, prostaglandin production may account for severe pain in some patients with mild disease.

Clinically, it is possible to determine whether there is a relationship between pain and endometriosis because of the hormonal sensitivity of the disease. It has been debated whether a laparoscopic diagnosis of chronic pelvic pain secondary to endometriosis is necessary to initiate treatment. Recent reports have suggested otherwise, including one study that showed significant efficacy of gonadotropin-releasing hormone (GnRH) agonist treatment based on empirical diagnosis (45). After induction of a hypoestrogenic state with GnRH analogues, those patients with pelvic pain and dysmenorrhea related to endometriosis should experience relief. The pain relief usually occurs within 2 months of treatment, but pain often returns to the pretreatment level by 18 months after treatment (46). During long-term (12 or more months) treatment with GnRH analogues, hormonal add-back therapy (i.e., norethindrone acetate, 5 mg daily, with or without estrogen) prevents the long-term hypoestrogenic side effects, such as bone loss, with continued pain relief (47). Intermenstrual pain that is not as consistently associated with endometriosis is as dysmenorrhea is somewhat less responsive to hormonal manipulation. Endometriosis may benefit from surgical intervention, such as electrodissection, laser vaporization, or excision. In fact, in one recent prospective, randomized, double-blinded study with 63 women, laparoscopic laser treatment benefited 90% of women who initially responded at 1-year follow-up (48).

Adhesions

Adhesions noted at the time of laparoscopy are often seen in the same general region of the abdomen as the pelvic pain complaint (49); however, neither the specific location (i.e., adnexa structures, parietal, visceral peritoneum, or bowel) nor density of the adhesions correlates consistently with the presence of pain symptoms (50). Uncontrolled prospective studies of adhesionolysis have not consistently demonstrated a significant reduction in pain scores (51). In one study of lysis of adhesions, a subgroup of women with anxiety, depression, multiple somatic symptoms, and social and occupational disruption responded poorly to adhesiolysis. The group without these symptoms did have significant improvement in pain (51). A prospective study, however, noted a significant improvement in pain on two of three methods of assessment only if the adhesions were dense and involved the bowel (52).

Symptoms

Noncyclic abdominal pain, sometimes increased with intercourse or activity, is a common pain complaint in women with adhesions, but there is no symptom pattern specific for adhesions. Chronic pelvic pain developing from adhesions likely results from restriction of bowel mobility and distention (53). Furthermore, dense adhesions involving bowel can result in a partial or complete bowel obstruction.

Signs

The abdominal wall must be carefully elevated for myofascial or neurologic sources of pain. Most women with adhesions with have had a prior surgical procedure with possible injury to abdominal wall structures that may be the cause of pain. Decreased mobility of pelvic organs or adnexal enlargement can often be noted in patients with adhesions.

Diagnosis

Diagnostic laparoscopy is recommended if other somatic causes are ruled out and the results of the psychological evaluation are negative. Recent advances in microlaparoscopy have enabled the development of a new technique known as “conscious pain mapping,” whereby physicians may better locate the specific adhesions associated with pelvic pain using local anesthesia and conscious sedation (54). In an observational study of 50 women using local anesthesia, manipulation of appendiceal and pelvic adhesions contributed to observed pelvic pain (55). Further studies are needed to correlate the lysis of such painful adhesions with pain relief.
Management

At this time, the causal role of adhesions in the genesis of pelvic pain is uncertain, and lysis is recommended only after thorough multidisciplinary evaluation and in the context of an integrated treatment approach that addresses stress, mood, and associated behavioral responses. Repeated surgical procedures for lysis are not recommended.

Pelvic Congestion

In 1954, Taylor suggested that emotional stress could lead to autonomic nervous system dysfunction manifested as smooth muscle spasm and congestion of the veins draining the ovaries and uterus (56). Transureterine venography in women with chronic pelvic pain often reveals delayed disappearance of contrast medium from the ureters and ovarian veins (57). Considering that pregnant and postpartum women have asymptomatic pelvic congestion, the role of congested veins in the causation of pelvic pain is uncertain. The specific neurotransmitters involved in mediating sympathetic efferent maintained pain syndrome are unknown.

Signs and Symptoms

Typical symptoms include lower abdominal and back pain, secondary dysmenorrhea, dyspareunia, abnormal uterine bleeding, chronic fatigue, and irritable bowel symptoms. Pain usually begins with ovulation and lasts until the end of the menses. The uterus is often bulky, and the ovaries are enlarged with multiple functional cysts. The uterus, parametria, and uterosacral ligaments are tender.

Diagnosis

Transureterine venography has been the primary method for diagnosis, although other modalities, such as pelvic ultrasound, magnetic resonance imaging, and laparoscopy, may demonstrate varicosities (58). Because of the cost and possible side effects of treatment, further management should be based on related symptoms and not simply on the presence of varicosities.

Management

Treatment of suspected pelvic congestion ranges from the less invasive hormonal suppression and cognitive behavioral pain management to the more invasive ovarian vein embolization or hysterectomy. Low-estrogen, progestin-dominated continuous oral contraceptives, high-dose progestins, and GnRH analogues often provide pain relief. Hormonal suppression should be the initial mode of treatment for women with suspected pelvic congestion. Medroxyprogesterone acetate, 30 mg daily, has been found to be useful (59). Concurrently, a multidisciplinary approach incorporating psychotherapy, behavioral pain management, or both is important. A positive interaction between medroxyprogesterone acetate and pain management has been noted (59). Technically more invasive, transcatheter embolotherapy selectively catheterizes the ovarian and internal iliac veins, followed by contrast venography and embolization (60). Several small, uncontrolled studies with limited follow-up have reported pain reduction with transcatheter embolization of pelvic veins (61–62 and 63). For women who have completed their childbearing, hysterectomy with possible oophorectomy is a reasonable option.

Salpingo-oophoritis

Patients with salpingo-oophoritis usually present with symptoms and signs of acute infection. Atypical or partially treated infection may not be associated with fever or peritoneal signs. Subacute or atypical salpingo-oophoritis is often a sequela of chlamydia or mycoplasma infection. Alternatively, a patient with multiple partners may develop frequent recurrent infections (64). Patients with initial gonococcal PID are more likely to develop recurrent infections (65). The mechanism for this increased susceptibility to future infections has not been delineated, although it has been suggested that the fallopian tube and cervix may lose some of their natural protective mechanisms against microorganisms.

Abdominal tenderness, cervical motion, and bilateral adnexal tenderness are typical of pelvic infection. A complete blood count and ESR as well as cervical study for gonorrhea and chlamydia should be performed. In all situations, laparoscopy, with peritoneal fluid cultures, is usually diagnostic. Patients with either abnormal ESR or abnormal clinical examination should be treated empirically for salpingo-oophoritis before laparoscopy.

Ovarian Remnant Syndrome

Chronic pelvic pain in a patient who has had a hysterectomy and bilateral salpingo-oophorectomy for severe endometriosis or PID may be caused by the ovarian remnant syndrome. Ovarian remnant syndrome results from residual ovarian cortical tissue that is left in situ after a difficult dissection in an attempt to perform an oophorectomy. Often, the patient has had multiple pelvic operations with the uterus and adnexa removed sequentially.

Symptoms

The patient usually complains of lateralizing pelvic pain, often cyclic with ovulation or the luteal phase, described as sharp and stabbing or as constant, dull, and nonradiating, possibly with associated genitourinary or gastrointestinal complaints (66). Symptoms tend to arise 2 to 5 years after initial oophorectomy. A tender mass in the lateral region of the pelvis is pathognomonic.

Diagnosis

Ultrasoundography usually confirms a mass with the ultrasonographic characteristics of ovarian tissue. In a patient who has had bilateral salpingo-oophorectomy and is not taking hormonal replacement, estradiol and follicle-stimulating hormone (FSH) assays reveal a characteristic premenopausal picture, although on occasion the remaining ovarian tissue may not be active enough to suppress FSH levels (67,68).

Management

Initial medical treatment with either danazol, high-dose progestins, or oral contraceptives usually provides mixed results. Patients usually experience relief of pain with a GnRH agonist, although these medications are impractical for long-term therapy. Those who achieve relief with GnRH agonists also were relieved by subsequent surgery (69). Laparoscopic examination is usually nonproductive because the ovarian mass may be missed or adhesions may prevent accurate diagnosis. Laparotomy is necessary for treatment, and the corrective surgery tends to be arduous, often involving inadvertent cystotomy, enterotomy, postoperative small bowel obstructions, and hematoma formation. Surgical pathology usually reveals the presence of ovarian tissue, sometimes with endometriosis, corpus luteum or follicle cysts, and fibrous adhesions (67,68).

Gastroenterologic Causes

The uterus, cervix, and adnexa share with the lower ileum, sigmoid colon, and rectum the same visceral innervation, with pain signals traveling through sympathetic nerves to spinal cord segments T10 to L1 (70). It is often difficult, therefore, to determine whether lower abdominal pain is of gynecologic or enterocoelic origin. Skillful medical history and examination are necessary to distinguish gynecologic from gastrointestinal etiology of pain.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is one of the more common causes of lower abdominal pain and may account for up to 60% of referrals to the gynecologist for chronic pelvic pain (71). The exact etiology of IBS is unknown; however, patients with IBS have pain with smaller volume of distention of the bowel than those without IBS (71). These patients also have an abnormal pain referral pattern with colonic distention. Visceral hypersensitivity or hyperalgesia has been postulated as the cause of
pain, although the cause of this hyperalgesia is not known (72).

**Symptoms**

The predominant symptom of IBS is abdominal pain. Other symptoms include abdominal distention, excessive flatulence, alternating diarrhea and constipation, increased pain before a bowel movement, decreased pain after a bowel movement, and pain exacerbated by events that increase gastrointestinal motility, such as high-fat diet, stress, anxiety, depression, and menses. The pain is usually intermittent, occasionally constant, cramplike, and more likely to occur in the left lower quadrant. The criteria for diagnosis include at least 12 weeks (not necessarily consecutive) in the preceding 12 months of abdominal discomfort or pain that has at least two of the following features: relief with defecation, onset associated with change in stool frequency, or onset associated with change in form (appearance) of stool.

**Signs**

On physical examination, the finding of a palpable tender sigmoid colon or discomfort during insertion of the finger into the rectum and finding hard feces in the rectum are suggestive of IBS (79).

**Diagnosis**

The diagnosis of IBS is usually based on history and physical examination, and although suggestive, especially in young women, the findings are not specific. In one study, 91% of patients with IBS had two or more IBS symptoms (abdominal distention, relief of pain with bowel movement, more frequent bowel movements with the onset of pain, looser bowel movements with the onset of pain), whereas 30% of patients with organic disease had two or more of these symptoms (73). Therefore, a complete blood count, stool sample to test for white cells and occult blood, and sigmoidoscopy or colonoscopy or barium enema are usually required, particularly in older individuals and in young individuals who have not responded to initial treatment. The results of these studies are all normal in patients with IBS.

**Management**

Current medical therapy for IBS is generally unsatisfactory, and placebo response rates are high (74). A multidisciplinary program consisting of medical and psychological approaches is recommended. The treatment consists of reassurance, education, stress reduction, bulk-forming agents, and low-dose tricyclic antidepressants. The multidisciplinary management approach addresses the cognitive, affective, and behavioral components of the pain. Therapy may decrease the intensity of noiceceptor stimulation as well as change the interpretation of the meaning of pain.

Inflammatory bowel disease, such as Crohn's disease or ulcerative colitis, infectious enterocolitis, intestinal neoplasms, appendicitis, and hernia must be ruled out with appropriate history and physical examination, complete blood count, and stool cultures as well as visualization of colonic mucosa when appropriate.

**Urologic Causes**

Chronic pelvic pain of urologic origin may be related to recurrent cystourethritis, urethral syndrome, sensory urgency of uncertain cause, as well as interstitial cystitis. With an appropriate diagnostic workup, infiltrating bladder tumors, ureteral obstruction, renal lithiasis, and endometriosis can easily be ruled out as possible causes.

**Urethral Syndrome**

Urethral syndrome is defined as a symptom complex including dysuria, frequency and urgency of urination, suprapubic discomfort, and often dyspareunia in the absence of abnormality of urethra or bladder. The cause of urethral syndrome is uncertain and has been attributed to a subclinical infection, urethral obstruction, and psychogenic and allergic factors (75).

**Symptoms**

Urinary urgency, frequency, suprapubic pressure, and other less frequent symptoms such as bladder or vaginal pain, urinary incontinence, postvoid fullness, dyspareunia, and suprapubic pain are commonly observed.

**Signs**

Physical and neurologic examinations should be performed. The anal reflex should document that S2 to S4 spinal segments have not been interrupted (75). Anatomic abnormalities, including pelvic relaxation, urethral caruncle, and hypoestrogenism, should be evaluated. The patient should also be evaluated for vaginitis. The urethra should be carefully palpated to detect purulent discharge.

**Diagnosis**

A clean catch or catheterized urine specimen for routine urinalysis and culture should be obtained to rule out urinary tract infection. As indicated, urethral and cervical cultures for chlamydia should be obtained, and a wet prep for vaginitis should be performed. Urethral syndrome should be considered if the results of urine and urethral cultures are negative, the evaluation does not disclose vulvovaginitis, and no allergic phenomenon causing contact dermatitis of the urethra can be detected. Ureaplasma, chlamydia, candida, trichomonas, gonorrhea, and herpes should be ruled out. Cystoscopic evaluation should be performed to rule out urethral diverticulum, interstitial cystitis, and cancer.

**Management**

Various forms of therapy have been suggested for urethral syndrome. Those patients in whom no infectious agent is present but who have sterile pyuria respond to a 2- to 3-week course of doxycycline or erythromycin (75). Long-term, low-dose antimicrobial prophylaxis is often used in women with urgency and frequency symptoms who have a history of recurrent urinary tract infections. Some of these women may continue to have symptoms when their urine is not infected and then redeveloped bacteria over time (75). It is recommended that all women be given a trial of local estrogen therapy for about 2 months. If there is no improvement after antibiotic or estrogen therapy, urethral dilation can be considered. Positive results also have been noted with biofeedback techniques (75).

**Interstitial Cystitis**

Interstitial cystitis occurs more often in women than men. Most patients are between 40 and 60 years of age. The cause of interstitial cystitis is unknown, although an autoimmune etiology is generally accepted (78).

**Symptoms**

Symptoms include severe and disabling urinary frequency and urgency, nocturia, dysuria, and occasional hematuria. Suprapubic, pelvic, urethral, vaginal, or perineal pain is common and can be relieved partially by emptying of the bladder.

**Signs**

Pelvic examination usually reveals anterior vaginal wall and suprapubic tenderness. Urinalysis may reveal microhematuria without pyuria, although results may be normal.
Orthopedic or rheumatologic consultation should be sought before initiating management for back pain unless the source could be referred gynecologic pain. Although the histologic features of the biopsy specimen are nonspecific, there is usually submucosal edema, vasodilation, and infiltration by macrophages, plasma cells, and eosinophils.

Management

Because the etiology is uncertain, management has been empirical. Various pharmaceutical approaches, including anticholinergic, antispasmodic, and antiinflammatory agents, have been used. Response to treatment also has been noted with the use of tricyclic antidepressants or pentosan polysulfate sodium, which is approved for therapy (77). Hydrostatic bladder distention may produce temporary relief by creating detrusor ischemia and decreased innervation of the bladder wall. Biofeedback and behavioral therapy has also been used with some success (79).

Neurologic and Musculoskeletal Causes

Nerve Entrapment

Abdominal cutaneous nerve injury or entrapment may occur spontaneously or within weeks to years after transverse suprapubic skin or laparoscopy incisions (35,79). The ilioinguinal or iliohypogastric nerves may become trapped between the transverse and internal oblique muscles, especially when the muscles contract. Alternatively, the nerve may be ligated or traumatized during the surgery. Symptoms of nerve entrapment include burning, aching pain in the dermatomal distribution of the involved nerve (78,80). Hip flexion and exercise exacerbate pain. The pain is usually judged as coming from the abdomen, not the skin.

Signs

On examination, the pain usually can be localized with the fingertip. The maximal point of tenderness in an iliohypogastric or ilioinguinal injury is usually at the rectus margin, medial and inferior to the anterior iliac spine. Tentative diagnosis is confirmed with the diagnostic nerve block with 0.25% bupivacaine. Patients usually report immediate relief of symptoms after injection, and at least 50% experience relief lasting longer than a few hours (35).

Management

Many patients may require no further intervention, although some patients require up to five biweekly injections. If injection is successful in producing only limited pain relief and there are no contributory visceral or psychological factors, cryoneurelysis or surgical removal of the involved nerve is recommended.

Myofascial Pain

Myofascial syndrome has been documented in about 15% of patients with chronic pelvic pain (81). These patients are noted to have trigger points if examined carefully (82). Trigger points are initiated by pathogenic autonomic reflex of visceral or muscular origin (82,83). The referred pain of the trigger point occurs in a dermatomal distribution, and it is thought to be due to nerves from the muscle or deeper structures sharing a common second-order neuron in the spinal cord. Painful trigger points characteristically can be abolished with the injection of local anesthetic into the painful points (82). Trigger points are often present in women with chronic pelvic pain irrespective of presence or type of underlying pathology. In one study, 89% of women with chronic pelvic pain had abdominal, vaginal, or lumbosacral trigger points (82). In the absence of the initial or continued organic pathology, various factors are theorized to predispose to the chronicity of the myofascial syndrome, including psychological, hormonal, and biomechanical factors (83,84).

Symptoms

Abdominal wall pain is often exacerbated during the premenstrual period or by stimuli to the dermatome of trigger points (e.g., full bladder, bowel, or any stimulation to organs that share the dermatome of the involved nerve) (36).

Signs

On examination, fingertip pressure on the trigger points evokes local and referred pain. Tensing of the rectus muscles by either straight leg lifting or raising the head off the table increases the pain. A specific jump sign can be elicited by palpation with fingertip or a cotton swab. An electric (tingling) sensation confirms correct needle placement (36,85).

Management

Injection of the trigger point with 3 mL of 0.25% bupivacaine provides relief that usually outlasts the duration of the anesthetic action. After four to five biweekly injections, the procedure should be abandoned if long-lasting relief is not obtained (82). Concomitant with injection of trigger points, multidisciplinary pain management should be undertaken, especially if anxiety, depression, history of physical or sexual abuse, sexual dysfunction, or social or occupational disruption are present.

Low Back Pain Syndrome

Women complaining of lower back pain without pelvic pain rarely have gynecologic pathology as the cause of their pain. However, low back pain may accompany gynecologic pathology. Back pain may be caused by gynecologic, vascular, neurologic, psychogenic, or respondologenic (related to the axial skeleton and its structure) pathology (4).

Symptoms

Women with low back pain syndrome often have pain occurring after trauma or physical exertion, in the morning on arising, or with fatigue. Nongynecologic low back pain can intensify with the menstrual cycle.

Signs

Examination consists of inspection, evaluation with movement, and palpation. Various anatomic structures in the spine should be considered as sources of pain. Muscles, vertebral joints, and disks (including lumbosacral junction, paravertebral sacrospinal muscles, and sacroiliac joints) are common sources of spondylogenic pain that must be examined carefully (26,85).

Diagnosis

Diagnostic imaging studies performed while the patient is standing, lying, and sitting with maximal flexion can be helpful. An elevated ESR suggests pain of inflammatory or neoplastic origin.

Management

Orthopedic or rheumatologic consultation should be sought before initiating management for back pain unless the source could be referred gynecologic pain.
Psychological Factors

From a psychological perspective, various factors may promote the chronicity of pain, including the meaning attached to the pain, the ability to redirect attention, personality, mood state, past experience, and reinforcement contingencies that may amplify or attenuate pain (2). The Minnesota Multiphasic Personality Inventory (MMPI) studies of women with chronic pelvic pain reveal a high prevalence of a convergence “V” profile (elevated scores on the hypochondriasis, hysteria, and depression scales). Studies of MMPI profiles of women with chronic pain without obvious pathology compared with women with endometriosis-related pain or controls suggest that MMPI profiles are unable to distinguish patients with obvious organic findings. Both pain groups differ from controls (2). Furthermore, treatment resulting in subjective improvement in pain severity and increased activity level produces a significant improvement in personality profile (88).

There is also a close relationship between depression and pain (87). Both give rise to similar behavior, such as behavioral and social withdrawal and decreased activity, and may be mediated by the same neurotransmitters, including as norepinephrine, serotonin, and endorphins (2). Antidepressants appear to relieve both depression and pain. Childhood physical and sexual abuse has also been noted to be more prevalent in women with chronic pelvic pain than those with other types of pain and controls (52% versus 12%) (88). In a comparison of women with chronic pelvic pain, women with nonpelvic chronic pain (headache), and pain-free women, a higher lifetime prevalence of major sexual abuse (56%) and physical abuse (50%) was found in the chronic pelvic pain group (89). Individual differences in personality and habitual coping strategies may also influence response to pain and pain recurrence.

Management Approach

In patients with no obvious pathology and in those with pathology that has an equivocal role in pain production, multidisciplinary therapy is usually preferable. This approach incorporates the skills of the gynecologist, psychologist, and ideally anesthesiologist. A low dose of a tricyclic antidepressant is combined with behavioral therapy directed toward reducing reliance on pain medication, increasing activity, and relieving the impact the pain has on the women’s overall lifestyle (2). Women with depression should be treated with an appropriate therapeutic dose of antidepressant medication (99). Only one small, randomized, controlled trial has looked at the effect of selective serotonin reuptake inhibitors on pelvic pain. It failed to show a significant difference in pain or functional ability in a short follow-up period (91). The approach to women with chronic pain must be therapeutic, supportive, and sympathetic. Offering regular follow-up appointments instead of asking the patient to return only if pain persists reinforces pain behavior. Specific skills can be taught to the patient using cognitive behavioral approaches. Women are offered ways to enhance opportunities for control of pain. Psychotherapy is indicated for women who have pronounced depression, sexual difficulties, or indications of past trauma. Various strategies, including relaxation techniques, stress management, sexual and marital counseling, hypnosis, and other psychological therapeutic approaches, have been found to be useful. Acupuncture may also be helpful (92). Diagnostic uterosacral, hypogastric, or epidural nerve blocks can be used (93).

Multidisciplinary Approach

Various studies of multidisciplinary pain management have been performed. Retrospective, uncontrolled studies revealed relief of pain in 85% of the subjects (92,94). One prospective randomized study revealed a similar response rate, which was significantly better than that of traditional therapy (95).

Surgical Therapy

Laparoscopy

Those women with disabling cyclic pain that does not respond to nonsteroidal antiinflammatory medication or oral contraceptives should undergo laparoscopic evaluation. Diagnostic laparoscopy has become a standard procedure in the evaluation of patients with chronic noncyclic pelvic pain; however, laparoscopy should be warranted only if other gynecologic somatic or visceral causes of pain have been eliminated. During diagnostic laparoscopy, endometriotic lesions should be excised for biopsy, and if infection is suspected, cultures should be performed. All visible endometriosis should be surgically excised or electrocauterized. Patients with dysmenorrhea may benefit from transection of the uterosacral ligaments. The uterosacral ligaments carry the principal afferent nerve supply from the uterus to the hypogastric nerve. The original procedure was performed by a colpotomy and was noted to have a success rate of 70% (98). Laparoscopic nerve ablation was found to relieve dysmenorrhea in 85% of patients (97). Nonrandomized retrospective and prospective studies have suggested that diagnostic laparoscopy provides a positive psychological effect on the treatment of chronic pelvic pain (99).

Lysis of Adhesions

The role of pelvic adhesions in pain is unclear (2). Adhesiolyis, even by laparoscopy, is frequently complicated by adhesion reformation (99). However, other etiologies must be treated first. Psychological consultation and management should precede or accompany the lysis of adhesions.

Presacral Neurectomy

Presacral neurectomy or sympathetomy was first described for dysmenorrhea (100). The discovery of highly successful medical therapies has largely supplanted presacral neurectomy; however, presacral neurectomy may be indicated for primary or secondary dysmenorrhea unrelied by traditional therapy and unresponsive to multidisciplinary pain management. The response rate to presacral neurectomy for secondary dysmenorrhea varies between 50% and 75% (2,99). The neurectomy only relieves pain deriving from the cervix, uterus, and proximal fallopian tubes (T1 to L2). The nerve supply to the adnexal structures (T9 to T10) bypasses the hypogastric nerve. Therefore, lateralizing visceral pain is unlikely to be relieved by presacral neurectomy. Intraoperative complications, such as hemorrhage or ureteral injury, can occur in a small percentage of cases. The sacral nerve supply is unaffected by division of the presacral nerve; thus, normal micturition, defecation, and parturition are preserved. A local anesthetic hypogastric block performed under fluoroscopic guidance can help to predict the response to this operation.

Hysterectomy

Hysterectomy has often been performed to cure pelvic pain; however, 30% of patients presenting to pain clinics have already undergone hysterectomy without experiencing pain relief (28). Hysterectomy is particularly useful for women who have completed childbearing and have secondary dysmenorrhea or chronic pain related to endometriosis, to uterine pathology, such as adenomyosis, or to pelvic congestion. Before recommending hysterectomy for pain or unilateral adnexectomy for unilateral pain, it is useful to apply the PREPARE pneumonic in discussions with the patient (101): the Procedure that is being done, Reason or indication, Expectation or desired outcome of the procedure, Probability that the outcome will be achieved, Alternatives and nonsurgical options, and Risks as well as Expense (see Chapter 3). Hysterectomy for central pelvic pain in women with dysmenorrhea, dyspareunia, and uterine tenderness provided relief of pain in 77% of women in one study (102). However, in a prospective cohort study on 103 women with chronic pelvic pain, a similar percentage of women in one prospective cohort study (103). Nevertheless, 25% of women in the retrospective study noted a persistence or worsening of pain at 1-year follow-up (104).

References

Genitourinary tract infections are among the most frequent disorders for which patients seek care from gynecologists. By understanding the pathophysiology of these diseases and having an effective approach to their diagnosis, physicians can institute appropriate antimicrobial therapy to treat these conditions and reduce long-term sequelae.

The Normal Vagina

Normal vaginal secretions are composed of vulvar secretions from sebaceous, sweat, Bartholin, and Skene glands; transudate from the vaginal wall; exfoliated vaginal and cervical cells; cervical mucus; endometrial and oviductal fluids; and microorganisms and their metabolic products. The type and amount of exfoliated cells, cervical mucus, and upper genital tract fluids are determined by biochemical processes that are influenced by hormone levels (1). Vaginal secretions may increase in the middle of the menstrual cycle because of an increase in the amount of cervical mucus. These cyclic variations do not occur when oral contraceptives are used and ovulation does not occur.

The vaginal desquamative tissue is made up of vaginal epithelial cells that are responsive to varying amounts of estrogen and progesterone. Superficial cells, the predominant cell type in women of reproductive age, predominate when estrogen stimulation is present. Intermediate cells predominate during the luteal phase because of progestogenic stimulation. Parabasal cells predominate in the absence of either hormone, a condition that may be found in postmenopausal women who are not receiving hormonal replacement therapy.

The normal vaginal flora is predominantly aerobic, with an average of six different species of bacteria, the most common of which is hydrogen peroxide–producing lactobacilli. The microbiology of the vagina is determined by factors that affect the ability of bacteria to survive (2). These factors include vaginal pH and the availability of glucose for bacterial metabolism. The pH of the normal vagina is lower than 4.5, which is maintained by the production of lactic acid. Estrogen-stimulated vaginal epithelial cells are rich in glycogen. Vaginal epithelial cells break down glycogen to monosaccharides, which can then be converted by the cells themselves and lactobacilli to lactic acid.

Normal vaginal secretions are floccular in consistency, white in color, and usually located in the dependent portion of the vagina (posterior fornix). Vaginal secretions can be analyzed by a wet-mount preparation. A sample of vaginal secretions is suspended in 0.5–1 mL of normal saline in a glass tube, transferred to a slide, covered with a slip, and assessed by microscopy. Some clinicians prefer to prepare slides by suspending secretions in saline placed directly on the slide. Secretions should not be placed on the slide without saline because this method causes drying of the vaginal secretions and does not result in a well-suspended preparation.

Microscopy of normal vaginal secretions reveals many superficial epithelial cells, few white blood cells (less than 1 per epithelial cell), and few, if any, clue cells. Clue cells are superficial vaginal epithelial cells with adherent bacteria, usually Gardnerella vaginalis, which obliterates the crisp cell border when visualized microscopically. Potassium hydroxide 10% (KOH) may be added to the slide, or a separate preparation can be made, to examine the secretions for evidence of fungal elements. The results are negative in women with normal vaginal microbiology. Gram stain reveals normal superficial epithelial cells and a predominance of gram-positive rods (lactobacilli).

Vaginal Infections

Bacterial Vaginosis

Bacterial vaginosis (BV) has previously been referred to as nonspecific vaginitis or Gardnerella vaginitis. It is an alteration of normal vaginal bacterial flora that results in the loss of hydrogen peroxide–producing lactobacilli and an overgrowth of predominantly anaerobic bacteria (3, 4). The most common form of vaginitis in the United States is BV (5). Anaerobic bacteria can be found in less than 1% of the flora of normal women. In women with BV, however, the concentration of anaerobes, as well as G. vaginalis and Mycoplasma hominis, is 100 to 1,000 times higher than in normal women. Lactobacilli are usually absent.

It is not known what triggers the disturbance of normal vaginal flora. It has been postulated that repeated alkalinization of the vagina, which occurs with frequent sexual intercourse or use of douches, plays a role. After normal hydrogen peroxide–producing lactobacilli disappear, it is difficult to reestablish normal vaginal flora, and recurrence of BV is common.

Numerous studies have shown an association of BV with significant adverse sequelae. Women with BV are at increased risk for pelvic inflammatory disease (PID) (6), postabortal PID (7), postoperative cuff infections after hysterecotomy (8), and abnormal cervical cytology (9). Pregnant women with BV are at risk for premature rupture of the membranes (10), preterm labor and delivery (11), chorioamnionitis, and postcesarean endometritis (11). It is not known whether screening for, and treatment of, BV will decrease the risk for these adverse sequelae.
Diagnosis

Bacterial vaginosis is diagnosed on the basis of the following findings (12):

1. A fishy vaginal odor, which is particularly noticeable following coitus, and vaginal discharge are present.
2. Vaginal secretions are gray and thin, and they coat the vaginal walls.
3. The pH of these secretions is higher than 4.5 (usually 4.7 to 5.7).
4. Microscopy of the vaginal secretions reveals an increased number of clue cells, and leukocytes are conspicuously absent. In advanced cases of BV, more than 20% of the epithelial cells are clue cells.
5. The addition of KOH to the vaginal secretions (the “whiff” test) releases a fishy, amine-like odor.

Culture of G. vaginalis is not recommended as a diagnostic tool because of its lack of specificity.

Treatment

Ideally, treatment of BV should inhibit anaerobes but not vaginal lactobacilli. The following treatments are effective (13):

1. Metronidazole, an antibiotic with excellent activity against anaerobes but poor activity against lactobacilli, is the drug of choice for the treatment of BV. A dose of 500 mg administered orally twice a day for 7 days should be used. Patients should be advised to avoid using alcohol during treatment with oral metronidazole and for 24 hours thereafter.
2. Metronidazole gel, 0.75%, one applicator (5 g) intravaginally once or twice daily for 5 days, may also be prescribed.
3. An alternative regimen uses a single, 2-g oral dose of metronidazole.

The overall cure rates range from 75% to 84% for the above regimens (13).

Clindamycin in the following regimens also is effective:

- Clindamycin cream, 2%, one applicator full (5 g) intravaginally at bedtime for 7 days
- Clindamycin, 300 mg, orally twice daily for 7 days
- Clindamycin ovules, 100 mg, intravaginally once at bedtime for 3 days

Many clinicians prefer intravaginal treatment because of a lack of systemic side effects such as mild-to-moderate gastrointestinal upset and unpleasant taste. Treatment of the male sexual partner has not been shown to improve therapeutic response and therefore is not recommended.

Trichomonal Vaginitis

Trichomonal vaginitis is caused by the sexually transmitted, flagellated parasite, Trichomonas vaginalis. The transmission rate is high; 70% of males contract the disease after a single exposure to an infected female, which suggests that the rate of male-to-female transmission is even higher. The parasite is an anaerobe that has the ability to generate hydrogen to combine with oxygen to create an anaerobic environment. It exists only in trophozoite form. Trichomonal vaginitis often accompanies BV, which can be diagnosed in up to 60% of patients with trichomonal vaginitis.

Diagnosis

Local immune factors and inoculum size influence the appearance of symptoms. Symptoms and signs may be much milder in patients with a smaller inoculum of trichomonads, and trichomonal vaginitis often is asymptomatic (14,15).

1. Trichomonal vaginitis is associated with a profuse, purulent, malodorous vaginal discharge that may be accompanied by vulvar pruritus.
2. Vaginal secretions may exude from the vagina.
3. In patients with high concentrations of organisms, a patchy vaginal erythema and colpitis macularis (“strawberry” cervix) may be observed.
4. The pH of the vaginal secretions is usually higher than 5.0.
5. Microscopy of the secretions reveals motile trichomonads and increased numbers of leukocytes.
6. Clue cells may be present because of the common association with BV.
7. The whiff test may also be positive.

Morbidity associated with trichomonal vaginitis may be related to BV. Patients with trichomonal vaginitis are at increased risk for postoperative cuff cellulitis following hysterectomy (8). Pregnant women with trichomonal vaginitis are at increased risk for premature rupture of the membranes and preterm delivery. Because of the sexually transmitted nature of trichomonal vaginitis, women with this infection should be tested for other sexually transmitted diseases (STDs), particularly Neisseria gonorrhoeae and Chlamydia trachomatis. Serologic testing for syphilis and human immunodeficiency virus (HIV) infection should also be considered.

Treatment

The treatment of trichomonal vaginitis can be summarized as follows:

1. Metronidazole is the drug of choice for treatment of vaginal trichomoniads. Both a single-dose (2 g orally) and a multidose (500 mg twice daily for 7 days) regimen are highly effective and have cure rates of about 95%.
2. The sexual partner should also be treated.
3. Metronidazole gel, although highly effective for the treatment of BV, should not be used for the treatment of vaginal trichomoniads.
4. Women who do not respond to initial therapy should be treated again with metronidazole, 500 mg, twice daily for 7 days. If repeated treatment is not effective, the patient should be treated with a single 2-g dose of metronidazole once daily for 3 to 5 days.
5. Patients who do not respond to repeated treatment with metronidazole and for whom the possibility of reinfection has been excluded should be referred for expert consultation. In these uncommon refractory cases, an important part of management is to obtain cultures of the parasite to determine its susceptibility to metronidazole.

Vulvovaginal Candidiasis

It is estimated that as many as 75% of women experience at least one episode of vulvovaginal candidiasis (VVC) during their lifetimes (16). Almost 45% of women will experience two or more episodes (17). Fortunately, few are plagued with a chronic, recurrent infection. Candida albicans is responsible for 85% to 90% of vaginal yeast infections. Other species of Candida, such as C. glabrata and C. tropicalis, can cause vulvovaginal symptoms and tend to be resistant to therapy. Candida are dimorphic fungi existing as blastospores, which are responsible for transmission and asymptomatic colonization, and as mycelia, which result from blastospore germination and enhance colonization and facilitate tissue invasion. The extensive areas of pruritus and inflammation often associated with minimal invasion of the lower genital tract epithelial cells suggest that an extracellular toxin or enzyme may play a role in the pathogenesis of this disease. A hypersensitivity phenomenon also may be responsible for the irritative symptoms associated with VVC; especially for patients with chronic, recurrent disease. Patients with symptomatic disease usually have an increased concentration of these microorganisms (<10^10/mL) compared with asymptomatic patients (<10^7/mL) (18).

Factors that predispose women to the development of symptomatic VVC include antibiotic use (19,20), pregnancy (21), and diabetes (22). Through a mechanism referred to as colonization resistance, lactobacilli prevent the overgrowth of the opportunistic fungi. Antibiotic use disturbs the normal vaginal flora, decreasing the concentration of lactobacilli and other normal flora, and thus allowing an overgrowth of fungi. Pregnancy and diabetes are both associated with a qualitative decrease
The symptoms of VVC consist of vulvar pruritus associated with a vaginal discharge that typically resembles cottage cheese.

1. The discharge can vary from watery to homogeneously thick. Vaginal soreness, dyspareunia, vulvar burning, and irritation may be present. External dysuria (“splash” dysuria) may occur when micturition leads to exposure of the inflamed vulvar and vestibular epithelium to urine. Examination reveals erythema and edema of the labia and vulvar skin. There may be discrete postulopapular peripheral lesions. The vagina may be erythematous with an adherent, whitish discharge. The cervix appears normal.
2. The pH of the vagina in patients with VVC is usually normal (4,5).
3. Fungal elements, either budding yeast forms or mycelia, appear within as many as 80% of cases. The results of saline preparation of the vaginal secretions usually are normal, although there may be a slight increase in the number of inflammatory cells in severe cases.
4. The whiff test is negative.
5. A presumptive diagnosis can be made in the absence of microscopy-proven fungal elements if the pH and the results of the saline preparation are normal. A fungal culture is recommended to confirm the diagnosis.

Treatment

1. Topically applied azole drugs are the most commonly available treatment for VVC and are more effective than nystatin (13) (Table 15.1). Treatment with azoles results in relief of symptoms and negative cultures among 80% to 90% of patients who have completed therapy. Symptoms usually take 2 to 3 days to resolve. There is a trend to shorten the duration of therapy to 1 to 3 days. Although the shorter period of therapy implies a shortened duration of treatment, because the short-course formulations have higher concentrations of the antifungal agent, they cause an inhibitory concentration in the vagina that persists for several days.

2. An oral antifungal agent, fluconazole, used in a single 150-mg dose, has been approved for the treatment of VVC. It appears to have equal efficacy when compared with topical azoles in the treatment of mild-to-moderate VVC (23). Patients should be advised that their symptoms will not disappear for 2 to 3 days so that they will not expect additional treatment. Patients with severe symptoms may benefit from an additional 150-mg dose given 72 hours after the first dose.
3. Adjunctive treatment with a weak topical steroid, such as 1% hydrocortisone cream, may be helpful in relieving some of the external irritative symptoms.

Inflammatory Vaginitis

Desquamative inflammatory vaginitis is a clinical syndrome characterized by diffuse exudative vaginitis, epithelial cell exfoliation, and a profuse purulent vaginal discharge (25). The cause of inflammatory vaginitis is unknown, but Gram stain findings reveal a relative absence of normal long gram-positive bacilli (lactobacilli) and their replacement with gram-positive cocci, usually streptococci. Women with this disorder have a purulent vaginal discharge, vulvovaginal burning or irritation, and dyspareunia. A less frequent complaint is vulvar pruritus. Vaginal erythema is present, and there may be an associated vulvar erythema, vulvovaginal ecchymotic spots, and colitis macularis. The pH of the vaginal secretions is uniformly higher than 4.5 in these patients.

Initial therapy is the use of 2% clindamycin cream, one applicator full (5 g) intravaginally once daily for 7 days. Relapse occurs in about 30% of patients, who should be retreated with intravaginal 2% clindamycin cream for 2 weeks. When relapse occurs in postmenopausal patients, supplementary hormonal replacement therapy should be considered.

Atrophic Vaginitis

Estrogen plays an important role in the maintenance of normal vaginal ecology. Women undergoing menopause, either occurring naturally or secondary to surgical removal of the ovaries, may develop inflammatory vaginitis, which may be accompanied by an increased, purulent vaginal discharge. In addition, they may note dyspareunia and postcoital bleeding resulting from atrophy of the vaginal and vulvar epithelium. Examination reveals atrophy of the external genitalia, along with a loss of the vaginal rugae. The vaginal mucosa may be somewhat friable in areas. Microscopy of the vaginal secretions shows a predominance of parabasal epithelial cells and an increased number of leukocytes.

Atrophic vaginitis is treated with topical estrogen vaginal cream. Use of 1 g of conjugated estrogen cream intravaginally each day for 1 to 2 weeks generally provides relief. Systemic estrogen replacement therapy should be considered to prevent recurrence of this disorder.

Cervicitis

The cervix is made up of two different types of epithelial cells: squamous epithelium and glandular epithelium. The cause of cervical inflammation depends on the epithelium affected. The ectocervical epithelium can become inflamed by the same microorganisms that are responsible for vaginitis. In fact, the ectocervical squamous epithelium is an extension of and is continuous with the vaginal epithelium. Trichomonas, candida, and herpes simplex virus (HSV) can cause inflammation of the ectocervix. Conversely, N. gonorrhoeae and C. trachomatis infect only the glandular epithelium and are responsible for mucopurulent endocervicitis (MPC) (26).
The diagnosis of MPC is based on the finding of a purulent endocervical discharge, generally yellow or green in color and referred to as “mucopus” (27).

1. After removal of ectocervical secretions with a large swab, a small cotton swab is placed into the endocervical canal and the cervical mucus is extracted. The cotton swab is inspected against a white or black background to detect the green or yellow color of the mucopus. In addition, edema, erythema, and friability of the zone of ectopy (glandular epithelium) are present. Although edema and erythema of the endocervix can be difficult to distinguish, friability or easily induced bleeding can be assessed by touching the ectropion with a cotton swab or spatulum.

2. Placement of the mucopus on a slide that can be Gram stained will reveal the presence of an increased number of neutrophils (>30 per high-power field). The presence of intracellular gram-negative diplococci, leading to the presumptive diagnosis of gonococcal endocervicitis, also may be detected. If the Gram stain results are negative for gonococci, the presumptive diagnosis is chlamydial MPC.

3. Tests for both gonorrhea (culture on Thayer-Martin media or polymerase chain reaction [PCR]) and chlamydia (cell culture, enzyme-linked immunosorbent assay [ELISA], chlamydial enzyme, direct fluorescent antibody [MicroTrak], or PCR) should be performed. The microbial etiology of endocervicitis is unknown in about 50% of cases in which gonococci or chlamydia are not detected.

Treatment of MPC consists of an antibiotic regimen recommended for the treatment of uncomplicated lower genital tract infection with both chlamydia and gonorrhea (13) (Table 15.2). It is imperative that all sexual partners be treated with a similar antibiotic regimen. MPC is commonly associated with BV, which, if not treated concurrently, leads to a significant persistence of the symptoms and signs of MPC.

Pelvic Inflammatory Disease

PID is caused by microorganisms colonizing the endocervix ascending to the endometrium and fallopian tubes. PID is a clinical diagnosis implying that the patient has upper genital tract infection and inflammation. The inflammation may be present at any point along a continuum that includes endometritis, salpingitis, and peritonitis (28)(29). It is now recognized that there is wide variation in many symptoms and signs among women with this condition, which makes the diagnosis of acute PID difficult. Many women with PID exhibit subtle or mild symptoms that are not readily recognized as PID. Consequently, delay in diagnosis and therapy probably contributes to the inflammatory sequelae in the upper reproductive tract (30).

In the diagnosis of PID, the goal is to establish guidelines that are sufficiently sensitive to avoid missing mild cases but sufficiently specific to avoid giving antibiotic therapy to women who are not infected. Genitourinary tract symptoms may indicate PID; therefore, the diagnosis of PID should be considered in women with any genital symptoms, including, but not limited to, lower abdominal pain, excessive vaginal discharge, menorrhagia, metrorrhagia, fever, chills, and urinary symptoms (31). Some women may develop PID without having any symptoms.

Pelvic organ tenderness, either uterine tenderness alone or uterine tenderness with adnexal tenderness, is present in patients with PID. Cervical motion tenderness suggests the presence of peritoneal inflammation, which causes pain when the peritoneum is stretched by moving the cervix and causing traction of the adnexa on the pelvic peritoneum. Direct or rebound abdominal tenderness may be present.

Evaluation of lower genital tract secretions, both vaginal and endocervical, is a crucial part of the workup of a patient with PID (32). In women with PID, an increased number of polymorphonuclear leukocytes may be detected in a wet mount of the vaginal secretions or in the mucopurulent discharge.

More elaborate tests may be used in women with severe symptoms because an incorrect diagnosis may cause unnecessary morbidity (33). These tests include endometrial biopsy to confirm the presence of endometritis, ultrasound or radiologic tests to characterize a tuboovarian abscess (TOA), and laparoscopy to confirm salpingitis visually.

Figure 15.1 Microorganisms originating in the endocervix ascend into the endometrium, fallopian tubes, and peritoneum, causing pelvic inflammatory disease (endometritis, salpingitis, peritonitis). (From Soper DE. Upper genital tract infections. In: Copeland LJ, ed. Textbook of gynecology. Philadelphia: WB Saunders, 1993:521.)

PID commonly is caused by the sexually transmitted microorganisms N. gonorrhoeae and C. trachomatis (28,29 and 30). Endogenous microorganisms found in the vagina, particularly the BV microorganisms, also often are isolated from the upper genital tract of women with PID. The BV microorganisms include anaerobic bacteria such as Prevotella and peptostreptococci as well as G. vaginalis. BV often occurs in women with PID, and the resultant complex alteration of vaginal flora may facilitate the ascending spread of pathogenic bacteria by enzymatically altering the cervical mucus barrier (31). Less frequently, respiratory pathogens such as Haemophilus influenzae, group A streptococci, and pneumococci can colonize the lower genital tract and cause PID.

PID is caused by microorganisms colonizing the endocervix ascending to the endometrium and fallopian tubes. PID is a clinical diagnosis implying that the patient has upper genital tract infection and inflammation. The inflammation may be present at any point along a continuum that includes endometritis, salpingitis, and peritonitis (Fig. 15.1).

Figure 15.1 Microorganisms originating in the endocervix ascend into the endometrium, fallopian tubes, and peritoneum, causing pelvic inflammatory disease (endometritis, salpingitis, peritonitis). (From Soper DE. Upper genital tract infections. In: Copeland LJ, ed. Textbook of gynecology. Philadelphia: WB Saunders, 1993:521.)

PID commonly is caused by the sexually transmitted microorganisms N. gonorrhoeae and C. trachomatis (28,29 and 30). Endogenous microorganisms found in the vagina, particularly the BV microorganisms, also often are isolated from the upper genital tract of women with PID. The BV microorganisms include anaerobic bacteria such as Prevotella and peptostreptococci as well as G. vaginalis. BV often occurs in women with PID, and the resultant complex alteration of vaginal flora may facilitate the ascending spread of pathogenic bacteria by enzymatically altering the cervical mucus barrier (31). Less frequently, respiratory pathogens such as Haemophilus influenzae, group A streptococci, and pneumococci can colonize the lower genital tract and cause PID.

Traditional, the diagnosis of PID has been based on a triad of symptoms and signs, including pelvic pain, cervical motion and adnexal tenderness, and the presence of fever. It is now recognized that there is wide variation in many symptoms and signs among women with this condition, which makes the diagnosis of acute PID difficult. Many women with PID exhibit subtle or mild symptoms that are not readily recognized as PID. Consequently, delay in diagnosis and therapy probably contributes to the inflammatory sequelae in the upper reproductive tract (32).

In the diagnosis of PID, the goal is to establish guidelines that are sufficiently sensitive to avoid missing mild cases but sufficiently specific to avoid giving antibiotic therapy to women who are not infected. Genitourinary tract symptoms may indicate PID; therefore, the diagnosis of PID should be considered in women with any genital symptoms, including, but not limited to, lower abdominal pain, excessive vaginal discharge, menorrhagia, metrorrhagia, fever, chills, and urinary symptoms (33). Some women may develop PID without having any symptoms.

Pelvic organ tenderness, either uterine tenderness alone or uterine tenderness with adnexal tenderness, is present in patients with PID. Cervical motion tenderness suggests the presence of peritoneal inflammation, which causes pain when the peritoneum is stretched by moving the cervix and causing traction of the adnexa on the pelvic peritoneum. Direct or rebound abdominal tenderness may be present.

Evaluation of lower genital tract secretions, both vaginal and endocervical, is a crucial part of the workup of a patient with PID (34). In women with PID, an increased number of polymorphonuclear leukocytes may be detected in a wet mount of the vaginal secretions or in the mucopurulent discharge.

More elaborate tests may be used in women with severe symptoms because an incorrect diagnosis may cause unnecessary morbidity (35). These tests include endometrial biopsy to confirm the presence of endometritis, ultrasound or radiologic tests to characterize a tuboovarian abscess (TOA), and laparoscopy to confirm salpingitis visually.
Table 15.3 Clinical Criteria for the Diagnosis of Pelvic Inflammatory Disease

Treatment

Therapy regimens for PID must provide empirical, broad-spectrum coverage of likely pathogens (13,36), including *N. gonorrhoeae, C. trachomatis*, gram-negative facultative bacteria, anaerobes, and streptococci. Recommended regimens for the treatment of PID are listed in Table 15.4. Hospitalization is recommended, especially when the diagnosis is uncertain, pelvic abscess is suspected, clinical disease is severe, or compliance with an outpatient regimen is in question. Hospitalized patients can be considered for discharge when their fever has lysed (<99.5°F for more than 24 hours), the white blood cell count has become normal, rebound tenderness is absent, and repeat examination shows marked amelioration of pelvic organ tenderness (37).

Table 15.4 CDC Guidelines for Treatment of Pelvic Inflammatory Disease

Sexual partners of women with PID should be evaluated and treated for urethral infection with chlamydia or gonorrhea (Table 15.2). Urethral tests from male sexual partners of women with nongonococcal, nonchlamydial PID commonly reveals the presence of one of these STDs (38,39).

Tuboovarian Abscess

TOA is an end-stage process of acute PID. TOA is diagnosed when a patient with PID has a pelvic mass that is palpable during bimanual examination. The condition usually reflects an agglutination of pelvic organs (tube, ovary, bowel) forming a palpable complex. Occasionally, an ovarian abscess can result from the entrance of microorganisms through an ovulatory site. Treatment of TOA involves the use of an antibiotic regimen administered in a hospital (Table 15.4). About 75% of women with TOA respond to antimicrobial therapy alone. Failure of medical therapy suggests the need for drainage of the abscess (40). Although this may require surgical exploration, percutaneous drainage guided by imaging studies (ultrasound or computed tomography scan) has been used successfully.

Other Major Infections

Genital Ulcer Disease

In the United States, most patients with genital ulcers have genital HSV or syphilis (41,42 and 43). Chancroid is the next most common cause of sexually transmitted genital ulcers, followed by the rare occurrence of lymphogranuloma venereum (LGV) and granuloma inguinale (donovanosis). These diseases are associated with an increased risk for HIV infection. Other infrequent and noninfectious causes of genital ulcers include abrasions, fixed drug eruptions, carcinoma, and Behçet's disease.

Diagnosis

A diagnosis based on history and physical examination often is inaccurate. Therefore, evaluation of all women with genital ulcers should include a serologic test for syphilis (43). Because of the consequences of inappropriate therapy, such as tertiary disease and congenital syphilis in pregnant women, diagnostic efforts are directed at excluding syphilis. An optimal workup of the patient with a genital ulcer includes the performance of a dark-field examination or direct immunofluorescence test for *Treponema pallidum*, culture or antigen test for HSV, and culture for *Haemophilus ducreyi*. Dark-field or fluorescent microscopes and selective media to culture for *H. ducreyi* are often not available in most offices and clinics. Even after complete testing, the diagnosis remains unconfirmed in one fourth of patients with genital ulcers. For this reason, most clinicians base their initial diagnosis and treatment recommendations on their clinical impression of the appearance of the genital ulcer (Fig. 15.2) and knowledge of the most likely cause in their patient population (42).

Figure 15.2 Showing the appearance of the ulcers of chancroid (A), herpes (B), and syphilis (C). The ulcer of chancroid has irregular margins and is deep with undermined edges. The syphilis ulcer has a smooth, indurated border and a smooth base. The genital herpes ulcer is superficial and inflamed. (Modified from Schmid GP, Shcalla WO, DeWitt WE. Chancroid. In: Morse SA, Moreland AA, Thompson SE, eds. Atlas of sexually transmitted diseases. Philadelphia: JB Lippincott, 1990.)
Several clinical presentations are highly suggestive of specific diagnoses:

1. A nonpainful and minimally tender ulcer, not accompanied by inguinal lymphadenopathy, is likely to be syphilis, especially if the ulcer is indurated. A nontreponemal rapid plasma reagin (RPR) test, or venereal disease research laboratory (VDRL) test, and a confirmatory treponemal test—fluorescent treponemal antibody absorption (FTA-ABS) or microhemagglutination—T. pallidum (MHA TP), should be used to diagnose syphilis presumptively. The results of nontreponemal tests usually correlate with disease activity and should be reported quantitatively.

2. Grouped vesicles mixed with small ulcers, particularly with a history of such lesions, are almost pathognomonic of genital herpes. Nevertheless, laboratory confirmation of the diagnosis is recommended because the diagnosis of genital herpes is traumatic for many women, alters their self-image, and affects their perceived ability to enter new sexual relationships and bear children. Culture is the most sensitive and specific test; sensitivity approaches 100% in the vesicle stage and 89% in the pustular stage and drops to as low as 33% in patients with ulcers. Nonculture tests are about 80% as sensitive as culture.

3. One to three extremely painful ulcers, accompanied by tender inguinal lymphadenopathy, are unlikely to be anything except chancroid. This is especially true if the adenopathy is fluctuant.

4. An inguinal bubo accompanied by one or several ulcers is most likely chancroid. If there is no ulcer, the most likely diagnosis is LGV.

**Treatment**

**Chancroid** Recommended regimens for the treatment of chancroid include azithromycin, 1 g orally in a single dose; ceftriaxone, 250 mg intramuscularly in a single dose; ciprofloxacin, 500 mg orally twice a day for 3 days; or erythromycin base, 500 mg orally 4 times daily for 7 days. Patients should be reexamined 3 to 7 days after initiation of therapy to ensure the gradual resolution of the genital ulcer, which can be expected to heal within 2 weeks unless it is unusually large.

**Herpes** A first episode of genital herpes should be treated with acyclovir, 400 mg orally three times a day; or famciclovir, 250 mg orally three times a day; or valacyclovir, 1.0 orally twice a day for 7 to 10 days or until clinical resolution is attained. Although these agents provide partial control of the symptoms and signs of clinical herpes, it neither eradicates latent virus nor affects subsequent risk, frequency, or severity of recurrences after the drug is discontinued. Daily suppressive therapy (acyclovir, 400 mg orally twice daily; or famciclovir, 250 mg twice daily; or valacyclovir, 1.0 g orally once a day) reduces the frequency of HSV recurrences by at least 75% among patients with six or more recurrences of HSV per year. Suppressive treatment does not totally eliminate symptomatic or asymptomatic viral shedding or the potential for transmission.

**Syphilis** Parenteral penicillin G administration is the preferred treatment of all stages of syphilis. Benzathine penicillin G, 2.4 million units intramuscularly in a single dose, is the recommended treatment for adults with primary, secondary, or early latent syphilis. The Jarisch-Herxheimer reaction is an acute febrile reaction—accompanied by headache, myalgia, and other symptoms—that may occur within the first 24 hours after any therapy for syphilis; patients should be advised of this possible adverse reaction.

**Latent syphilis** is defined as those periods after infection with T. pallidum when patients are seroreactive but show no other evidence of disease. Patients with latent syphilis of longer than 1 year's duration or of unknown duration should be treated with benzathine penicillin G, 7.2 million units total, administered as three doses of 2.4 million units intramuscularly each, at 1-week intervals. All patients with latent syphilis should be evaluated clinically for evidence of tertiary disease (e.g., aortitis, neurosyphilis, gumma, and iritis). Quantitative nontreponemal serologic tests should be repeated at 6 months and again at 12 months. An initially high titer (1:32) should decline at least fourfold (two dilutions) within 12 to 24 months.

**Genital Warts**

External genital warts (EGWs) are a manifestation of human papillomavirus (HPV) infection (4). The nononcogenic HPV types 6 and 11 are usually responsible for EGWs. The warts tend to occur in areas most directly affected by coitus, namely the posterior fourchette and lateral areas on the vulva. Less frequently, warts can be found throughout the vulva, in the vagina, and on the cervix. Minor trauma associated with coitus can cause breaks in the vulvar skin, allowing direct contact between the viral particles from an infected male and the basal layer of the epithelium of his susceptible sexual partner. Infection may be latent or may cause viral particles to replicate and produce a wart. EGWs are highly contagious; more than 75% of sexual partners develop this manifestation of HPV infection when exposed.

The goal of treatment is removal of the warts; it is not possible to eradicate the viral infection. Treatment is most successful in patients with small warts that have been present for less than 1 year. It has not been determined whether treatment of EGWs reduces transmission of HPV. Selection of a specific treatment regimen depends on the anatomic site, size, and number of warts, as well as expense, efficacy, convenience, and potential adverse effects (Table 15.5). Recurrences more often result from reactivation of subclinical infection than reinfection by a sex partner; therefore, examination of sex partners is not absolutely necessary. However, many of these sex partners may have EGWs and may benefit from therapy and counseling concerning transmission of warts.

**Table 15.5 Treatment Options for External Genital and Perianal Warts**

**Human Immunodeficiency Virus**

It is estimated that almost 20% of individuals with HIV are women. Intravenous drug use and heterosexual transmission each are responsible for about 40% of acquired immunodeficiency syndrome (AIDS) cases in women in the United States (45). Infection with HIV produces a spectrum of disease that progresses from an asymptomatic state to full-blown AIDS. The pace of disease progression in untreated adults is variable. The median time between infection with HIV and the development of AIDS is 10 years, with a range from a few months to more than 12 years. In a study of adults infected with HIV, symptoms developed in 70% to 85% of infected adults, and AIDS developed in 55% to 60% within 12 years after infection. The natural history of the disease can be significantly altered by antiretroviral therapy. Viruses with altered immune function are at increased risk for infection with HIV-induced attherosclerosis (TB), bacterial pneumonia, and Pneumocystis carinii pneumonia (PCP). Because of its impact on the immune system, HIV affects the diagnosis, evaluation, treatment, and follow-up of many other diseases and may decrease the efficacy of antimicrobial therapy for some STDs.

**Diagnosis**

Infection is most often diagnosed by HIV type 1 antibody tests. Antibody testing begins with a sensitive screening test such as ELISA or a rapid assay. If confirmed by Western blot or other supplemental testing, a positive antibody test result means a person is infected with HIV and is capable of transmitting the virus to others. HIV antibody is detectable in more than 95% of patients within 6 months of infection. Women diagnosed with any STD, particularly genital ulcer disease, should be offered HIV testing (42). Women at risk for STD, such as those with multiple sexual partners or whose partners have multiple sexual partners, should be offered HIV testing.
The initial evaluation of an HIV-positive woman includes screening for diseases associated with HIV such as TB and STDs, administration of recommended vaccinations (hepatitis B, pneumococcal, and influenza), and behavioral and psychosocial counseling. Intraepithelial neoplasia is strongly associated with HPV infection and has been found to occur in high frequency in women co-infected with HIV and HPV.

**Treatment**

Decisions regarding the initiation of antiretroviral therapy should be guided by monitoring the laboratory parameters of HIV RNA (viral load) and CD4 T-cell count, as well as the clinical condition of the patient. The primary goals of antiretroviral therapy are maximal and durable suppression of viral load, restoration or preservation of immunologic function, improvement of quality of life, and reduction of HIV-related morbidity and mortality. For the most part, women with acute retroviral syndrome, those within 6 months of HIV seroconversion, and all symptomatic patients should be offered treatment. In addition, treatment should be offered to those women with fewer than 350 CD4 T cells or plasma HIV RNA levels exceeding 30,000 copies/mL (bDNA assay). Patients must be willing to accept therapy to avoid the emergence of resistance due to poor compliance. It has been shown that dual nucleoside regimens plus a protease inhibitor provide a better durable clinical benefit than monotherapy.

In addition, patients with less than 200 CD4 T cells/µL should receive prophylaxis against opportunistic infections such as trimethoprim-sulfamethoxazole or aerosol pentamidine for the prevention of PCP pneumonia.

**Urinary Tract Infection**

**Acute Cystitis**

Women with acute cystitis generally have an abrupt onset of multiple, severe urinary tract symptoms including dysuria, frequency, and urgency associated with suprapubic or low back pain. Suprapubic tenderness may be noted on physical examination. Urinalysis reveals pyuria and sometimes hematuria. Several factors increase the risk for cystitis, including sexual intercourse, the use of a diaphragm and a spermicide, delayed postcoital micturition, and a history of a recent urinary tract infection (47,48 and 49).

*Escherichia coli* is the most common pathogen isolated from the urine of young women with acute cystitis, and it is present in 80% of cases (50). *Staphylococcus saprophyticus* is present in an additional 5% to 15% of patients with cystitis. The pathophysiology of cystitis in women involves the colonization of the vagina and urethra with coliform bacteria from the rectum. For this reason, the effects of an antimicrobial agent on the vaginal flora play a role in the eradication of bacteriuria.

**Treatment**

High concentrations of *trimethoprim* and the fluoroquinolones in vaginal secretions result in eradicating *E. coli* but minimally altering normal anaerobic and microaerophilic vaginal flora. An increasing linear trend in the prevalence of resistance among *E. coli* (9% to 18%) to *trimethoprim* and *trimethoprim-sulfamethoxazole* has been noted. In contrast, no such increase in resistance was noted with *nitrofurantoin* and *ciprofloxacin*. *Nitrofurantoin* (macrocrystals, 100 mg orally twice daily for 7 days) or a *fluoroquinolone* (*ciprofloxacin*, 250 mg orally twice daily for 3 days) are the optimal choices for empirical 3-day therapy for uncomplicated cystitis (51).

In patients with typical symptoms, an abbreviated laboratory workup followed by empirical therapy is suggested. The diagnosis can be presumed if pyuria is detected by microscopy or leukocyte esterase testing. Urine culture is not necessary, and a short course of antimicrobial therapy should be given. No follow-up visit or culture is necessary unless symptoms persist or recur.

**Recurrent Cystitis**

About 20% of premenopausal women with an initial episode of cystitis have recurrent infections. More than 90% of these recurrences are caused by exogenous reinfection. Recurrent cystitis should be documented by culture to rule out resistant microorganisms. Patients may be treated by one of three strategies: (a) continuous prophylaxis, (b) postcoital prophylaxis, or (c) therapy initiated by the patient when symptoms are first noted.

Postmenopausal women may also have frequent reinfections. Hormonal replacement therapy or topically applied estrogen cream, along with antimicrobial prophylaxis, is helpful in treating these patients.

**Urethritis**

Women with dysuria caused by urethritis have a more gradual onset of mild symptoms, which may be associated with abnormal vaginal discharge or bleeding related to concurrent cervicitis. Patients may also have a new sex partner or experience lower abdominal pain. Physical examination may reveal the presence of mucepidermal cervicitis or vulvovaginal herpetiform lesions. *C. Trachomatis*, *N. gonorrhoeae*, or genital herpes may cause acute urethritis. *Pyuria* is present on urinalysis, but hematuria is rarely seen. Treatment regimens for chlamydia and gonococcal infections are presented in Table 15.2

Occasionally, vagnitis caused by *C. albicans* or trichomomas is associated with dysuria. On careful questioning, patients generally describe uterine dysuria, sometimes associated with vaginal discharge, and pruritus and dyspareunia. They usually do not experience urgency or frequency. *Pyuria* and hematuria are absent.

**Acute Pyelonephritis**

The clinical spectrum of acute, uncomplicated pyelonephritis in young women ranges from gram-negative sepsicemia to a cystitis-like illness with mild flank pain. *E. coli* accounts for more than 80% of these cases. Microscopy of unspun urine reveals pyuria and gram-negative bacteria. A urine culture should be obtained in all women with suspected pyelonephritis; blood cultures should be performed in those who are hospitalized because results are positive in 15% to 20% of cases. In the absence of nausea and vomiting and severe illness, outpatient oral therapy can be given safely. Patients who have nausea and vomiting, are moderately to severely ill, and are pregnant should be hospitalized. Outpatient treatment regimens include *trimethoprim-sulfamethoxazole* (160 to 800 mg every 12 hours) or a *quinolone* (*ciprofloxacin*, 200 to 300 mg every 12 hours) for 10 to 14 days. Inpatient treatment regimens include the use of parenteral *cefotaxime* (1 to 2 g daily), ampicillin (1 g every 6 hours), and *gentamicin* (especially if *Enterococcus* species are suspected) or *aztreonam* (1 g every 8 to 12 hours). Symptoms should resolve after 48 to 72 hours. If fever and flank pain persist after 72 hours of therapy, ultrasound or computed tomography should be considered to rule out a perinephric or intrarenal abscess or ureteral obstruction. A follow-up culture should be obtained 2 weeks after the completion of therapy.

Chapter 16 Intraepithelial Disease of the Cervix, Vagina, and Vulva

Kenneth D. Hatch
Jonathan S. Berek

Intraepithelial disease frequently occurs and often coexists in the cervix, vagina, and vulva. The cause and epidemiologic basis are common in all three locations, and treatment typically is ablative and conservative. Early diagnosis and management are essential to prevent disease from progressing to invasive cancer.

Cervical Intraepithelial Neoplasia

The concept of preinvasive disease of the cervix was introduced in 1947, when it was recognized that epithelial changes could be identified that had the appearance of invasive cancer but were confined to the epithelium (1). Subsequent studies showed that if these lesions are not treated, they can progress to cervical cancer (2). Improvements in cytologic assessment led to the identification of early precursor lesions called dysplasia, which signaled possible development of future cancer. For a number of years, carcinoma in situ (CIS) was treated very aggressively (most often with hysterectomy), whereas dysplasias were believed to be less significant and were not treated or were treated by colposcopic biopsy and cryosurgery. The concept of cervical intraepithelial neoplasia (CIN) was introduced in 1968, when Richart indicated that all dysplasias have the potential for progression (3). It is now recognized that most CIN 1 lesions regress spontaneously if untreated (4); nevertheless, CIN refers to a lesion that may progress to invasive carcinoma. This term is equivalent to the term dysplasia, which means abnormal maturation; consequently, proliferating metaplasia without mitotic activity should not be called dysplasia. Squamous metaplasia should not be diagnosed as dysplasia (or CIN) because it does not progress to invasive cancer.

The criteria for the diagnosis of intraepithelial neoplasia may vary according to the pathologist, but the significant features are cellular immaturity, cellular disorganization, nuclear abnormalities, and increased mitotic activity. The extent of the mitotic activity, immature cellular proliferation, and nuclear atypicality identify the degree of neoplasia. If the mitoses and immature cells are present only in the lower one third of the epithelium, the lesion usually is designated as CIN 1. Involvement of the middle and upper thirds is diagnosed as CIN 2 and CIN 3, respectively (Fig. 16.1).

Figure 16.1 Diagram of the different grades of cervical intraepithelial neoplasia.

Cervical Anatomy

The cervix is composed of columnar epithelium, which lines the endocervical canal, and squamous epithelium, which covers the exocervix (5). The point at which they meet is called the squamocolumnar junction (SCJ) (Fig. 16.2 and Fig. 16.3).
The SCJ rarely remains restricted to the external os. Instead, it is a dynamic point that changes in response to puberty, pregnancy, menopause, and hormonal stimulation (Fig. 16.4). In neonates, the SCJ is located on the exocervix. At menarche, the production of estrogen causes the vaginal epithelium to fill with glycogen. Lactobacilli act on the glycogen to the pH, stimulating the subcolumnar reserve cells to undergo metaplasia (5).

Metaplastic epithelium, found at the SCJ, begins in the subcolumnar reserve cell (Fig. 16.4). Under stimulation of lower vaginal acidity, the reserve cells proliferate, lifting the columnar epithelium. The immature metaplastic cells have large nuclei and a small amount of cytoplasm without glycogen. As the cells mature normally, they produce glycogen, eventually forming the four layers of epithelium. The metaplastic process begins at the tips of the columnar villi, which are exposed first to the acid vaginal environment. As the metaplasia replaces the columnar epithelium, the central capillary of the villus regresses, and the epithelium flattens out, leaving the epithelium with its typical vascular network. As metaplasia proceeds into the cervical clefts, it replaces columnar epithelium and similarly flattens the epithelium. The deeper clefts, however, may not be completely replaced by the metaplastic epithelium, leaving mucous-secreting columnar epithelium trapped under the squamous epithelium. Some of these glands open onto the surface; others are completely encased, with mucus collecting in nabothian cysts. Gland openings and nabothian cysts mark the original SCJ and the outer edge of the original transformation zone (5).

Normal Transformation Zone

The original squamous epithelium of the vagina and exocervix is described as having four layers (5):

1. The basal layer is a single row of immature cells with large nuclei and a small amount of cytoplasm.
2. The parabasal layer includes two to four rows of immature cells that have normal mitotic figures and provide the replacement cells for the overlying epithelium.
3. The intermediate layer includes four to six rows of cells with larger amounts of cytoplasm in a polypoidal shape separated by an intercellular space. Intercellular bridges, where differentiation of glycogen production occurs, can be identified with light microscopy.
4. The superficial layer includes five to eight rows of flattened cells with small uniform nuclei and a cytoplasm filled with glycogen. The nucleus becomes pyknotic, and the cells detach from the surface (exfoliation). These cells form the basis for Papanicolaou (Pap) testing.

Columnar Epithelium Columnar epithelium has a single layer of columnar cells with mucus at the top and a round nucleus at the base. The glandular epithelium is composed of numerous ridges, clefts, and infoldings and, when covered by squamous metaplasia, leads to the appearance of gland openings. Technically, the endocervix is not a gland, but the term gland openings is often used.

Metaplastic Epithelium Metaplastic epithelium, found at the SCJ, begins in the subcolumnar reserve cell (Fig. 16.4). Under stimulation of lower vaginal acidity, the reserve cells proliferate, lifting the columnar epithelium. The immature metaplastic cells have large nuclei and a small amount of cytoplasm without glycogen. As the cells mature normally, they produce glycogen, eventually forming the four layers of epithelium. The metaplastic process begins at the tips of the columnar villi, which are exposed first to the acid vaginal environment. As the metaplasia replaces the columnar epithelium, the central capillary of the villus regresses, and the epithelium flattens out, leaving the epithelium with its typical vascular network. As metaplasia proceeds into the cervical clefts, it replaces columnar epithelium and similarly flattens the epithelium. The deeper clefts, however, may not be completely replaced by the metaplastic epithelium, leaving mucous-secreting columnar epithelium trapped under the squamous epithelium. Some of these glands open onto the surface; others are completely encased, with mucus collecting in nabothian cysts. Gland openings and nabothian cysts mark the original SCJ and the outer edge of the original transformation zone (5).

Human Papillomavirus

The cytologic changes of HPV were first recognized by Koss and Durfee (6) in 1956 and given the term koilocytosis. Their significance was not recognized until 20 years later, when Meisels and colleagues (7) reported these changes in mild dysplasia (Fig. 16.5). Molecular biologic studies have demonstrated high levels of HPV...
DNA and capsid antigen, indicating productive viral infection in these koilocytic cells (8). The HPV genome has been demonstrated in all grades of cervical neoplasia (9). As the CIN lesions become more severe (Fig. 16.6), the koilocytes disappear, the HPV copy numbers decrease, and the capsid antigen disappears, indicating that the virus is not capable of reproducing in less differentiated cells (10). Instead, it appears that portions of the HPV DNA become integrated into the host cell. Integration of the transcriptionally active DNA into the host cell appears to be necessary for malignant growth (11). Malignant transformation appears to require the expression of E6 and E7 oncoproteins produced by HPV (12). Because HPV will not grow in cell culture, there is no direct evidence of the carcinogenesis of HPV. However, a cell culture system has been described for growing keratinocytes that allows for stratification and will produce differentiated specific keratinase (13). When normal cells are transfected with the plasmid-containing HPV-16, the transfected cells produced cytologic abnormalities identical to those seen in intraepithelial neoplasia. The E6 and E7 oncoproteins are identifiable in the transfected cell lines, providing the strongest laboratory evidence of a cause-and-effect relationship (14). Cervical cancer cell lines that contain active copies of HPV 16 or 18 (SiHa, HeLa, C 4-11, Ca Ski) demonstrate the presence of HPV-16 E6 and E7 oncoproteins (15).

Figure 16.5 Cervical intraepithelial neoplasia grade 1 with koilocytosis. The normal maturation process and differentiation from the basal and parabasal layers to the intermediate and superficial layers are maintained. In the upper layers, koilocytes are characterized by perinuclear halos, well-defined cell borders, and nuclear hyperchromasia, irregularity, and enlargement. (From Fu YS, Woodruff JD. Pathology. In: Berek JS, Hacker NF, eds. Practical gynecologic oncology, 2nd ed. Baltimore: Williams & Wilkins, 1994:118, with permission.)

Figure 16.6 Cervical intraepithelial neoplasia grade 3 with the entire thickness of the epithelium replaced by abnormal cells that have large hyperchromatic, irregular nuclei. The normal maturation is lost. Mitotic figures are seen in the superficial layers. (left upper corner). (From Fu YS, Woodruff JD. Pathology. In: Berek JS, Hacker NF, eds. Practical gynecologic oncology, 2nd ed. Baltimore: Williams & Wilkins, 1994:119, with permission.)

HPV DNA can be detected in most women with cervical neoplasia (16,17). There is a 10-fold or greater risk for cervical neoplasia associated with the detection of HPV DNA. The relative risk for neoplasia associated with HPV is as high as 40, with a lower 95% confidence limit of 15 (16). The percentage of intraepithelial neoplasia apparently attributed to HPV infection approaches 90% (17).

Although the number of known genital HPV types now exceeds 20, only certain types count for about 90% of high-grade intraepithelial lesions and cancer (HPV-16, -18, -31, -33, -35, -39, -45, -51, -52, -56, and -58) (17). Type 16 is the most common HPV type in invasive cancer and in CIN 2 and CIN 3 and is found in 47% of women in both categories (18). It is also the most common HPV type in women with normal cytology.

Unfortunately, HPV-16 is not very specific; it can be found in 16% of women with low-grade lesions and in up to 14% of women with normal cytology. HPV-18 is found in 23% of women with invasive cancers, 5% of women with CIN 2 and CIN 3, 5% of women with HPV and CIN 1, and fewer than 2% of patients with negative findings (17). Therefore, HPV-18 is more specific than HPV-16 for invasive tumors.

Usually, HPV infections do not persist. Most women have no apparent clinical evidence of disease, and the infection is eventually suppressed or eliminated (19). Other women exhibit low-grade cervical lesions that may regress spontaneously. A minority of women exposed to HPV develop persistent infection that may progress to CIN (15,19). Factors that may have a role in this progression include smoking, contraceptive use, infection with other sexually transmitted diseases, or nutrition (15,18). Any factor that influences the integration of HPV DNA into the human genome may cause progression to invasive disease (20).

Papanicolaou Test Classification

In 1988, the first National Cancer Institute (NCI) workshop was held in Bethesda, Maryland, resulted in the development of the Bethesda System for cytologic reporting (21). A standardized method of reporting cytology findings was needed to facilitate peer review and quality assurance. Recently, the terminology was refined in the Bethesda III System (2001) potentially premalignant squamous lesions fall into three categories: atypical squamous cells (ASC), low-grade squamous intraepithelial lesions (LSIL), and high-grade squamous intraepithelial lesions (HSIL) (22). The ASC category is subdivided into two categories: those of unknown significance (ASC-US), and those in which high-grade lesions must be excluded (ASC-H). When normal cells are transfected with the plasmid-containing HPV-16, the transfected cells produced cytologic abnormalities identical to those seen in intraepithelial neoplasia. The E6 and E7 oncoproteins are identifiable in the transfected cell lines, providing the strongest laboratory evidence of a cause-and-effect relationship (14). Cervical cancer cell lines that contain active copies of HPV 16 or 18 (SiHa, HeLa, C 4-11, Ca Ski) demonstrate the presence of HPV-16 E6 and E7 oncoproteins (15).

Table 16.1. Comparison of Cytology Classification Systems
Cellular changes associated with HPV (i.e., koilocytosis and CIN 1) are incorporated within the category of LSIL because the natural history, distribution of HPV types, and cytologic features of both of these lesions are the same (20). Long-term follow-up studies have shown that lesions properly classified as koilocytosis progress to high-grade intraepithelial neoplasia (HSIL) in 14% of cases (25) and that lesions classified as mild dysplasia progress to severe dysplasia or CIN in 16% of cases (4). It was initially thought that lesions classified as koilocytosis would contain only low-risk HPV types, such as 6 and 11, whereas high-risk HPV types, such as 16 and 18, would be limited to true neoplasms, including CIN 1, thus justifying the distinction. Histopathologic and molecular virologic correlation, however, has demonstrated a similar heterogeneous distribution of low- and high-risk HPV types in both koilocytosis and CIN 1 (23). Studies evaluating the diagnostic validity of LSIL and CIN terminology have demonstrated a lack of interobserver and intraobserver reproducibility (23). The greatest lack of reproducibility is between koilocytosis and CIN 1 (25). Thus, on the basis of clinical behavior, molecular biologic findings, and morphologic features, HPV changes and CIN 1 appear to be the same disease. The rationale for combining CIN 2 and CIN 3 into the category of HSIL is similar. The biologic studies reveal the similar mix of high-risk HPV types in the two lesions, and the separation of the lesions has been shown to be irreproducible (24,29). In addition, the management of CIN 2 and CIN 3 is similar, so that separation serves no useful clinical purpose.

Diagnosis

The Papanicolaou Test

The Pap test has been successful in reducing the incidence of cervical cancer by 79% and the mortality by 70% since 1950 (26). Despite this, there will be 4,100 deaths in the United States in 2002 (27), and cases of cancer continue to occur in patients who have had regular Pap tests. The Agency for Health Care and Policy Research (AHCRPR) undertook a literature review of conventional cervical cytology testing techniques and compared them to newer technologies designed to reduce the false-negative rate (28). The AHCRPR project analyzed five reports and concluded that the sensitivity of conventional cytologic testing in detecting cervical cancer lesions was 51%. This is a false-negative rate of 49%. Previously, it had been widely believed that sensitivity of the Pap test was in the 80% range (29). Recommendations for Pap test screening were based on this perceived 80% sensitivity. The recommendation that three annual Pap tests be performed is predicated on a false-negative rate that would reduce the risk for missed lesions to less than 1% after the first three tests. If the test sensitivity were 80%, then the sensitivity of three negative tests would be 99.2%, which achieves the screening goal. However, the 51% test sensitivity would have a sensitivity of only 86.8% after three tests.

It is obvious that improvement in the conventional Pap test technique is necessary. False-negative errors occur in sampling, preparation, and interpretation. Sampling errors occur because a lesion is too small to exfoliate or the device used did not pick up the cells and transfer them to the glass slide. Preparation errors may occur because fixation on the glass slide, leading to air-drying and an inability to interpret the results. The slide may also be too thick and obscured by vaginal discharge, blood, or mucus. The thick slide also leads to poor fixation because the fixative does not penetrate the cell sample. Interpretive errors occur when the slide contains diagnostic cells that the screening technician did not identify.

Sampling and preparation errors can be alleviated by using a liquid-based media to collect the cytologic sample. The AHCRPR reported that liquid-based cytology assessment improved the sensitivity of the Pap test to the stated goal of 80%. The cell sample is collected with an endocervical brush used in combination with a plastic spatula or a plastic broom. The sample is then rinsed in a vial containing liquid preservative. This technique transfers 80% to 90% of the cells to the liquid media, as compared with the only 10% to 20% transferred to the glass slide with conventional cytologic testing. In addition, using liquid-based media eliminates air-drying and the cells retrieved from the liquid preservative, which traps the large epithelial cells, separating them from the small blood and inflammatory cells. This leads to a thin layer of diagnostic cells properly preserved and more easily interpreted by the cytologist. This technique reduces the rate of unsatisfactory smears encountered with conventional cytologic testing by 70% to 90% (32). Liquid-based cytology is now performed by more than 50% of the laboratories in the United States.

A second new technology of cervical cytologic assessment, the AutoPap Screening System, has been approved by the U.S. Food and Drug Administration for primary screening and rescreening of samples initially read as normal. This technique uses an automated microscope coupled to a special digital camera. The system scans the slide and uses computer imaging techniques to analyze each field of view on the slide. Computer algorithms are then used to rank each slide on the basis of the probability that the sample may contain an abnormality. The selected slides are then reviewed by a cytotechnologist or a cytopathologist. This technique has reduced the false-negative rate by 32% (33). The AutoPap Screening System is not in widespread use at the moment.

Atypical Squamous Cells

The ASC category is restricted to those test results disclosing abnormal cells that are truly of unknown significance. The ASC category does not include benign, reactive, and reparative changes that should be coded as normal in the Bethesda system. Because of the lack of diagnostic criteria and the fear of medical-legal action, the diagnosis has become quite common, ranging from 3% to 25% in some centers (34). When standardized diagnostic criteria are used, the rate of ASC results should be 3% to 5% (35). The older term, ASCUS (Bethesda II classification) is now subdivided into ASC-US and ASC-H (Bethesda III classification).

The cytologic diagnosis of ASCUS is associated with a 10% to 20% incidence of CIN 1 and a 3% to 5% risk for CIN 2 or 3 (36,37,38 and 39). It has become apparent that CIN 1 is most often a benign HPV infection and will regress spontaneously in more than 60% of the cases (40); therefore, the goals of triage of an ASCUS Pap test result is to identify more advanced CIN 2 and 3 lesions.

Triage options include the following: 1) Repeat Pap test every 4 to 6 months with referral for colposcopy if any subsequent abnormality is detected; 2) Immediate colposcopy; 3) HPV testing.

The option of repeat Pap testing is weakened by the 20% to 50% false-negative rate in identifying CIN lesions as well as the noncompliance of the patient. About 50% of patients will still undergo colposcopy because of subsequent abnormal Pap test results, making this option nearly as costly as immediate colposcopy (36). Immediate colposcopy is assumed to be the most sensitive method of detecting CIN 2 or 3 (35,36). Because 80% of patients will not have significant lesions, it is important to not overinterpret the colposcopic findings and to be conservative in performing biopsies. There is also the risk that pathologists will overinterpret the biopsy results and the patient will not benefit from the time and cost of the evaluation. Several studies have documented the usefulness of HPV testing in the assessment of ASCUS Pap test results (41-43). These studies have shown that HPV testing can identify patients 90% of the patients with CIN 2 or 3 lesions.

To compare the aforementioned triage method in a prospective randomized fashion, the NCI funded an ASCUS/LSIL Triage Study (ALTS) whose results for ASCUS were recently published (44). Patients with ASCUS or LSIL were randomized to three triage arms: (a) immediate colposcopy, (b) HPV test, and (c) conservative management by repeat Pap test. There were 1,163 women in the immediate colposcopy group, and 14 refused the examination. The results of colposcopy are assumed to reflect the prevalent disease rates, which were as follows: CIN 1, 14.3%; CIN 2, 16.1%; and CIN 3, 5%. Thus, 75% of the women with ASCUS had negative colposcopic results, 25% of the women had positive colposcopic results. The HPV test results were positive in 6.1% of the patients, and 6.1% of the patients did not return for colposcopy. Of the 494 who underwent colposcopy, the results were as follows: CIN 1, 22.5%; CIN 2, 11.9%; and CIN 3, 15.6%. The sensitivity of HPV test was 95.9% for the detection of CIN 2 and 96.3% for the detection of CIN 3.

In the conservatively managed group, only one follow-up Pap test was reported. To be effective, it is recognized that Pap test must be done every 6 months. Despite this, the results of the single follow-up Pap test were included. Using a cutoff that includes any positive finding of ASCUS or greater, the sensitivity is 85% for CIN 2 and 85.3% for CIN 3, with 56.6% of patients being referred for colposcopy. If LSIL is used as a cutoff, 26.2% of the patients are referred, with sensitivity of 64.0% for both CIN 2 and 3. Using HSIL as the cutoff, 6.9% are referred, and the sensitivity falls to 44%.

The conclusion of the ALTS trial is that HPV triage is highly sensitive in identifying CIN 2 and 3 lesions, with an acceptable rate of referral for colposcopy. Cost-effective analysis of the findings will await the completion of the conservative arm of the study.

In 2001, the American Society for Cytology and Cervical Pathology (ASCCP) sponsored an NCI Consensus Conference to provide guidelines for the management of abnormal cervical cytology. They utilized information from the ALTS Trial and used Bethesda III terminology. Women with ASL-US should be managed with 1) a program of 2 repeat pap smears with referral of any abnormality to colposcopy 2) immediate colposcopy 3) testing for high risk type HPV. Testing for HPV DNA is the preferred method when liquid-based cytology is used. Women who are positive will be referred for colposcopy, and those who are negative will return to yearly cytology (41).
Low-grade Squamous Intraepithelial Lesions

The cytologic diagnosis of LSIL is reproducible and accounts for 1.6% of cytologic diagnoses (35). About 75% of the patients have CIN, with 20% being CIN 2 or 3 (36-38 and 39). These patients require additional evaluation. The ALTS trial closed the HPV test arm early because the HPV positivity rate was 82% and, therefore, was not a valid discriminator in determining the presence of disease. The immediate colposcopy arm and cytology follow-up have not been published. Until these data are available, the standard practice is to perform colposcopy to evaluate a single LSIL result.

High-grade Squamous Intraepithelial Lesions

Any woman with a cytologic specimen suggesting the presence of HSIL should undergo colposcopy and directed biopsy. After colposcopically directed biopsy and determination of the distribution of the lesion, ablative therapy and destruction of the entire T-zone should be performed.

Colposcopy Findings

Acetowhite Epithelium Epithelium that turns white after application of acetic acid (3% to 5%) is called acetowhite epithelium (28). The application of acetic acid coagulates the proteins of the nucleus and cytoplasm and makes the proteins opaque and white (5).

The acetic acid does not affect mature, glycogen-producing epithelium because the acid does not penetrate below the outer one third of the epithelium. The cells in this region have very small nuclei and a large amount of glycogen (not protein). These areas appear pink during colposcopy. Dysplastic cells are those most affected. They contain large nuclei with abnormally large amounts of chromatin (protein). The columnar villi become “plumper” after acetic acid is applied; these cells are then easier to see. They appear slightly white, particularly in the presence of the beginning signs of metaplasia. The immature metaplastic cells have larger nuclei and also show some effects of the acetic acid. Because the metaplastic epithelium is very thin, it is not as white or opaque as CIN but instead appears gray and filmy (5).

Leukoplakia Translated literally, leukoplakia is white plaque (5). In colposcopic terminology, this plaque is white epithelium visible before application of acetic acid. Leukoplakia is caused by a layer of keratin on the surface of the epithelium. Immature squamous epithelial cells have the potential to develop into keratin-producing cells or glycogen-producing cells. In the vagina and on the cervix, the normal differentiation is toward glycogen. Keratin production is abnormal in the cervicovaginal mucosa. Several things can cause leukoplakia, including HPV; keratinizing CIN; keratinizing carcinoma; chronic trauma from diaphragm, pessary, or tampon use; and radiotherapy.

Leukoplakia should not be confused with the white plaque of a monilial infection, which can be completely wiped off with a cotton-tipped applicator. Currently, the most common reason for leukoplakia is HPV infection (Fig. 16.7). Because it is not possible to see through the thick keratin layer to the underlying vasculature during colposcopy, such areas should undergo biopsy to rule out keratinizing carcinoma.

Figure 16.7 Cervical intraepithelial neoplasia type 1, mild dysplasia associated with human papillomavirus infection of the cervix. There is a shiny, snow-white color and a micropapillary surface contour. (From Berek JS, Hacker NF, eds. Practical gynecologic oncology, 2nd ed. Baltimore: Williams & Wilkins, 1994:207, with permission.)

Punctation Punctation refers to dilated capillaries terminating on the surface, which appear from the ends as a collection of dots (Fig. 16.8). When these vessels occur in a well-demarcated area of acetowhite epithelium, they indicate an abnormal epithelium—most often CIN (5) (Fig. 16.9). The punctate vessels are formed as the metaplastic epithelium migrates over the columnar villi. Normally, the capillary regresses; however, when CIN occurs, the capillary persists and appears more prominent.

Figure 16.8 Diagram of punctuation. The central capillaries of the columnar villi are preserved and produce the punctate vessels on the surface.

Figure 16.9 Human papillomavirus/cervical intraepithelial neoplasia type 1 presents as a white lesion with surface spicules.
Mosaic Terminal capillaries surrounding roughly circular or polygonal-shaped blocks of acetowhite epithelium crowded together are called mosaic because their appearance is similar to mosaic tile (Fig. 16.10). These vessels form a “basket” around the blocks of abnormal epithelium. They may arise from a coalescence of many terminal punctate vessels or from the vessels that surround the cervical gland openings (5). Mosaicism tends to be associated with higher-grade lesions and CIN 2 (Fig. 16.11) and CIN 3 (Fig. 16.12).

Figure 16.10 Mosaic pattern. This pattern develops as islands of dysplastic epithelium proliferate and push the ends of the superficial blood vessels away, creating a pattern that looks like mosaic tiles.

Figure 16.11 Human papillomavirus/cervical intraepithelial neoplasia grade 2. Cribriform pattern of HPV at periphery with mosaicism and punctation near the squamocolumnar junction.

Figure 16.12 Cervical intraepithelial neoplasia grade 3, showing a white lesion with associated punctation and coarse mosaicism.

**Atypical Vascular Pattern** Atypical vascular patterns are characteristic of invasive cervical cancer and include looped vessels, branching vessels, and reticular vessels. These patterns are discussed in Chapter 31.

**Endocervical Curettage** The entire coagulant from the endocervical curettage (ECC), placed on a piece of filter paper or brown paper towel, is immersed in 10% buffered formalin or Bouin’s solution. Absorbent paper towels should be avoided because they disintegrate when they become wet. The cheapest paper towels provide the best surface.

**Cervical Biopsy** The cervical biopsy sample is placed on a dry paper towel. The biopsy should be oriented on its side with the surface at right angles to the surface of the paper. It should be allowed to dry for a minute to ensure attachment to the piece of paper and then placed in the fixative with the specimen down. The specimen and paper will float, and the specimen will stay attached to the undersurface of the paper with its proper orientation. This allows the pathologist to orient the biopsy in the paraffin block and avoid tangential sectioning.

**Correlation of Findings**

Ideally, both the pathologist and colposcopist should review the colposcopic findings and the results of cytologic assessment, cervical biopsy, and ECC before deciding therapy (45,46 and 47). This is particularly true when operators are first learning the technique of colposcopy. The cytology results should not be sent to one laboratory and the histology results to another. The colposcopist should not treat the report but rather treat the disease. When the cytology and biopsy results correlate, the colposcopist can be reasonably certain that the worst lesion has been identified. If the cytology indicates a more significant lesion than the histology, the patient should undergo further evaluation and additional biopsies as necessary. An algorithm for the evaluation, treatment, and follow-up of an abnormal Pap test is presented in Fig. 16.13.
Colposcopic Terminology

CIN 1

The spontaneous regression rate of biopsy-proven CIN 1 is 60% to 85% in prospective studies (48,49,50, and 51). The regressions typically occur within a 2-year follow-up with cytology and colposcopy. This information has led to the recommendation that patients who have biopsy diagnoses of CIN 1 with satisfactory colposcopy and who agree to the evaluation every 6 months may be treated by observation. If the lesions progress during follow-up or persist at 2 years, ablative treatment should be performed.

For patients who prefer treatment and for those who progress or persist, the choice of treatment is optional. A randomized prospective trial comparing cryosurgery to laser and laser electrosurgical excision procedure (LEEP) showed no difference in persistent disease rate (4%) or recurrent disease rate (17%) (52). Cryosurgery has the advantage of low cost and ease of use. The disadvantages are lack of tissue specimen, inability to adapt to lesion size, and posttreatment vaginal discharge.

CIN 2 and 3

There is agreement that all CIN 2 and 3 lesions require treatment. This recommendation is based on a metaanalysis showing that CIN 2 progresses to CIS in 20% of cases and to invasion in 5%. Progression of CIS to invasion is 5% (49).

Although CIN can be treated with a variety of techniques, the preferred treatment for CIN 2 and 3 has become LEEP. These techniques allow a specimen to be sent for evaluation and enable the pathologist to identify occult microinvasive cancer or adenomatous lesions. This ensures that adequate treatment of these lesions is accomplished. The persistent and recurrent disease rates are 4% to 10% (52,53).

Treatment of CIN

Most of the ablative techniques used to treat CIN can be performed in an outpatient setting, which is one of the main objectives in the management of this disease. Because all therapeutic modalities carry an inherent recurrence rate of up to 10%, cytologic follow-up at about 3-month intervals for 1 year is necessary. Ablative therapy is appropriate when the following conditions exist:

1. There is no evidence of microinvasive or invasive cancer on cytology, colposcopy, ECC, or biopsy.
2. The lesion is located on the ectocervix and can be seen entirely.
3. There is no involvement of the endocervix as determined by colposcopy and ECC.

Cryotherapy

Cryotherapy destroys the surface epithelium of the cervix by crystallizing the intracellular water, resulting in the eventual destruction of the cell. The temperature needed for effective destruction must be in the range of (–20° to –30°C). Nitrous oxide (–89°C) and carbon dioxide (–65°C) produce temperatures below this range and, therefore, are the most commonly used gases for this procedure.

The technique believed to be most effective is a freeze-thaw-freeze method in which an ice ball is achieved 5 mm beyond the edge of the probe. The time required for this process is related to the pressure of the gas; the higher the pressure, the faster the ice ball is achieved.

Cryotherapy has been shown to be an effective method of treatment for CIN with very acceptable failure rates under certain conditions (54,55,56, and 57). It is a relatively safe procedure with few complications. Cervical stenosis is rare but can occur. Posttreatment bleeding is uncommon and is usually related to infection.

Cure rates are related to the grade of the lesion; CIN 3 has a greater chance of failure (Table 16.2). Townsend has shown that cures are also related to the size of the lesion; those "covering most of the ectocervix" have failure rates as high as 42%, compared with a 7% failure rate for lesions less than 1 cm in diameter (58). Positive findings on ECC also can reduce the cure rate significantly. Endocervical gland involvement is important because the failure rate in women with gland involvement was 27%, compared with 9% in those who did not have such involvement (59).

Table 16.2. Results of Cryotherapy for Cervical Intraepithelial Neoplasia (CIN) Compared to Grade of CIN

Cryotherapy should be considered acceptable therapy when the following criteria are met:

1. Cervical intraepithelial neoplasia, grade 1 to 2
2. Small lesion
3. Ectocervical location only
4. Negative ECC findings
5. No endocervical gland involvement on biopsy

Laser

Laser vaporization therapy may be chosen for patients in whom the presence of invasive cancer has been ruled out, the entire lesion can be seen, and ECC results are negative (60,61,62,63,64, and 65). Laser vaporization is particularly applicable in the following situations:

1. Large lesions that the cryoprobe cannot adequately cover
2. Irregular cervix with a "fish mouth" appearance and deep clefts
3. Extension of disease to the vagina or satellite lesions on the vagina
4. Lesions with extensive glandular involvement in which the treatment must reach beyond the deepest gland cleft.

The major advantage of laser vaporization therapy is the ability to control exactly the depth and width of destruction by direct vision through the colposcope. Several studies have demonstrated that CIN can be found at an average of 1.2 mm and up to a depth of 5.2 mm inside the cervical crypts, regardless of whether the lesion is located in the exocervix or endocervix (59). Wright has shown that destruction or resection of the tissue to a depth of 3.8 mm ablates all the involved glands in 99.7% of cases (62). Nevertheless, the tissue should be ablated to a depth of 7 mm, which is the location of the deepest endocervical gland. Both CIN 2 and CIN 3 with glandular involvement have deeper crypt involvement than CIN 1 lesions without endocervical gland involvement (61).

The other major advantage of laser therapy is the rapid posttreatment healing phase. This process takes about 3 to 4 weeks, after which time a new epithelium has formed completely and, in most cases, has a mature glycogen-containing epithelium. The healed cervix has a normal appearance with a small visible transformation zone at the cervical os.

**Tissue Interaction** When the laser beam contacts tissue, its energy is absorbed by the water in the cells, causing it to boil instantly. The cells explode into a puff of vapor (thus the term laser vaporization). The protein and mineral content is incinerated by the heat and leaves a charred appearance at the base of the exposed area. The depth of laser destruction is a function of the power of the beam (in watts), the area of the beam (in millimeters squared), and the length of time the laser remains in the tissue. The beam must be moved uniformly across the tissue surface to prevent deep destruction. The laser beam vaporizes a central area and leaves a narrow zone of heat necrosis surrounding the laser crater. The goal of laser vaporization is to minimize this area of tissue necrosis. This goal is accomplished by using high wattage (20 watts) with medium beam size (1.5 mm) and moving the beam uniformly but quickly over the surface. The zone of thermal necrosis will be 0.1 mm when the laser is used in this manner. Some lasers have a function called super pulse, in which the laser beam is electronically switched off and on thousands of times per second, thereby allowing the tissue to cool between pulses to create less thermal necrosis.

**Results of Laser Therapy** Laser therapy has extremely varied results (60, 61, 62, 63, 64, 65, 66, 67). In general, the earlier reports showed a lower success rate; the improvement in success rate is attributed to the realization that the entire transformation zone needed to be treated, not just the individual identified lesions (Table 16.3). The therapeutic efficacy of laser conization versus knife conization is shown in Table 16.4, and a comparison of intraoperative and postoperative bleeding with the two procedures is listed in Table 16.5.

The carbon dioxide laser is an excellent tool for the treatment of CIN. In properly selected patients, the success rate with laser vaporization is higher than 95% (Table 16.4). For patients who need diagnostic conization, the cone can be obtained by laser excision performed on an outpatient basis with less blood loss and fewer complications than with a cold knife conization (67, 68, 69, 70, and 71).

**Loop Electrosurgical Excision**

Loop electrosurgical excision is a valuable tool for the diagnosis and treatment of CIN (73, 74, 75, 76, 77, 78, 79, 80, 81, 82, and 83). It has the advantage of being able to perform simultaneously a diagnostic and therapeutic operation during one outpatient visit (61, 62, 63, 64, 65, 66, 67, 68, 69, 70, and 71).

The tissue effect of electricity depends on the concentration of electrons (size of the wire), the power (watts), and the water content of the tissue. If low power or a large-diameter wire is used, the effect will be electrocautery, and the thermal damage to tissue will be extensive. If the power is high (35 to 55 watts) and the wire loop is small (0.5 mm), the effect will be electrosurgical, and the tissue will have little thermal damage. The actual cutting is a result of a steam envelope developing at the interface between the wire loop and the water-laden tissue. This envelope is then pushed through the tissue, and the combination of electron flow and acoustical events separates the tissue. After the excision, a 5-mm diameter ball electrode is used, and the power is set at 50 watts. The ball is placed near the surface so that a spark occurs between the ball and the tissue. This process is called electrofulguration, and it results in some thermal damage that leads to hemostasis. If too much...
fulguration occurs, the patient will develop an eschar with more discharge, and the risk for infection and late bleeding will be higher.

Loop excision should not be used before identification of an intraepithelial lesion that requires treatment. The risk of the “see and treat” philosophy is that in women with only metaplasia, the entire transformation zone will be removed along with varying amounts of the cervical canal, thus potentially compromising fertility (81, 82, and 83). This is particularly true of young women, who may have large, immature transformation zones with extensive acetowhite areas.

Complications following loop electrosurgical excision are fairly minimal and compare favorably with those following laser ablation and conization. Intraoperative hemorrhage, postoperative hemorrhage, and cervical stenosis can occur but at acceptably low rates, as noted in Table 16.6. The SCJ is visible in more than 90% of patients after this procedure.

Table 16.6. Complications of Electrosurgical Excision

One advantage of loop excision over other ablative procedures is the ability to diagnose unsuspected invasive disease (Table 16.7). The loop has several advantages over the laser:

1. Treatment time is shorter.
2. It is easier to learn.
3. There is no hazard to eyesight.
4. Equipment breakdowns occur less often.
5. The cone sample is better.
6. There is less handling of the tissues.
7. Discomfort is reduced.

One study of these two modes of therapy compared pain and operative time in a randomized fashion (77). Electrosurgical excision showed an advantage over laser therapy (Table 16.8).

Table 16.8. Grade of Discomfort of Large-loop Excision Versus Laser Conization

The most important issue in selecting therapy is whether the loop is an effective means of eradicating CIN. A combined literature series indicated a recurrent rate of about 4% (Table 16.9). This rate compares favorably with the recurrence rate for other types of procedures used in the treatment of CIN.

Table 16.9. Unsuspected Invasion in Electrosurgical Excision Specimens
Conization

Conization of the cervix plays an important role in the management of CIN. Before the availability of colposcopy, conization was the standard method of evaluating an abnormal Pap test result. Conization is both a diagnostic and therapeutic procedure and has the advantage over ablative therapies of providing tissue for further evaluation to rule out invasive cancer (67,68,69,70,71 and 72).

Conization is indicated for diagnosis in women with HSIL based on a Pap test under the following conditions:

1. Limits of the lesion cannot be visualized with colposcopy.
2. The SCJ is not seen at colposcopy.
3. ECC histologic findings are positive for CIN 2 or CIN 3.
4. There is a lack of correlation between cytology, biopsy, and colposcopy results.
5. Microinvasion is suspected based on biopsy, colposcopy, or cytology results.
6. The colposcopist is unable to rule out invasive cancer.

Lesions with positive margins are more likely to recur after conization (67,68 and 69) (Table 16.10). Dempouloas and associates (84) has shown that endocervical gland involvement also is predictive of recurrence (23.6% with gland involvement compared with 11.3% without gland involvement).

Table 16.9. Results of Loop Electrosurgical Excision

Conization

Hysterectomy

Hysterectomy is currently considered too radical for treatment of CIN. Coppleson (85) reported 38 cases of invasive cancer occurring after hysterectomy among 8,998 women (0.4%). The incidence of significant bleeding, infection, and other complications, including death, is higher with hysterectomy than with other means of treating CIN. There are some situations in which hysterectomy remains a valid and appropriate method of treatment for CIN:

1. Microinvasion
2. CIN 3 at limits of conization specimen
3. Poor compliance with follow-up
4. Other gynecologic problems requiring hysterectomy, such as fibroids, prolapse, endometriosis, and pelvic inflammatory disease

Glandular Cell Abnormalities

Atypical Glandular Cells of Undetermined Significance

The Bethesda system includes a category for glandular cell abnormalities (21). These cells may be classified as (a) adenocarcinoma or (b) atypical glandular cells of undetermined significance (AGUS). Atypical endocervical cells are important because of their risk for significant disease. In a series of 63 patients from whom subsequent cervical biopsy or hysterectomy specimens were evaluated, 17 women had CIN 2 or CIN 3, 5 women had adenocarcinoma in situ, and 2 women had invasive adenocarcinoma (86). An additional 8 patients had CIN 1, and 2 women had endometrial hyperplasia. Overall, 32 patients (50.8%) had significant cervical lesions. This is a much higher positive rate than that for ASCUS Pap test results.

In adenocarcinoma in situ (AIS), the endocervical glandular cells are replaced by tall columnar cells with nuclear stratification, hyperchromasia, irregularity, and increased mitotic activity (87). Cellular proliferation results in crowded, cribriform glands. However, the normal branching pattern of the endocervical glands is maintained. Most neoplastic cells resemble those of the endocervical mucinous epithelium. Endometrioid and intestinal cell types occur less often. About 50% of women with cervical AIS also have squamous CIN. Thus, some of the AIS lesions represent incidental findings in specimens removed for treatment of squamous neoplasia. Because AIS is located near or above the transformation zone, conventional cervical specimens may not be effective to sample AIS. Obtaining specimens by cytobrush may improve detection of AIS. If the focus of AIS is small, cervical biopsy and ECC may have negative findings. In such cases, a more comprehensive survey of the cervix in the form of conization is necessary. This type of specimen also allows exclusion of coexisting invasive adenocarcinoma. The term microinvasion should not be used to describe adenocarcinomas. Once the gland has been invaded, there is no definable technique for identifying the true “depth of invasion” because the invasion may have originated from the mucosal surface or the periphery of the underlying glands. The “breakthrough” of the basement membrane cannot truly be described; therefore, the tumor is either AIS or invasive adenocarcinoma.

With the recent apparent increase in invasive adenocarcinoma of the endocervix, more attention has been directed toward AIS. There is evidence that AIS may progress to invasive cancer (75). Boone and colleagues reported a series of 52 cases of adenocarcinoma of the uterine cervix in which the results of 18 endocervical biopsies were interpreted as negative 3 to 7 years before the presentation with cancer (87). In 5 of these cases, AIS was found.

Bertrand and associates studied the anatomic distribution of AIS in 23 women (88). All 23 patients had AIS involving both the surface and the glandular endocervical epithelium, often with the deepest glandular cleft also involved. The entire endocervical canal was at risk; nearly half of the patients had lesions between 1.5 and 3 cm from the external os. Fifteen patients had multifocal disease, 3 had unifocal disease, and 5 patients had AIS of undermined type. Eleven of the 23 patients had squamous intraepithelial lesions as well as AIS. Munz reported 40 patients with AIS who had cervical conization (89). Twenty-three of 40 (58%) had coexisting squamous intraepithelial lesions, and 2 patients had invasive squamous cell carcinoma. Of the 22 patients who underwent hysterectomy, the margins on the cone specimen were positive in 10 patients, and 70% had residual AIS, including 2 patients with foci of invasive adenocarcinoma. One of the 12 patients with negative margins had focal residual adenocarcinoma in the hysterectomy specimen. Eighteen women had conization only with negative margins and had no relapse of disease after a medium interval of 3 years. Thus, positive margins on the conization specimen are significant findings in these patients.

Poyner and coauthors published the results of a more alarming study of 28 patients with AIS (90). Of the 8 patients with positive margins who underwent repeat conization or hysterectomy, 3 had residual AIS, and 1 patient had invasive adenocarcinoma. Four of 10 patients with negative margins who underwent hysterectomy or repeat conization had residual AIS. One patient in whom the cone margin could not be evaluated was found to have invasive adenocarcinoma. Of the 15 patients treated conservatively with repeat conization of the cervix and close follow-up, 7 (47%) had a recurrent glandular lesion detected after the conization, including invasive adenocarcinoma in two women. More disturbing is the finding that a glandular lesion was not suspected in 48% of the patients, based on Pap test and ECC.
AIS must be considered a serious cancer precursor of adenocarcinoma. The entire endocervical canal is at risk, and detection of the lesion with cytologic assessment or ECC may not be reliable. Any patient with a positive cone margin should undergo repeat conization. If fertility is not desired, a hysterectomy should be performed because of the risk for recurrence, even in the presence of negative margins.

**Vaginal Intraepithelial Neoplasia**

Vaginal intraepithelial neoplasia (VAIN) often accompanies CIN and is believed to have a similar cause (91). VAIN lesions may be extensions onto the vagina from the CIN, or they may be satellite lesions occurring mainly in the upper vagina. Because the vagina does not have a transformation zone with immature epithelial cells to be infected by HPV, the mechanism of entry of HPV is by way of skin abrasions from coitus or tampon use. As these abrasions heal with metaplastic squamous cells, the HPV may begin its growth in a manner similar to that in the cervical transformation zone (Fig. 16.14).

![Figure 16.14 Vaginal condylomas in the posterior fornix.](image)

**Signs**

VAIN lesions are asymptomatic. Because they often accompany active HPV infection, the patient may complain of vulvar warts or an odoriferous vaginal discharge from vaginal warts.

**Screening**

Women with an intact cervix should undergo routine cytologic screening. Because VAIN is nearly always accompanied by CIN, the Pap test result is likely to be positive when VAIN is present. The vagina should be carefully inspected by colposcopic examination at the time of colposcopy for any CIN lesion. Particular attention should be paid to the upper vagina. Women who have persistent positive Pap test results after treatment of CIN should be examined carefully for VAIN. For women in whom the cervix has been removed for cervical neoplasia, Pap testing should be performed at regular intervals initially, depending on the diagnosis and severity of lesion, and yearly thereafter.

**Diagnosis**

Colposcopic examination and directed biopsy are the mainstays of diagnosis of VAIN. Typically, the lesions are located along the vaginal ridges, are ovoid in shape and slightly raised, and often have surface spicules. VAIN 1 lesions usually are accompanied by a significant amount of koliocytosis, indicating their HPV origin (Fig. 16.15). As the lesions progress to VAIN 2, they have a thicker acetowhite epithelium, a more raised external border, and less iodine uptake (Fig. 16.16). When VAIN 3 occurs, the surface may become papillary, and the vascular patterns of punctuation and mosaic may occur (Fig. 16.17). Early invasion is typified by vascular patterns similar to those of the cervix.

![Figure 16.15 Human papillomavirus/vaginal intraepithelial neoplasia grade 1.](image)

![Figure 16.16 Vaginal intraepithelial neoplasia grade 2.](image)
Figure 16.17 Vaginal intraepithelial neoplasia grade 3. The lesion is located in the center of human papillomavirus spicules with partial uptake of Lugol’s stain.

**Treatment**

Patients with VAIN 1 and HPV infection do not require treatment. These lesions often regress, are often multifocal, and recur quickly when treated with ablative therapy. VAIN 2 lesions are generally treated by laser ablation. VAIN 3 lesions are more likely to harbor an early invasive lesion. Hoffman and colleagues reported 32 patients who underwent upper vaginectomy for VAIN 3 (92). Occult invasive carcinoma was found in 9 patients (28%). It is recommended in older patients that VAIN 3 lesions located in the dimples of the vaginal cuff be excised to rule out occult invasive cancer. VAIN 3 lesions that are adequately sampled to rule out invasive disease can be treated with laser therapy.

Cryosurgery should not be used in the vagina because the depth of injury cannot be controlled and inadvertent injury to the bladder or rectum may occur. Superficial fulguration with electrosurgical ball cautery may be used under colposcopic control to observe the depth of destruction by wiping away the epithelial tissue as it is ablated. Excision is an excellent method for treatment of upper vaginal lesions in a small area. Occasionally, total vaginectomy will be required for a VAIN 3 lesion occupying the entire vagina. It should be accompanied by a split-thickness skin graft. This aggressive treatment for widespread vaginal lesions should not be used for VAIN 2.

The malignant potential of VAIN appears to be less than that of CIN. In a review of 136 cases of CIS of the vagina over a 30-year period (91), 4 cases (3%) progressed to invasive vaginal cancer despite the use of various treatment methods.

**Vulvar Intraepithelial Disease**

**Vulvar Dystrophies**

In the past, terms such as leukoplakia, lichen sclerosis et atrophicus, primary atrophy, sclerotic dermatosis, atrophic and hyperplastic vulvitis, and kraurosis vulvae have been used to denote disorders of epithelial growth and differentiation (93). In 1966, Jeffcoate (94) suggested that these terms did not refer to separate disease entities because their macroscopic and microscopic appearances were variable and interchangeable. He assigned the generic term chronic vulvar dystrophy to the entire group of lesions.

The International Society for the Study of Vulvar Disease (ISSVD) recommended that the old “dystrophy” terminology be replaced by a new classification under the pathologic heading “nonneoplastic epithelial disorders of skin and mucosa.” This classification is shown in Table 16.11. In all cases, diagnosis requires biopsy of suspicious-looking lesions, which are best detected by careful inspection of the vulva in a bright light aided, if necessary, by a magnifying glass (95).

**Table 16.11. Classification of Epithelial Vulvar Diseases**

The malignant potential of these nonneoplastic epithelial disorders is low, particularly now that the lesions with atypia are classified as vulvar intraepithelial neoplasia (VIN). However, patients with lichen sclerosis and concomitant hyperplasia may be at particular risk (96).

**Vulvar Intraepithelial Neoplasms**

As with the vulvar dystrophies, there has been confusion regarding the nomenclature for VIN. Four major terms have been used: erythroplasia of Queyrat, Bowen’s disease, carcinoma in situ simplex, and Paget’s disease. In 1976, the ISSVD decreed that the first three lesions were merely gross variants of the same disease process and that all of these entities should be included under the umbrella term squamous cell carcinoma in situ (stage 0) (81). In 1986, the ISSVD recommended the term vulvar intraepithelial neoplasia (Table 16.11).

VIN is graded as 1 (mild dysplasia), 2 (moderate dysplasia), or 3 (severe dysplasia or CIS) on the basis of cellular immaturity, nuclear abnormalities, maturation disturbance, and mitotic activity. In VIN 1, immature cells, cellular disorganization, and mitotic activity occur predominantly in the lower one third of the epithelium, whereas in VIN 3, immature cells with scantly cytoplasm and severe chromatinic alterations occupy most of the epithelium (Fig. 16.16). Dyskeratotic cells and mitotic figures occur in the superficial layer. The appearance of VIN 2 is intermediate between VIN 1 and VIN 3. Additional cytopathic changes of HPV infection, such as perinuclear halos with displacement of the nuclei by the intracytoplasmic viral protein, thickened cell borders, binucleation, and multinucleation, are common in the superficial layers of VIN, especially in VIN 1 and VIN 2. These viral changes are not definitive evidence of neoplasia but are indicative of viral exposure (97). Most vulvar condylomas are associated with HPV-6 and -11, whereas HPV-16 is detected in more than 80% of VIN cases by molecular techniques.
VIN 3 can be unifocal or multifocal. Typically, multifocal VIN 3 presents with small hyperpigmented lesions on the labia major (Fig. 16.19). Some cases of VIN 3 are more confluent, extending to the posterior fourchette and involving the perineal tissues. The term *bowenoid papulosis (bowenoid dysplasia)* has been used to describe multifocal VIN lesions ranging from grade 1 to 3. Clinically, patients with Bowenoid papulosis present with multiple small pigmented papules (40% of cases) that are usually less than 5 mm in diameter. Most women with these lesions are in their 20s, and some are pregnant. After childbirth, the lesions may regress spontaneously. However, the term Bowenoid papulosis is no longer recommended by the ISSVD.

**Figure 16.19 Vulvar intraepithelial neoplasia grade 3 (VIN 3). A:** A multifocal VIN 3 lesion with multiple small hyperpigmented lesions on the labia major. **B:** VIN 3 with more confluent hyperpigmented areas on the posterior fourchette with extensive perianal involvement. (From Berek JS, Hacker NF, eds. *Practical gynecologic oncology,* 2nd ed. Baltimore: Williams & Wilkins, 1994:213, with permission.)

**Paget's Disease of the Vulva**

Extramammary Paget's disease of the vulva (AIS) was described 27 years after the description by Sir James Paget of the mammary lesion that now bears his name (98). Some patients with vulvar Paget's disease have an underlying adenocarcinoma, although the precise frequency is difficult to ascertain.

Most cases of vulvar Paget's disease are intraepithelial. Because these lesions demonstrate apocrine differentiation, the malignant cells are believed to arise from undifferentiated basal cells, which convert into an appendage type of cell during carcinogenesis (Fig. 16.20). The “transformed cells” spread intraepithelially throughout the squamous epithelium and may extend into the appendages. In most patients with an underlying invasive carcinoma of the apocrine sweat gland, Bartholin gland, or anorectum, the malignant cells are believed to migrate through the dermal ductal structures and reach the epidermis. In such cases, metastasis to the regional lymph nodes and other sites can occur.

**Figure 16.20 Paget's disease of vulva.** The epidermis is permeated by abnormal cells with vacuolated cytoplasm and atypical nuclei. This heavy concentration of abnormal cells in the parabasal layers is typical of Paget's disease. (From Fu YS, Woodruff JD, Pathology. In: Berek JS, Hacker NF, eds. *Practical gynecologic oncology,* 2nd ed. Baltimore: Williams & Wilkins, 1994:162, with permission.)

Paget's disease must be distinguished from superficial spreading melanoma. All sections should be studied thoroughly using differential staining, particularly periodic acid–Schiff (PAS) and mucicarmine stains. Mucicarmine has routinely positive results in the cells of Paget's disease and negative results in melanotic lesion.

**Clinical Features**

Paget's disease of the vulva predominantly affects postmenopausal white women, and the presenting symptoms are usually pruritus and vulvar soreness. The lesion has an eczematoid appearance macroscopically and usually begins on the hair-bearing portions of the vulva (Fig. 16.21). It may extend to involve the mons pubis, thighs, and buttocks. Extension to involve the mucosa of the rectum, vagina, or urinary tract also has been described (99). The more extensive lesions are usually raised and velvety in appearance.
A second synchronous or metachronous primary neoplasm is associated with extramammary Paget's disease in about 30% of patients (100). Associated carcinomas have been reported in the cervix, colon, bladder, gallbladder, and breast. When the anal mucosa is involved, there usually is an underlying rectal adenocarcinoma (98).

Treatment

VIN

The treatment of VIN has varied from wide excision to the performance of a superficial or "skinning" vulvectomy (101,102,103 and 104). Although the treatment originally recommended for CIS of the vulva was wide excision, fears that the disease frequently was preinvasive led to the widespread use of superficial vulvectomy (103). Because progression is relatively uncommon, typically occurring in 5% to 10% of cases (101), extensive surgery is not warranted. This is particularly true because many VIN lesions are found in premenopausal women.

The therapeutic alternatives for VIN are (a) simple excision, (b) laser ablation, and (c) superficial vulvectomy with or without split-thickness skin grafting. Excision of small foci of disease produces excellent results and has the advantage of providing a histopathologic specimen. Although multifocal or extensive lesions may be difficult to treat by this approach, it offers the potential for the most cosmetic result. Repeat excision is often necessary but can typically be accomplished without vulvectomy (102,103). The carbon dioxide laser can be used for multifocal lesions but is unnecessary for unifocal disease. The disadvantages are that it can be painful and costly and does not provide a histopathologic specimen (105).

Superficial vulvectomy is appropriate for extensive and recurrent VIN (104). The goal of the treatment is to extirpate all of the disease while preserving as much of the normal vulvar anatomy as possible. The anterior vulva and the clitoris should be preserved if possible. In some patients, the disease extends up the anus, which also must be resected. When this is the case, the excision should be made to close the vulvar defect primarily, reserving the use of skin grafts for instances in which the vulvar defect cannot be closed because the resection is too extensive. Split-thickness skin grafts can be harvested from the thighs or buttocks, but the latter is more easily concealed (106).

Paget's Disease

Unlike squamous cell CIS, in which the histologic extent of disease usually correlates closely with the macroscopic lesion, Paget's disease usually extends well beyond the gross lesion (107). This extension results in positive surgical margins and frequent local recurrence unless a wide local excision is performed (108). Underlying adenocarcinomas are usually apparent clinically, but this finding does not occur invariably; therefore, the underlying dermis should be removed for adequate histologic evaluation. For this reason, laser therapy is unsatisfactory in treating primary Paget's disease. If invasive adenocarcinoma is present, it should be treated in the same manner as a squamous vulvar cancer. This treatment usually requires radical vulvectomy and at least an ipsilateral inguinal-femoral lymphadenectomy.

Recurrent lesions are almost always in situ, although there has been at least one report of an underlying adenocarcinoma in recurrent Paget's disease (109). In general, it is reasonable to treat recurrent lesions with surgical excision.

References

An abnormal gestation is either intrauterine or extrauterine. Extrauterine or ectopic pregnancy occurs when the fertilized ovum becomes implanted in tissue other than the endometrium. Although most ectopic gestations are located in the ampullary segment of the fallopian tube, such pregnancies may also occur in other sites (Table 17.1). Abnormal intrauterine pregnancy often results in pregnancy loss early in gestation. Such abnormalities can be related to a number of factors. With both abnormal intrauterine and extrauterine gestation, early recognition is key to diagnosis and management.

<td>Spontaneous Abortion</td>
<td>Anembryonic gestation, inevitable abortion, incomplete abortion, and completed abortion are types of first-trimester abortions. About 15% to 20% of known pregnancies terminate in spontaneous abortion. With the use of serial human chorionic gonadotropin (hCG) measurements to detect early subclinical pregnancy losses, the percentage increases to 30%. About 80% of spontaneous pregnancy losses occur in the first trimester; the incidence decreases with each gestational week. In a study of 347 patients with a first-trimester pregnancy documented by ultrasound, the overall pregnancy loss was 6.1% to 4.2% in patients without bleeding and 12.4% in patients with bleeding. In women who have had one prior spontaneous abortion, the rate of spontaneous abortion in a subsequent pregnancy is about 20%; in women who have had three consecutive losses, the rate is 50%. The causes of this condition are varied and most often unknown. Patients should be reassured that, in most cases, spontaneous abortion does not recur.</td>

#### Threatened Abortion

Threatened abortion is defined as vaginal bleeding before 20 weeks of gestation. It occurs in about 30% to 40% of all pregnancies. The bleeding is usually light and may be associated with mild lower abdominal or cramping pain. It is often not possible to differentiate clinically between threatened abortion, completed abortion, and ectopic pregnancy in an unruptured tube. The differential diagnosis in these patients includes consideration of possible cervical polyps, vaginitis, cervical carcinoma, gestational trophoblastic disease, ectopic pregnancy, trauma, and foreign body. On physical examination, the abdomen usually is not tender and the cervix is closed. Bleeding can be seen coming from the os, and there is no cervical motion or adnexal tenderness. Although most patients experience bleeding at
Independent factors consistently shown to increase the risk for tubal pregnancy include the following:

- Conceptions, although there is no increase in the incidence of chromosomal abnormalities in ectopic pregnancies.
- Myoelectrical activity is responsible for propulsive activity in the fallopian tube.
- Damage to the mucosal portion of the tube or fimbria accounts for about half of all tubal pregnancies.
- Tubal diverticula may result in abnormalities that entrap the blastocyst or impede transport.
- A mean sac diameter greater than 13 mm without a visible yolk sac or a mean sac diameter greater than 17 mm lacking an embryo predicts nonviability in all cases.

There is no effective therapy for a threatened intrauterine pregnancy. Bedrest, although advocated, is not effective. Progesterone or sedatives should not be used. All patients should be counseled and reassured so that they understand the situation. Treatment should be given for any vaginal infection.

**Inevitable Abortion**

With an inevitable abortion, the volume of bleeding is often greater, and the cervical os is open and effaced, but no tissue has been passed. Most patients have cramplike lower abdominal pain, and some have cervical motion or adnexal tenderness. When it is certain that the pregnancy is not viable before the cervical os is dilated or excessive bleeding is present, suction curettage should be performed. Blood type and Rh determination and a complete blood count should be obtained if there is any concern about the amount of bleeding. Rh(D) immune globulin (RhOgAM) should be given either before or after the uterus is evacuated if the patient's blood is Rh negative.

**Incomplete Abortion**

An incomplete abortion is a partial expulsion of the pregnancy tissue. Before 6 weeks of gestation, the placenta and fetus are generally passed together, but after this time, they are often passed separately. Although most patients have vaginal bleeding, only some have passed tissue. Lower abdominal cramping is invariably present, and the pain may be described as resembling labor. On physical examination, the cervix is dilated and effaced, and bleeding is present. Often, clots are admixed with products of conception. If the bleeding is profuse, the patient should be examined promptly for tissue protruding from the cervical os; removal of this tissue with a ring forceps reduces the bleeding. A vasovagal bradycardia may occur and responds to removal of the tissue. All patients with an incomplete abortion should undergo suction curettage as quickly as possible. A complete blood count, maternal blood type, and Rh determination should be obtained; Rh-negative patients should receive Rh(D) immune globulin.

If the patient is febrile, broad-spectrum antibiotic therapy should be administered before suction curettage is performed to reduce the incidence of postabortal endometritis and pelvic inflammatory disease, thereby reducing potential deleterious effects on fertility. The antibiotic regimen chosen should be similar to the regimens used for treatment of pelvic inflammatory disease (PID). In patients who do not have clinical signs of infection, prophylactic antibiotic therapy should be instituted. Suggested regimens include doxycycline (100 mg orally twice daily), tetracycline (250 mg orally four times daily for 5 to 7 weeks) or another antibiotic of similar spectrum.

**Ectopic Gestation**

**Incidence**

The most comprehensive data available on ectopic pregnancy rates have been collected by the Centers for Disease Control and Prevention (Fig. 17.1). They show a significant increase in the number of ectopic pregnancies in the United States during the past 20 years. In 1989, the latest year for which statistics were published, there were an estimated 88,400 ectopic pregnancies, at a rate of 16 ectopic pregnancies per 1,000 reported pregnancies. These numbers represent a fivefold increase compared with the 1970 rates. The highest rates occurred in women aged 35 to 44 years (27.2 per 1,000 reported pregnancies). When the data are analyzed by race, the risk for ectopic pregnancy among African Americans and other minorities (20.8 per 1,000) is 1.6 times greater than the risk among whites (13.4 per 1,000). In 1988, 44 deaths were attributed to complications of ectopic pregnancy, which represents 15% of all maternal deaths. The risk for death is higher for African Americans and other minorities than for whites. For both races, teenagers have the highest mortality rates, but the rate for African American and other minority teenagers is almost five times that for white teenagers. After an ectopic pregnancy, there is a 7- to 13-fold increase in the risk for a subsequent ectopic pregnancy. The chance that a subsequent pregnancy will be intrauterine is 50% to 80%, and the chance that the pregnancy will be tubal is 10% to 25%; the remaining patients will be infertile.

Many variables make accurate assessment of risk very difficult (e.g., size and location of the ectopic pregnancy, status of the contralateral adnexa, treatment method, and history of infertility).

**Etiology and Risk Factors**

Tubal damage results from inflammation, infection, and surgery. Inflammation and infection may cause damage without complete tubal obstruction. Complete blockage may result from salpingitis, incomplete tubal ligation, tubal fertility surgery, partial salpingectomy, or congenital midsegment tubal atresia. Damage to the mucosal portion of the tube or fimbria accounts for about half of all tubal pregnancies. Tubal diverticula may result in abnormalities that entrap the blastocyst or impede transport. Tubal pregnancy may occur in a blocked tube with contralateral tubal patency, with the sperm migrating across the abdomen to fertilize an egg released from the blocked side.

Myoelectrical activity is responsible for propulsive activity in the fallopian tube. This activity facilitates movement of the sperm and ova toward each other and propels the zygote toward the uterine cavity. Estrogen increases smooth muscle activity, and progesterone decreases muscle tone. Aging results in progressive loss of myoelectrical activity along the fallopian tube, which may explain the increased incidence of tubal pregnancy in perimenopausal women. Hormonal control of the muscular activity in the fallopian tube may explain the increased incidence of tubal pregnancy associated with failures of the morning-after pill, minipill, progestosterone-containing intrauterine devices (IUDs), and ovulation induction. Blighted ova occur more commonly in tubal conceptions than in intrauterine conceptions, although there is no increase in the incidence of chromosomal abnormalities in ectopic pregnancies.

Independent factors consistently shown to increase the risk for tubal pregnancy include the following:

1. Previous laparoscopically proven PID
2. Previous tubal pregnancy
3. Current IUD use
4. Previous tubal surgery for infertility

Many other factors, including contraceptive choice, prior surgery, previous pregnancies, and fertility status, also have been identified.

Pelvic Infection

The relationship of PID, tubal obstruction, and ectopic pregnancy is well documented. In a study of 415 women with laparoscopically proven PID, the incidence of tubal obstruction increased with successive episodes of PID. 13% after one episode, 35% after two, and 75% after three. Furthermore, after one episode of PID, the ratio of ectopic to intrauterine pregnancy was 1 in 24, a sixfold increase over the incidence for women with laparoscopically negative results (1 in 147). In a prospective study of 1,204 patients followed until first pregnancy after infection, 47 of 746 (6%) women with laparoscopically documented PID had a tubal gestation, which is significantly higher than the 0.9% incidence in the control group (20).

Chlamydia is an important pathogen causing tubal damage and subsequent tubal pregnancy. Because many cases of chlamydia salpingitis are indolent, cases may not be recognized or, if recognized, may be treated on an outpatient basis. Chlamydia has been cultured from 7% to 30% of patients with tubal pregnancy (7,21). A strong association between chlamydia infection and tubal pregnancy has been shown with serologic tests for chlamydia (22,23,24 and 25). Conception is three times as likely to be tubal in women with anti–Chlamydia trachomatis titers higher than 1:84 than in those women whose titers were negative (7,26).

Contraceptive Use

Inert and copper-containing IUDs prevent both intrauterine and extrauterine pregnancies (27,28). Women who conceive with an IUD in place, however, are 0.4 to 0.8 times more likely to have a tubal pregnancy than those not using contraceptives. However, because IUDs prevent implantation more effectively in the uterus than in the tube, a woman conceiving with an IUD is 6 to 10 times more likely to have a tubal pregnancy than if she conceives without using contraception (27,28).

With copper IUDs, 4% of contraceptive failures are tubal pregnancies. Progestrone-only contraceptives are less effective than copper IUDs in preventing tubal pregnancy; 17% of failures result in tubal pregnancy. Furthermore, the rate of ectopic pregnancy in women using progesterone IUDs is higher than in women not using contraceptives: 1.9 per 100 woman-years (versus 0.5 for copper IUDs) (29). This finding suggests that failures occur for different reasons. Although all IUDs prevent intrauterine implantation, copper IUDs prevent fertilization by cytotoxic and phagocytic effects on the sperm and oocytes. Progesterone-containing IUDs are probably less effective in preventing conception.

Duration of IUD use does not increase the absolute risk for tubal pregnancy (1.2 per 1,000 years of exposure), but with increasing use, there is an increase in the percentage of pregnancies that are tubal (30). It is unclear whether past use of IUDs increases the risk for tubal pregnancy. Only past use of the Dalkon shield is associated with a twofold increased risk (31). One study showed that previous use of an IUD for longer than 2 years was associated with a fourfold risk, but this risk was present for only the first year after discontinuation of IUD use (27). However, subsequent studies have found no increased risk for tubal pregnancy following IUD use (30,32).

The risk of the pregnancy being ectopic with combination oral contraceptive use has been calculated to be 0.5% to 4% (27,28,33). Past use of oral contraceptives does not increase the subsequent risk for ectopic pregnancy (3). Progesterone-only contraceptives, including oral contraceptives (minipill) and subdermal implants (Norplant), protect against both intrauterine and ectopic pregnancy when compared with no contraceptive use. If a pregnancy does occur, however, the chance of the pregnancy being ectopic is 4% to 10% for the minipill (34,35) and up to 30% if pregnancy occurs while implants are in place (36,37). Condom and diaphragm use protects against both intrauterine and ectopic pregnancy, and there is no increased incidence of ectopic pregnancy (30,33,38).

Sterilization

The greatest risk for pregnancy, including ectopic pregnancy, occurs in the first 2 years after sterilization (39). Despite a greater proportion of poststerilization failures resulting in ectopic pregnancy, the absolute rate of ectopic pregnancy is decreased. Calculating cumulative lifetime risk for ectopic pregnancy according to method of contraception, sterilized women have a lower cumulative risk for ectopic pregnancy than IUD users or nonusers of contraception, and women using barrier methods or oral contraceptives have the lowest risk (40).

The risk for tubal pregnancy after any sterilization procedure is 5% to 16% (10,39,40). The risk depends on the sterilization technique: about half of postelectrocautery failures are ectopic, compared with 12% after nonlaparoscopic, nonelectrocautery procedures (41). Laparoscopic coagulation has a reduced risk for pregnancy compared with mechanical devices. A fourfold to fivefold increased risk is associated with salpingostomy, neosalpingostomy, fimbrioplasty, anastomosis, and lysis of complex peritubal and periovarian adhesions (7,11,43). After tubal surgery, the overall rate of ectopic pregnancy is 2% to 7%, and the viable intrauterine pregnancy rate is 50%.

There has been a concern that conservation of the tube at the time of removal of an ectopic pregnancy would increase the risk for recurrent ectopic pregnancy. However, after either tubal removal or conservation, the rates for intrauterine pregnancy (40%) and ectopic pregnancy (12%) have been found to be identical (44). In another study, the incidence of ectopic pregnancy could be predicted by the status of the contralateral tube: normal (7%), abnormal (18%), or absent (25%) (45). In a study of pregnancy outcomes of 1,152 patients treated for ectopic pregnancy, preservation of the tube did not increase the incidence of repeat ectopic pregnancy, but it did improve overall fertility rates (45).

Sterilization reversal also increases risk for ectopic pregnancy. The exact risk depends on the method of sterilization, site of tubal occlusion, residual tube length, coexisting disease, and surgical technique. In general, the risk for reanastomosing a cauterized tube is about 15%, and it is less than 3% for reversal of Pomeroy or tubal ligation (35,42). Although there is general agreement that an increased risk for ectopic pregnancy is associated with a ruptured appendix (43,44), one study did not confirm this finding (44).

Prior Abdominal Surgery

Many patients with ectopic pregnancies have a history of previous abdominal surgery (7,48). The role of abdominal surgery in ectopic pregnancy is unclear. In one study, there appeared to be no increased risk for cesarean delivery, ovarian surgery, or removal of an unruptured appendix (49). Other studies have shown that ovarian cystectomy or wedge resection increases the risk for ectopic pregnancy, presumably as a result of peritubal scarring (50,51). Although there is general agreement that an increased risk for ectopic pregnancy is associated with a ruptured appendix (7,43), some studies have not confirmed this finding (49).

Other Causes

Abortion

There is no established association between ectopic pregnancy and spontaneous abortion (7,9,52). With recurrent abortion (fewer than two consecutive abortions) the risk is increased 2 to 4 times. This may reflect a shared risk factor, such as with luteal phase defect. Uncomplicated elective abortion, regardless of the number of procedures or gestational age at which they were performed, is not associated with increased risk (7,8,53,54). In areas with a high incidence of illegal abortion, the risk is increased 10-fold. Presumably, this increased incidence is secondary to postoperative infection and improperly performed procedures (54).

Infertility

Although the incidence of ectopic pregnancy increases with age and parity, there is also a significant increase in nulliparous women undergoing infertility treatment (7,8,44). For nulliparous women, conceptions after at least 1 year of unprotected intercourse are 2.6 times more likely to be tubal (55). Additional risks for fertile women are associated with specific treatments, including reversal of sterilization, tuboplasty, ovulation induction, and in vitro fertilization (IVF).
Hormonal alterations characteristic of clomiphene citrate and gonadotropin ovulation-induction cycles may predispose tubal implantation. About 1.1% to 4.6% of conceptions associated with ovulation induction are ectopic pregnancies (8, 55). In many of these patients, the results of hysterosalpingography are normal, and there is no evidence of intraoperative tubal pathology. Hyperstimulation, with high estrogen levels, may play a role in tubal pregnancy (56, 57); however, not all studies have shown this relationship (58).

The first pregnancy obtained with IVF was a tubal pregnancy (59). About 2% to 8% of IVF conceptions are tubal. Tubal factor infertility is associated with a further increased risk of 17% (60, 61 and 52). Predisposing factors are unclear but may include placement of the embryo high in the uterine cavity, fluid reflux into the tube, and a predisposing tubal factor that prevents the refluxed embryo from returning to the uterine cavity.

Salpingitis Isthmica Nodosa Salpingitis isthmica nodosa (SIN) is a noninflammatory pathologic condition of the tube in which tubal epithelium extends into the myosalpinx and forms a true diverticulum. The reported prevalence ranges from 1 in 146 to 11 in 100. This condition is found more often in the tubes of women with an ectopic pregnancy than in nonpregnant women (17, 63, 64). Myometrial electrical activity over the diverticula has been found to be abnormal (19). Whether tubal pregnancy is caused by SIN or whether the association is coincidental is unknown.

Endometriosis or Leiomyomas Endometriosis or leiomyomas can cause tubal obstruction. However, neither is commonly associated with ectopic pregnancy.

Diethylstilbestrol Women exposed to diethylstilbestrol (DES) in utero who subsequently conceive are at increased risk for ectopic pregnancy. In several case-control studies, these women were more than twice as likely to have a tubal pregnancy (65, 66). The Collaborative Diethylstilbestrol-Adenosis Project, which monitored 327 DES-exposed women, found that about 50% had uterine cavity abnormalities (67). In DES-exposed women, the risk for ectopic pregnancy was 13% in those who had uterine abnormalities compared with 4% in those who had a normal uterus. No specific type of defect was related to the risk for ectopic pregnancy.

Smoking Current cigarette smoking is associated with a more than twofold increased risk for tubal pregnancy (28, 51, 67, 68 and 69). A case-control study showed a dose relationship: current smokers of more than 20 cigarettes a day had a relative risk of 2.5 compared with nonsmokers, whereas smokers of 1 to 10 cigarettes had a risk of 1.3 (68). Alterations of tubal motility, ciliary activity, and blastocyst implantation are associated with nicotine intake.

Histologic Characteristics

Chorionic villi, usually found in the lumen, are pathognomonic findings of tubal pregnancy. Gross or microscopic evidence of an embryo is seen in two thirds of cases (70). An unruptured tubal pregnancy is characterized by irregular dilation of the tube, with a blue discoloration caused by hematosalpinx. The ectopic pregnancy may not be readily apparent. Bleeding associated with tubal pregnancies is mainly extraluminal but may be luminal (hematosalpinx) and may extrude from the fimbriated end. A hematoma is often seen surrounding the distal segment of the tube. Patients who have tubal pregnancies that spontaneously resolve and those treated with methotrexate frequently have an enlargement of the ectopic mass associated with blood dots and extrusion of tissue from the fimbriated end. Hemoperitoneum is nearly always present but is confined to the cul-de-sac unless tubal rupture has occurred. The natural progression of tubal pregnancy is either expulsion from the fimbriated end (tubal abortion), involution of the conceptus, or rupture, usually around the eighth gestational week. Some tubal pregnancies form a chronic inflammatory mass that is associated with involution and reestablishment of menses and thus is difficult to diagnose. Extensive histologic sampling may be required to disclose a few ghost villi.

Histologic findings associated with tubal gestation include evidence of chronic salpingitis and SIN. Inflammation associated with salpingitis causes adhesions as a result of fibrin deposition. Healing and cellular organization lead to permanent scarring between folds of tissue. This scarring may allow transport of sperm but not the passage of the larger blastocyst. About 45% of patients with tubal pregnancies have pathologic evidence of prior salpingitis (71).

The etiology of SIN is unknown but is speculated to be an adenomyosis-like process or, less likely, inflammation (72, 73). This condition is rare before puberty, indicating a noncongenital origin. Tubal diverticula are identified in about half of patients who have ectopic pregnancies, as opposed to 5% of women who do not have ectopic pregnancies (17).

Histologic findings include the Arias-Sella reaction, which is characterized by localized hyperplasia of endometrial glands that are hypersecretory (74). The cells have enlarged nuclei that are hyperchromatic and irregular. The Arias-Sella reaction is a nonspecific finding that can be seen in patients with intrauterine pregnancies (Fig. 17.2).

Figure 17.2 The Arias-Stella reaction of the endometrium. The glands are closely packed and hypersecretory with large, hyperchromatic nuclei suggesting malignancy. (From Berek JS, Hacker NF. Practical gynecologic oncology, 2nd ed. Baltimore: Williams & Wilkins, 1994:125, with permission.)

Diagnosis

The diagnosis of ectopic pregnancy is complicated by the wide spectrum of clinical presentations, from asymptomatic cases to acute abdomen and hemodynamic shock. The diagnosis and management of a ruptured ectopic pregnancy is straightforward; the primary goal is achieving hemostasis. If an ectopic pregnancy can be identified before rupture or irreparable tubal damage, consideration may be given to optimizing future fertility. With patients presenting earlier in the disease process, the number of those without symptoms or with minimal symptoms has increased. Therefore, there must be a high degree of suspicion of ectopic pregnancy, especially in areas of high prevalence. History and physical examination identify patients at risk, improving the probability of detection of ectopic pregnancy before rupture.

History

Patients who have an ectopic pregnancy generally have an abnormal menstrual pattern or the perception of a spontaneous pregnancy loss. Pertinent history includes the menstrual history, previous pregnancy, history of infertility, current contraceptive status, risk factor assessment, and current symptoms.

The classic symptom triad of ectopic pregnancy is pain, amenorrhea, and vaginal bleeding. This symptom group is present in only about 50% of patients, however, and is most typical in patients in whom an ectopic pregnancy has ruptured. Abdominal pain is the most common presenting complaint, but the severity and nature of the pain vary widely. There is no pathognomonic pain that is diagnostic of ectopic pregnancy. Pain may be unilateral or bilateral and may occur in the upper or lower abdomen. The pain may be dull, sharp, or crampy and either continuous or intermittent. With rupture, the patient may experience transient relief of the pain, as stretching of the tubal serosa ceases. Shoulder and back pain, thought to result from hemoperitoneal irritation of the diaphragm, may indicate intrabdominal hemorrhage.

Physical Examination
The physical examination should include measurements of vital signs and examination of the abdomen and pelvis. Frequently, the findings before rupture and hemorrhage are nonspecific, and vital signs are normal. The abdomen may be nontender or mildly tender, with or without rebound. The uterus may be slightly enlarged, with findings similar to a normal pregnancy (75). Cervical motion tenderness may or may not be present. An adnexal mass may be palpable in up to 50% of cases, but the mass varies markedly in size, consistency, and tenderness. A palpable mass may be the corpus luteum and not the ectopic pregnancy. With rupture and intraabdominal hemorrhage, the patient develops tachycardia followed by hypotension. Bowel sounds are decreased or absent. The abdomen is distended, with marked tenderness and rebound tenderness. Cervical motion tenderness is present. Frequently, the pelvic examination is inadequate because of pain and guarding.

History and physical examination may or may not provide useful diagnostic information. The accuracy of the initial clinical evaluation is less than 50% (76). Additional tests are frequently required to differentiate early viable intrauterine pregnancy or suspected ectopic or abnormal intrauterine pregnancy.

### Laboratory Assessment

Quantitative b-hCG measurements are the diagnostic cornerstone of ectopic pregnancy. The HCG enzyme immunoassay, with a sensitivity of 25 mIU/mL, is an accurate screening test for detection of ectopic pregnancy. The assay is positive in virtually all documented ectopic pregnancies.

#### Reference Standards

There are three reference standards for b-hCG measurement. The World Health Organization introduced the First International Standard (1st IS) in the 1930s. Testing for hCG and its subunits have improved over the years. The Second International Standard (2nd IS), introduced in 1964, has varying amounts of hCG a and b subunits. A purified preparation of b-hCG is now available. Originally referred to as the First International Reference Preparation (1st IRP), the test standard is now referred to as the Third International Standard (3rd IS). Although each standard has its own scale, as a general rule, the 2nd IS is about half of the 3rd IS. For example, if a level is reported as 500 mIU/mL (2nd IS), it is equivalent to a level of 1,000 mIU/mL (3rd IS). The assay standard used must be known in order to interpret hCG results correctly (77). In several recent articles, attention has been drawn to a problem known as phantom HCG, in which the presence of heterophile antibodies or proteolytic enzymes causes a false-positive HCG result. Because the antibodies are large glycoproteins, significant quantities of the antibody are not excreted in the urine. Thus, in the patient with hCG levels less than 1,000 mIU/mL, a confirmatory positive urine pregnancy test should be obtained before instituting treatment (78–79).

#### Doubling Time

The HCG level correlates with the gestational age (80). During the first 6 weeks of amenorrhea, the serum hCG level increases exponentially. Thus, during this time period, the doubling time of hCG is relatively constant, regardless of the initial level. After the sixth week of gestation, when the hCG levels are higher than 6,000 to 10,000 mIU/mL, the HCG rise is slower and not constant (81).

The HCG doubling time can differentiate an ectopic pregnancy from an intrauterine pregnancy—a 66% rise in the hCG level over 48 hours (85% confidence limits of normal) occurs in only 10% of patients with viable intrauterine pregnancies (82). About 15% of patients with viable intrauterine pregnancies have less than 66% rise in hCG level over 48 hours, and a similar percentage with an ectopic pregnancy have more than a 66% rise. If the sampling interval is reduced to 24 hours, the overlap between normal and abnormal pregnancies is even greater. Patients with a normal intrauterine pregnancy usually have more than a 50% rise in the hCG level over 48 hours when the starting level is less than 2,000 mIU/mL. The HCG pattern that is most predictive of an ectopic pregnancy is one that has reached a plateau (a doubling time of more than 7 days). Failing levels, a half-life of less than 1.4 days is rarely associated with an ectopic pregnancy, whereas a half-life of more than 7 days is most predictive of ectopic pregnancy.

Serial hCG levels are usually required when the initial ultrasound examination is indeterminate (i.e., when there is no evidence of an intrauterine gestation or extrauterine cardiac activity consistent with an ectopic pregnancy). When the hCG level is less than 2,000, doubling time predicts viable intrauterine gestation (normal rise) versus nonviability (subnormal rise). With normally rising levels, a second ultrasound is performed when the level is expected (by extrapolation) to reach 2,000 mIU/mL. Abnormally rising levels (less than 2,000 mIU/mL) indicate a nonviable pregnancy. The location (i.e., intrauterine versus extrauterine) must be determined surgically, either by laparoscopy or dilation and curettage. Indeterminate ultrasonography results, and an hCG level of less than 2,000 mIU/mL is diagnostic of nonviable gestation, either ectopic pregnancy or a complete abortion. As a general rule, a completed abortion has a rapidly falling hCG level (50% over 48 hours), whereas levels of an ectopic pregnancy rise or plateau.

#### Single hCG Level

A single hCG measurement has limited usefulness because there is considerable overlap of values between normal and abnormal pregnancies at a given gestational age. The ectopic pregnancy site and hCG level do not correlate (83). Also, many patients in whom the diagnosis of ectopic pregnancy is being considered are uncertain about their menstrual dates. A single hCG level may be useful when measured by sensitive enzyme immunoassays that, if negative, exclude a diagnosis of ectopic pregnancy. Measurement of a single level may also be helpful in predicting pregnancy outcome after timed conceptions using advanced reproductive technology. If the hCG level is more than 300 mIU/mL on day 16 to 18 after artificial insemination, there is an 88% chance of a live birth (84). If the hCG level is less than 300 mIU/mL, the chance of a live birth is only 22%. Also, a single hCG level may facilitate the interpretation of ultrasonography when an intrauterine gestation is not visualized. An hCG level greater than the ultrasound discriminatory zone indicates a possible extrauterine pregnancy. However, determination of serial hCG levels may be needed to differentiate an ectopic pregnancy from a completed abortion. Further tests are required for patients in whom ultrasonography examinations are inconclusive and hCG levels are below the discriminatory zone.

#### Serum Progesterone

In general, the mean serum progesterone level in patients with ectopic pregnancies is lower than that in patients with normal intrauterine pregnancies (85,86). However, in studies of more than 5,000 patients with first-trimester pregnancies, a spectrum of progesterone levels in patients with both normal and abnormal pregnancies has been found (87–89). About 70% of patients with a viable intrauterine pregnancy have serum progesterone levels higher than 25 ng/mL, whereas only 1.5% of patients with ectopic pregnancies have serum progesterone levels higher than 25 ng/mL, and most of these pregnancies exhibit cardiac activity (87,88) and (89).

A serum progesterone level of less than 5 ng/mL is highly suggestive of an abnormal pregnancy, but it is not 100% predictive. The risk for a normal pregnancy with a serum progesterone level of less than 5 ng/mL is about 1 in 1,500 (90). Because of this, serum progesterone measurements alone cannot be used to predict pregnancy nonviability.

#### Other Endocrinologic Markers

In an effort to improve early ectopic pregnancy detection, various endocrinologic and protein markers have been studied. Estradiol levels increase slowly from conception until 6 weeks of gestation and then rise rapidly as placental production of estradiol increases (85,86). Also, many patients in whom the diagnosis of ectopic pregnancy is being considered are uncertain about their menstrual dates. A single hCG measurement has limited usefulness because there is considerable overlap of values between normal and abnormal pregnancies at a given gestational age. The ectopic pregnancy site and hCG level do not correlate (83).

Maternal serum creatinine kinase has been studied as a marker for ectopic pregnancy diagnosis (94). Maternal serum creatinine kinase levels were significantly higher in all patients with tubal pregnancy when compared with those in patients who had missed abortions or normal intrauterine pregnancies, but no correlation was found between the creatine kinase level and the clinical presentation of the patient, and there was no correlation with the HCG levels.

Schwangerschafts protein 1 (SP-1), also known as pregnancy-associated plasma protein C (PAPP-C) or pregnancy-specific b-glycoprotein (PSB), is produced by the syncytiotrophoblast (92). The main advantage of SP, level assessment may be in the diagnosis of conception after recent HCG administration. A level of 2 ng/mL might be used for the diagnosis of conception; however, it is doubtful that a diagnosis can be established before delay of menses. Although the SP level increases late in all patients with a nonviable pregnancy, a single SP level does not have prognostic value (95).

Relaxin is a protein hormone produced solely by the corpus luteum of pregnancy. It appears in the maternal serum at 4 to 5 weeks of gestation, peaks at about 10 weeks of gestation, and decreases until term (96). Relaxin levels are significantly lower in ectopic pregnancies and spontaneous abortions than in normal intrauterine pregnancies. Prorenin and active renin levels are significantly higher in viable intrauterine pregnancies than in either ectopic pregnancies or spontaneous abortions, with a single level of more than 33 pg/mL excluding the diagnosis of ectopic pregnancy (97). However, the clinical utility of relaxin, prorenin, and renin levels in
diagnosing ectopic pregnancy has not yet been determined.

CA125 is a glycoprotein, the origin of which is uncertain during pregnancy. Levels of CA125 rise during the first trimester and return to a nonpregnancy range during the second and third trimesters. After delivery, maternal serum concentrations increase again (98,99). CA125 levels have been studied in an effort to predict spontaneous abortion. Although a positive correlation has been found between elevated CA125 levels 18 to 22 days after conception and spontaneous abortion, repeat measurements at 6 weeks of gestation did not correlate with outcome (100). Conflicting results have been reported—one study showed a higher serum CA125 level in normal than in ectopic pregnancies 2 to 4 weeks after a missed menses, whereas another study found higher CA125 levels for ectopic pregnancies compared with normal pregnancies (101,102).

Maternal serum a-fetoprotein (AFP) levels are elevated in ectopic pregnancies (103,104); however, the use of AFP measurements as a screening technique for ectopic pregnancy has not been studied. A combination of AFP with three other markers—b-hCG, progesterone, and estradiol—has a 98.5% specificity and 94.5% accuracy for the prediction of ectopic pregnancy.

C-reactive protein is an acute-phase reactant that increases with trauma or infection. Levels of this protein are lower in patients with ectopic pregnancy than in patients with an acute infectious process. Thus, when an infectious process is part of the differential diagnosis, measurement of C-reactive protein may be beneficial (105).

Ultrasound

Improvements in ultrasonography have resulted in the earlier diagnosis of intrauterine and ectopic gestations (106). However, the sensitivity of the b-hCG assay usually allows the diagnosis of pregnancy before direct visualization by ultrasonography.

The complete examination should include both transvaginal and transabdominal ultrasonography. Transvaginal ultrasonography is superior to transabdominal ultrasonography in evaluating intraocular structures. The closeness of the vaginal probe to the pelvic organs allows use of higher frequencies (5 to 7 mHz), which improves resolution. The diagnosis of an intrauterine pregnancy can be made 1 week earlier with transvaginal than with transabdominal ultrasound. The demonstration of an empty uterus, detection of adnexal masses and free peritoneal fluid, and direct signs of ectopic pregnancy are more reliably established with a transvaginal procedure (107,108,109,110 and 111). Transabdominal ultrasonography permits visualization of both the pelvis and abdominal cavity and should be included as part of the complete ectopic pregnancy evaluation to detect adnexal masses and hemoperitoneum.

The earliest ultrasonicographic finding of an intrauterine pregnancy is a small fluid space and the gestational sac, surrounded by a thick echogenic ring, located eccentrically within the endometrial cavity. The earliest normal gestational sac is seen at 5 weeks of gestation with transabdominal ultrasonography and at 4 weeks of gestation with transvaginal ultrasonography (112). As the gestational sac grows, a yolk sac is seen within it, followed by an embryo with cardiac activity.

The appearance of a normal gestational sac may be simulated by intrauterine fluid collection, the pseudogestational sac, which occurs in 8% to 29% of patients with ectopic pregnancy (113,114 and 115). This ultrasonicographic lucency, centrally located, probably represents bleeding into the endometrial cavity by the decidual cast. Clots within this lucency may mimic a fetal pole.

Morphologically, identification of the double decidual sac sign (DDSS) is the best known method of ultrasonographically differentiating true sacs from pseudosacs (116). The double sac, believed to be the decidua capsularis and parietalis, is seen as two concentric echogenic rings separated by a hypoechoic space. Although useful, there are some limitations of sensitivity and specificity—the DDSS sensitivity ranges from 64% to 95% (115). Pseudosacs may occasionally appear as the DDSS; intrauterine sacs of failed pregnancies may appear as pseudosacs.

The appearance of a yolk sac within the gestational sac is superior to the DDSS in proving an intrauterine pregnancy (117). The yolk sac is consistently visible on transabdominal ultrasonography with a gestational sac size of 2 cm, and on transvaginal ultrasonography at a gestational sac size of 0.6 to 0.8 cm (118,119). Intrauterine sacs smaller than 1 cm on transabdominal ultrasonography and smaller than 0.6 cm on transvaginal ultrasonography are considered indeterminate. Larger sacs without DDSS or yolk sac represent either a failed intrauterine or ectopic pregnancy.

The presence of cardiac activity within the uterine cavity is definitive evidence of an intrauterine pregnancy. This finding essentially eliminates the diagnosis of ectopic pregnancy because the incidence of combined intrauterine and extrauterine pregnancy is 1 in 30,000.

The demonstration of an adnexal gestational sac with a fetal pole and cardiac activity is the most specific but least sensitive sign of ectopic pregnancy, occurring in only 10% to 17% of cases (105,120,121). The recognition of other characteristics of ectopic pregnancy has improved ultrasonographic sensitivity. Adnexal rings (fluid sacs with thick echogenic rings) that have a yolk sac or nonliving embryo are accepted as specific ultrasonographic signs of ectopic pregnancy (122). Adnexal rings are visualized in 22% of ectopic pregnancies using transabdominal ultrasonography and in 36% using transvaginal ultrasonography (107). Other studies have identified adnexal rings in 33% to 50% of ectopic pregnancies (105,121). The adnexal ring may not always be apparent because bleeding around the sac results in the appearance of a nonspecific adnexal mass.

Complex or solid adnexal masses are frequently associated with ectopic pregnancy (1,13,19); however, the mass may represent a corpus luteum, endometrioma, hydrosalpinx, ovarian neoplasm (e.g., dermoid cyst), or pedunculated fibroid. Free cul-de-sac fluid is frequently associated with ectopic pregnancy and is no longer considered evidence of rupture. The presence of intrabdominal free fluid should raise concern about tubal rupture (123).

Accurate interpretation of ultrasonography findings requires correlation with the hCG level (discriminatory zone) (114,119,122,124). All viable intrauterine pregnancies can be visualized by transabdominal ultrasonography for serum hCG levels higher than 6,500 mIU/mL; none are seen at 6,000 mIU/mL. Nonvisualization of an intrauterine gestation with serum hCG levels higher than 6,500 mIU/mL indicates an abnormal (failed intrauterine or ectopic) pregnancy. Intrauterine sacs seen at hCG levels below the discriminatory zone are abnormal and represent either failed intrauterine pregnancies or the pseudogestational sacs of ectopic pregnancy. If there is no definite sign of an intrauterine gestation (the empty uterus sign) and the hCG level is below the discriminatory zone, the differential diagnosis includes the following considerations:

1. Normal intrauterine pregnancy too early for visualization
2. Abnormal intrauterine gestation
3. Recent abortion
4. Ectopic pregnancy
5. Nonpregnant

The discriminatory zone has been lowered progressively with improvements in ultrasonography resolution. Discriminatory zones for transvaginal ultrasonography have been reported at levels from 1,000 to 2,000 mIU/mL (114,115,122,124). Discriminatory zones vary according to the expertise of the examiner and capability of the equipment.

Although the discriminatory zone for intrauterine pregnancy is well established, there is no such zone for ectopic pregnancy. Levels of hCG have not been shown to correlate with the size of ectopic pregnancy. Regardless of how high the hCG level may be, nonvisualization does not exclude ectopic pregnancy. An ectopic pregnancy may be present anywhere in the abdominal cavity, making ultrasonographic visualization difficult.

Doppler Ultrasound

A Doppler shift occurs whenever the source of an ultrasound beam is moving. The usual sources of Doppler-shifted frequencies are red blood cells. The presence of intravascular blood flow, flow direction, and flow velocity can be determined (125). Pulsed Doppler provides ultrasonographic control over which vessels are sampled. The vascular information is provided both by the shape of the time-velocity waveform (high- or low-resistance flow) and by its systolic, diastolic, and mean velocities (or Doppler frequency shifts) (126). Color-flow Doppler ultrasonography analyzes very-low-amplitude signals from an entire ultrasound tomogram; the Doppler shift is
Once tissue is obtained by curettage, it is found to be 100% accurate in a randomized clinical trial (127-129). When hCG levels and transvaginal ultrasonography are available in a pregnancy: clinical diagnosis and management. New York: McGraw-Hill, 1993;186, with permission.)

Figure 17.3 When floated in saline, chorionic villi are often readily distinguishable as lacy fronds of tissue. (From Stovall TG, Ling FW. Extraterine pregnancy: clinical diagnosis and management. New York: McGraw-Hill, 1993:186, with permission.)

When frozen section is not available, serial hCG levels permit rapid diagnosis. After evacuation of an abnormal intrauterine pregnancy, the hCG level decreases by 15% within 12 to 24 hours. A borderline fall may represent interassay variability. A repeat level should be obtained in 24 to 48 hours to confirm the decline. If the uterus is evacuated and the pregnancy is extrauterine, the hCG level plateaus or continues to increase, indicating the presence of extrauterine trophoblastic tissue.

Culdocentesis

Culdocentesis has been used widely as a diagnostic technique for ectopic pregnancy. With the use of hCG testing and transvaginal ultrasound, however, culdocentesis is rarely indicated. The purpose of the procedure is to determine the presence of nonclotting blood, which increases the likelihood of ruptured ectopic pregnancy. After exposing the posterior vaginal fornix with a bivalve vaginal speculum, the posterior lip of the cervix is grasped with a tenaculum. The cul-de-sac is then entered through the posterior vaginal wall with an 18- to 20-gauge spinal needle with a syringe attached. As the cul-de-sac is entered, suction is applied, and the intraperitoneal contents are aspirated. If nonclotting blood is obtained, the results are positive. In the presence of serous fluid, results are negative. A lack of fluid return or clotted blood is nondiagnostic. Histologically, if the culdocentesis results were positive, laparotomy was performed for a presumed diagnosis of ruptured tubal pregnancy. However, the results of culdocentesis do not always correlate with the status of the pregnancy. Although about 70% to 90% of patients with ectopic pregnancy have a hemoperitoneum demonstrated by culdocentesis, only 50% of patients have a ruptured tube (131). Furthermore, about 6% of women with positive culdocentesis results do not have an ectopic gestation at the time of laparotomy. Nondiagnostic taps occur in 10% to 20% of patients with ectopic pregnancy and, therefore, are not definitive.

Laparoscopy

Laparoscopy is the gold standard for the diagnosis of ectopic pregnancy. Generally, the fallopian tubes are easily visualized and evaluated, although the diagnosis of ectopic pregnancy is missed in 3% to 4% of patients who have very small ectopic gestations. The ectopic gestation is usually seen distorting the normal tubal architecture. With earlier diagnosis, there is an increasing possibility that a small ectopic pregnancy may not be visualized. Pelvic adhesions or previous tubal damage may compromise assessment of the tube. False-positive results occur when tubal dilation or discoloration is misinterpreted as an ectopic pregnancy, in which case the tube can be incised unnecessarily and damaged.

Diagnostic Algorithm

The presenting symptoms and physical findings of patients with an unruptured ectopic pregnancy are similar to those of patients with a normal intrauterine pregnancy (89). History, risk factor assessment, and physical examination are the initial steps in the management of suspected ectopic pregnancy. Patients in a hemodynamically unstable condition should undergo immediate surgical intervention. Patients with a stable, relatively asymptomatic condition may be assessed as outpatients. If the diagnosis of ectopic pregnancy can be confirmed without laparoscopy, several potential benefits result. First, both the anesthetic and surgical risks of laparoscopy are avoided; second, medical therapy becomes a treatment option. Because many ectopic pregnancies occur in histologically normal tubes, resolution of intrauterine pregnancy is often achieved. A similar high-velocity, low-impedance flow characterizes ectopic pregnancies. The addition of Doppler to the ultrasonicographic evaluation of suspected ectopic pregnancy improves diagnostic sensitivity for individual diagnoses: from 71% to 87% for ectopic pregnancy, from 24% to 59% for failed intrauterine pregnancy, and from 90% to 99% for normal intrauterine pregnancy (125,126,130).

Dilation and Curettage

Uterine curettage is performed when the pregnancy has been confirmed to be nonviable and the location of the pregnancy cannot be determined by ultrasonography. The decision to evacuate the uterus in the presence of a positive pregnancy test must be made with caution to avoid the unintentional disruption of a viable intrauterine pregnancy. Although suction curettage traditionally has been performed in the operating room, it can now be accomplished under local anesthesia on an outpatient basis. Endometrial sampling methods (e.g., a Novak curettage or Pipelle endometrial sampling device) are accurate in diagnosing abnormal uterine bleeding, but their reliability for intrauterine pregnancy evacuation has not been studied. These devices might miss intrauterine villi and falsely suggest the diagnosis of ectopic pregnancy.

It is essential to confirm the presence of trophoblastic tissue as rapidly as possible so that therapy may be instituted. Once tissue is obtained by curettage, it can be added to saline, in which it will float (Fig. 17.3). Decidual tissue does not float. Chorionic villi are usually identified by their characteristic lacy frond appearance. The sensitivity and specificity of this technique are 95% when the tissue is examined with the aid of a dissecting microscope. Because flotation of curettage is not 100% accurate in differentiating an intrauterine from extraterine gestation, histologic confirmation or serial hCG level measurement is required. A rapid assessment of the presence of chorionic villi may be obtained with frozen section, which avoids the at least 48-hour waiting period for permanent histologic evaluation. Immunocytochemical staining techniques have been used to identify intermediate trophoblasts that are not normally identified by light microscopy (74).

The waveform in the uterine arteries in the nongravid state and in the first trimester of pregnancy shows a high-resistance (little or no diastolic flow), low-velocity pattern. Conversely, a high-velocity, low-resistance signal is localized to the area of developing placentation (127,128) and (129). This pattern, seen near the endometrium, is associated with normal and abnormal intrauterine pregnancies and is termed peritrophoblastic flow. Whereas transvaginal ultrasonography requires a well-developed double decidual sac (or possibly cardiac activity) to localize an intrauterine gestation, the use of Doppler techniques allows detection of an intrauterine pregnancy at an earlier date. The combined use of Doppler and two-dimensional imaging allows the differentiation of pseudogestational sacs and true intrauterine gestational sacs (130) and the differentiation of the empty uterus sign as either the presence of an intrauterine pregnancy (normal and abnormal) or absence of an intrauterine pregnancy (with an increased risk for ectopic pregnancy) (129).

Diagnostic Algorithm

The presenting symptoms and physical findings of patients with an unruptured ectopic pregnancy are similar to those of patients with a normal intrauterine pregnancy (89). History, risk factor assessment, and physical examination are the initial steps in the management of suspected ectopic pregnancy. Patients in a hemodynamically unstable condition should undergo immediate surgical intervention. Patients with a stable, relatively asymptomatic condition may be assessed as outpatients.
In the identification of an intrauterine gestational sac or pregnancy effectively excludes the presence of an extrauterine pregnancy. If the patient has a rising hCG level of more than 2,000 mIU/mL, and no intrauterine gestational sac is identified, the patient is considered to have an extrauterine pregnancy and can be treated without further testing. Adnexal cardiac activity, when seen, definitively confirms the diagnosis of ectopic pregnancy. A tubal mass as small as 1 cm can be identified and characterized. Masses greater than 3.5 cm with cardiac activity or larger than 4 cm without cardiac activity should not be treated with medical therapy.

Suction curettage is used to differentiate nonviable intrauterine pregnancies from ectopic gestations (less than 50% rise in hCG level over 48 hours, an hCG level of less than 2,000 mIU/mL, and an indeterminate sonogram). Performance of this procedure avoids unnecessary use of methotrexate in patients with abnormal intrauterine pregnancy that can only be diagnosed by evacuating the uterus. An unlikely potential problem with suction curettage is missing either an early nonviable intrauterine pregnancy or combined intrauterine and extraterine pregnancies.

Treatment

Ectopic pregnancy can be treated either medically or surgically. Both methods are effective, and the choice depends on the clinical circumstances, the site of the ectopic pregnancy, and the available resources.

Surgical Treatment

Operative management is the most widely used treatment for ectopic pregnancy. There has been debate about which surgical procedure is best. Salpingo-oophorectomy was once considered appropriate because it was theorized that this technique would eliminate transperitoneal migration of the ovum or zygote, which was thought to predispose to recurrent ectopic pregnancy (134). Ovarian removal results in all ovulations occurring on the side with the remaining normal fallopian tube. Subsequent studies have not confirmed that ipsilateral oophorectomy increases the likelihood of conceiving an intrauterine pregnancy; therefore, this practice is not recommended (135).

Salpingectomy Versus Salpingostomy

Linear salpingostomy is currently the procedure of choice when the patient has an unruptured ectopic pregnancy and wishes to retain her potential for future fertility. The products of conception are removed through an incision made into the tube on its antimesenteric border. The procedure can be accomplished with either a needle tip cautery, laser, scalpel, or scissors. It can be done by operative laparoscopic techniques or laparotomy. In a study in which patients treated with either salpingectomy or salpingostomy were followed for a period of 3 years to about 12.5 years, there was no difference in pregnancy rates (136). A history of infertility is the most significant determinant of future fertility, and such patients are probably served better by salpingectomy to decrease their subsequent chance of a recurrent ectopic pregnancy. Linear salpingostomy is as effective as segmental resection with primary reanastomosis, even for ectopic pregnancies occurring in the isthmic tubal segment, and it is technically less difficult and has a shorter operative time (137).

Miling the tube to effect a tubal abortion has been advocated; if the pregnancy is fimbrial, this technique may be effective. However, when milking was compared with linear salpingostomy for ampullary ectopic pregnancies, milking was associated with a twofold increase in the recurrent ectopic pregnancy rate (138).

Laparotomy Versus Laparoscopy

Salpingostomy, salpingectomy, or segmental resection can be accomplished by laparoscopy or laparotomy. The approach used depends on the hemodynamic stability of the patient, the size and location of the ectopic mass, and the surgeon's expertise. Laparotomy is indicated when the patient becomes hemodynamically unstable, whereas laparoscopy is reserved for patients who are hemodynamically stable. A ruptured ectopic pregnancy does not necessarily require laparotomy. However, if large blood clots are present or the intraabdominal blood cannot be evacuated in a timely manner, laparotomy should be considered. Operative management is described (139). Laparotomy is chosen for the management of most ovarian and abdominal pregnancies. In some cases, the patient may have extensive abdominal or pelvic adhesive disease, making laparoscopy difficult and laparotomy more feasible.

Laparoscopy has advantages over laparotomy for management of ectopic pregnancy. In a case-control study of 50 patients comparing the use of laparoscopy and laparotomy for ectopic pregnancy management, hospital stay was significantly shorter (1.3 ± 0.8 versus 3.0 ± 1.1 days), operative time was shorter (78 ± 26 versus 104 ± 27 minutes), and convalescence was shorter (9 ± 8 versus 26 ± 16 days) in the laparoscopy group (140). In a randomized study in which 30 patients in each group were compared, patients undergoing laparoscopic management had less estimated blood loss, shorter hospital stay, equivalent tubal pregnancy rates, and similar pregnancy and persistent trophoblast rates (141). In another study, patients were assigned during alternate months to undergo laparoscopic management (n = 28) or laparotomy (n = 37) (142). There were no differences in operative time, although patients undergoing laparoscopy had a significant decrease in blood loss, postoperative hospital stay, narcotic requirement, and time to return to normal activity. Laparoscopic management was associated with significant cost savings when compared with laparotomy (more than $5,528 ± $1,586 versus more than $6,793 ± $105). Using a prospective analysis, 105 patients with tubal pregnancy were stratified with regard to age and risk factors and then randomized to undergo either laparoscopic management or laparotomy (143). Subsequently, 73 patients underwent second-look laparoscopy to assess the degree of adhesion formation. Patients treated by laparotomy had significantly more adhesions at the surgical site than those treated by laparoscopy, but tubal patency rates were similar. Pregnancy rates were not analyzed.

Reproductive Outcome

Reproductive outcome after ectopic pregnancy is usually evaluated by determining tubal patency by hysterosalpingography, the subsequent intrauterine pregnancy rate, and the recurrent ectopic pregnancy rate. Pregnancy rates are similar in patients treated by either laparoscopy or laparotomy. Tubal patency on the ipsilateral side after conservative laparoscopic management is about 84%.

In a study of 143 patients followed after undergoing laparoscopic procedures for ectopic pregnancy, the overall intrauterine pregnancy rates for laparoscopic salpingostomy (60%) and laparoscopic salpingectomy (54%) were not significantly different (144). If the patient had evidence of tubal damage, pregnancy rates (42%) were significantly lower than in those women who did not have tubal damage (79%). In another study, the reproductive outcome of 188 patients followed for a mean of 7.2 years (range, 3 to 15 years) was reported after conservation by laparotomy for ectopic pregnancy (145). An intrauterine pregnancy occurred in 83 (70%) patients, with a recurrent ectopic pregnancy rate of 13%, suggesting that reproductive outcome after an ectopic pregnancy treated by laparotomy is similar to that of patients undergoing laparoscopic or medical management. Thus, when compared with medical therapy, surgical management appears to have equal reproductive outcome,

Figure 17.4 Nonlaparoscopic algorithm for diagnosis of ectopic pregnancy.
Medical Treatment

The drug most frequently used for medical management of ectopic pregnancy is methotrexate, although other agents have been studied, including potassium chloride (KCl), hyperosmolar glucose, prostaglandins, and RU-486. These agents may be given systemically (intravenously, intramuscularly, or orally) or locally (laparoscopic direct injection, transvaginal ultrasound-directed injection, or retrograde salpingography).

Methotrexate

Methotrexate is a folic acid analogue that inhibits dehydrofolate reductase and thereby prevents synthesis of DNA. It has been used extensively in the treatment of gestational trophoblastic disease (see Chapter 34). Commonly reported side effects include leukenopenia, thrombocytopenia, bone marrow aplasia, ulcerative stomatitis, diarrhea, and hemorrhagic enteritis. Other reported side effects include alopecia, dermatitis, elevated liver enzyme levels, and pneumonitis (146). However, no significant side effects have been reported at the low doses used for ectopic pregnancy treatment. Minor side effects have been reported with multiple doses; citrovorum factor reduces the incidence of these side effects and is generally used when prolonged treatment is required. Importantly, long-term follow-up of women treated with methotrexate for gestational trophoblastic disease shows no increase in congenital malformations, spontaneous abortions, or tumors recurring after chemotherapy (147). A smaller total dose of methotrexate is required, and shorter treatment duration is used for treatment of ectopic pregnancy than for gestational trophoblastic disease.

Initially, methotrexate was used for the treatment of trophoblastic tissue left in situ after exploration for an abdominal pregnancy (146). In 1982, Tanaka and colleagues treated an unruptured interstitial gestation with a 15-day course of intramuscular methotrexate (149). The use of methotrexate for primary treatment of ectopic pregnancy has been reported in more than 300 patients (150,151,152,153,154,155,156,157,158 and 159).

A trial of intramuscular methotrexate (1 mg/kg/day) followed by citrovorum factor (0.1 mg/kg/day) on alternate days was given to 100 patients with a success rate of 98% (153,155). This outpatient treatment protocol used methotrexate plus citrovorum factor given only until the hCG level began to decline. Treatment was given until there was at least a 15% decline between two consecutive daily hCG levels. Citrovorum factor is given on the day after the methotrexate is administered, even if no further methotrexate is indicated. Once methotrexate is discontinued, hCG levels are measured weekly until the results are negative. A second course of methotrexate plus citrovorum factor is given only if there is a plateau or rise in the hCG level. Of the 96 patients successfully treated, 17 required only one methotrexate and citrovorum factor dose, and 19 required four doses. Four patients treated with methotrexate failed therapy and required surgical treatment for tubal rupture, and each of these cases differed with respect to ectopic pregnancy size, hCG level, and time of rupture. Of five ectopic pregnancies with cardiac activity, four were successfully treated. No conclusions can be drawn regarding risk factors or predictors of ectopic pregnancy rupture.

Single-dose intramuscular methotrexate for ectopic pregnancy treatment was administered to 31 patients with an injection of 50 mg/m² without citrovorum factor. Of 30 patients, 29 (96.7%) were successfully treated, and no patients experienced methotrexate-related side effects. Some 200 patients have now been treated using the single-dose protocol outlined in Table 17.3. Compared with the multidose protocol, single-dose methotrexate is less expensive, patient acceptance is greater because less monitoring is required during treatment, the incidence of side effects is decreased, and the treatment results and prospects for future fertility are comparable.

Table 17.3. Single-dose Methotrexate Protocol for Ectopic Pregnancy

Initiating Methotrexate Table 17.4 outlines a checklist that should be followed by the physician before initiating methotrexate. It also lists instructions that are helpful to the patient.

Patient Follow-up After intramuscular administration of methotrexate, patients are monitored on an outpatient basis. Patients who report severe pain or pain that is prolonged are evaluated by measuring hematocrit levels and performing transvaginal ultrasonography. The ultrasonography findings during follow-up, although not usually helpful, can be used to provide reassurance that the tube has not ruptured (160). Cul-de-sac fluid is very common, and the amount of fluid may increase if a tubal abortion occurs. However, it is usually not necessary to intervene surgically unless the patient has a precipitous drop in hematocrit levels or she becomes hemodynamically unstable.

Patients are asked not to become pregnant for at least 2 months after treatment. Hysterosalpingography can be performed, although the procedure is not mandatory.

Candidates for Methotrexate In order to maximize the safety of treatment and to eliminate the possibility of treating in the presence of a nonviable or early viable intrauterine pregnancy, patients considered candidates for methotrexate treatment should include those to whom the following factors apply:

1. An hCG level is present after salpingostomy or salpingotomy.
2. A rising or plateaued hCG level is present at least 12 to 24 hours after suction curettage.
3. An intrauterine gestational sac or fluid collection is detected by transvaginal ultrasound, the hCG level is greater than 2,000 mIU/mL, and an ectopic pregnancy mass of at least 3.5 to 4 cm is demonstrated.
Ultrasound findings should be interpreted with caution because most unruptured ectopic pregnancies will be accompanied by fluid in the cul-de-sac.

**Side Effects** Opponents of methotrexate therapy cite potential side effects as the reason not to use it. Most reported side effects have occurred in patients treated with intravenous methotrexate with higher doses and for more prolonged treatment courses than are now required. When using the single-dose intramuscular regimen, the incidence of side effects is less than 1%, and the failure rate is comparable to that of conservative laparoscopic surgery. One problem that remains puzzling is the inability to predict treatment failures with the use of methotrexate. However, the same is true with conservative surgical procedures; thus, the need to monitor hCG levels after either salpingostomy or methotrexate remains. In a review of more than 350 women treated with intramuscular methotrexate, Lipscomb and associates found that a high hCG concentration was the most important factor associated with failure of treatment with a single-dose methotrexate protocol (161). In patients with an hCG level of less than 10,000 mIU/mL, the overall success rate was 93.4%, as compared with 60.7% when the hCG level was greater than 10,000 mIU/mL. Although surgical management of ectopic pregnancy remains the mainstay of treatment worldwide, methotrexate treatment is appropriate in select patient populations.

**Reproductive Function** Although there are few data, reproductive function after methotrexate treatment can be assessed on the basis of tubal patency and pregnancy outcome. Tubal patency is reported to be 50% to 100%, with a mean of 71%, after systemic methotrexate treatment. In two separate reports of 23 and 62 patients, the tubal patency rates on the ipsilateral side were 81.4% and 82.3%, respectively (156,162). Pregnancy outcome after methotrexate administration was reported in a group of 14 patients who attempted pregnancy after multiple intramuscular doses. Of these 14 women, 11 (78.6%) became pregnant; 10 of 11 (90.9%) were intrauterine pregnancies, and one (9%) was an extraterine pregnancy (156). The mean time from first attempting to achieving pregnancy was 2.3 months (range, 1 to 4 months). In another study of 49 patients who were attempting pregnancy after completion of single-dose intramuscular methotrexate administration, 39 (80%) became pregnant; 34 (87%) were intrauterine pregnancies, and 5 (13%) were ectopic pregnancies (163). The mean time from attempting to achieving pregnancy was 3.2 ± 1.1 months. In 87 pregnancies after methotrexate therapy, the combined intrauterine pregnancy rate was 86%, and the ectopic pregnancy rate was 14%.

In a combined series of 527 patients treated by laparoscopic linear salpingostomy or salpingotomy, the intrauterine pregnancy rate was 54%, and the recurrent ectopic pregnancy rate was 13% (184). Comparison of laparoscopically treated patients with methotrexate-treated patients suggests that the two methods have similar reproductive outcomes.

**Other Drugs and Techniques**

Salpingocentesis is a technique in which agents such as KCl, methotrexate, prostaglandins, and hyperosmolar glucose are injected into the ectopic pregnancy transvaginally using ultrasound guidance, by transcervical tubal cannulation, or by laparoscopy. Agents injected under ultrasound guidance have included methotrexate (165,166,167,168), KCl (170), combined methotrexate and KCl (171.1, and prostaglandin E2 (172). The potential advantages of salpingocentesis include a one-time injection with the potential avoidance of systemic side effects. Reproductive function after this form of treatment has not been reported. Because of the limited experience, this treatment cannot be recommended until there is further study.

Agents injected into the amniotic sac at laparoscopy have included prostaglandin E2 (173), hyperosmolar glucose (174), and methotrexate (175). This method has the obvious disadvantage of requiring laparoscopy, but it can be used if laparoscopy has been performed. Other agents reported for the treatment of ectopic pregnancy include RU-486 (176) and anti-hCG antibody (177).

**Types of Ectopic Pregnancy**

**Spontaneous Resolution**

Some ectopic pregnancies resolve by resorption or by tubal abortion, obviating the need for medical or surgical therapy (178,179,180,181 and 182). The proportion of ectopic pregnancies that resolve spontaneously and the reason they do so while others do not are unknown. There are no specific criteria for patient selection that predict successful outcome after spontaneous resolution. A falling hCG level is the most common indicator used, but ectopic pregnancy rupture can occur even with falling hCG levels.

**Persistent Trophoblastic Tissue**

Persistent ectopic pregnancy occurs when a patient has undergone conservative surgery (e.g., salpingostomy, fimbrial expression) and viable trophoblastic tissue remains. Histologically, there is no identifiable embryo, the implantation is usually medial to the previous tubal incision, and residual chorionic villi are usually confined to the tubal musculins. Perloneal trophoblastic tissue implants may also be responsible for persistence (163,184,185,186,187 and 188). The incidence of persistent ectopic pregnancy has increased with the increased use of surgery that conserves the tubes. Persistence is diagnosed when the hCG levels plateau after conservative surgery. Persistent ectopic gestation is best diagnosed by an initial measurement of serum hCG or progesterone 6 days postoperatively and at 3-day intervals thereafter (189). Risk factors for persistent ectopic pregnancy are based on the type of surgical procedure, the initial hCG level, the duration of amenorrhea, and the size of the ectopic pregnancy. A slower decline of serum hCG levels has been seen in patients treated by salpingostomy compared with patients treated by salpingectomy. The incidence of persistence after laparoscopic linear salpingostomy ranges from 3% to 20% (169,190). It is uncertain whether the incidence of persistent ectopic pregnancy is the same or greater when the procedure is performed by laparoscopy versus laparotomy. In a review of medical records from 157 patients who underwent salpingostomy for intact ampullary ectopic pregnancy, 16 of 103 patients (16%) undergoing laparoscopic salpingostomy were treated for persistent ectopic pregnancy, whereas 1 of 54 women (2%) who had salpingostomy by laparotomy was treated for persistent ectopic pregnancy (195). Lundoff and colleagues reported that 23% of women with a preparoceptive hCG level of less than 3,000 mIU/mL, developed persistent ectopic pregnancy, whereas only 1 of 67 with a level of more than 3,000 mIU/mL persisted (197). They also noted that 36% of women with an hCG level of more than 1,000 mIU/mL on the second postoperative day and 64% of patients with an hCG level of more than 1,000 mIU/mL on the seventh postoperative day developed persistence. Amenorrhea of less than 7 weeks' duration and ectopic mass smaller than 2 cm have also been reported to increase the risk for persistent ectopic pregnancy (185,187).

Treatment of persistent ectopic pregnancy can be either surgical or medical; surgical therapy consists of either repeat salpingostomy or, more commonly, salpingectomy. Methotrexate offers an alternative to patients who are hemodynamically stable at the time of diagnosis. Methotrexate may be the treatment of choice because the persistent trophoblastic tissue may not be confined to the tube and, therefore, not readily identifiable during repeat surgical exploration (190,191 and 192).

**Chronic Ectopic Pregnancy**

Chronic ectopic pregnancy is a condition in which the pregnancy does not completely resorb during expectant management. The condition arises when there is persistence of the chorionic villi with bleeding into the tubal wall, which is distended slowly and does not rupture. It may also arise from chronic bleeding from the fimbriated end of the fallopian tube with subsequent tamponade. In a series of 50 patients with a chronic ectopic pregnancy, pain was present in 86%, vaginal bleeding was present in 68%, and both symptoms were present in 56% (193). Ninety percent of the patients had amenorrhea ranging from 5 to 16 weeks (mean, 9.6 weeks). Most patients develop a pelvic mass that is usually symptomatic. The hCG level is usually low but may be absent; ultrasound may be helpful in the diagnosis, and rarely, bowel involvement or uterine compression or obstruction exists (193,194).

This condition is treated surgically with removal of the affected tube. Often, the ovary must be removed because there is inflammation with subsequent adhesion development. A hematoma may be present secondary to chronic bleeding.

**Nontubal Ectopic Pregnancy**
Cervical Pregnancy

The incidence of cervical pregnancy in the United States ranges from 1 in 2,400 to 1 in 50,000 pregnancies (195). A variety of conditions are thought to predispose to the development of a cervical pregnancy, including previous therapeutic abortion, Asherman's syndrome, previous cesarean delivery, diethylstilbestrol exposure, leiomyomas, and IVF (195,196 and 197).

The diagnostic criteria for cervical pregnancy were established based on histologic analysis of a hysterectomy specimen (195). Clinical criteria include the following findings (197):

1. The uterus is smaller than the surrounding distended cervix.
2. The internal os is not dilated.
3. Curettage of the endometrial cavity is nonproductive of placental tissue.
4. The external os opens earlier than in spontaneous abortion.

Ultrasonographic diagnostic criteria have also been described that are helpful in differentiating a true cervical pregnancy from an ongoing spontaneous abortion (Table 17.5). Magnetic resonance imaging of the pelvis has also been used in this situation (198). Other potential diagnoses that must be differentiated from cervical pregnancy include cervical carcinoma, cervical or prolapsed submucous leiomyomas, trophoblastic tumor, placenta previa, and low-lying placenta.

When a cervical pregnancy is diagnosed before surgery, the preoperative preparation should include blood typing and cross-matching, establishment of intravenous access, and detailed informed consent. This consent should include the possibility of hemorrhage that may require transfusion or hysterectomy. Nonsurgical treatment, including intraamniotic and systemic methotrexate administration, has been used successfully (199,200). The diagnosis may not be suspected until the patient is undergoing suction curettage for a presumed incomplete abortion and hemorrhage occurs. In some cases, bleeding is light, whereas in others, there is hemorrhage. Various techniques that can be used to control bleeding include uterine packing, lateral cervical suture placement to ligate the lateral cervical vessels, and insertion of an intracervical 30-mL Foley catheter in an attempt to tamponade the bleeding. Alternatively, angiographic artery embolization can be used; or, if laparotomy is required, an attempt can be made to ligate the uterine or internal iliac arteries (201,202 and 203). When none of these methods is successful, hysterectomy is required.

Ovarian Pregnancy

A pregnancy confined to the ovary represents 0.5% to 1% of all ectopic pregnancies and is the most common type of nontubal ectopic pregnancy. The incidence ranges from 1 in 40,000 to 1 in 7,000 deliveries (204,205). The diagnostic criteria were described in 1878 by Spiegelberg (Table 17.6). Unlike tubal gestation, ovarian pregnancy is associated with neither PID nor infertility. The only risk factor associated with the development of an ovarian pregnancy is the current use of an intrauterine device.

Patients have symptoms similar to those of ectopic pregnancies in other sites. Misdiagnosis is common because it is confused with a ruptured corpus luteum in up to 75% of cases (204). As with other types of ectopic pregnancy, an ovarian pregnancy has also been reported after hysterectomy (206). Ultrasonography has made preoperative diagnosis possible in some cases (207).

The treatment of ovarian pregnancy has changed. Whereas oophorectomy has been advocated in the past, ovarian cystectomy has become the preferred treatment (208). It is possible to perform cystectomy using laparoscopic techniques (209,210). Treatment with methotrexate or prostaglandin injection has also been reported (210).

Abdominal Pregnancy

Abdominal pregnancies are classified as primary and secondary. Table 17.7 lists criteria for classifying a primary abdominal pregnancy. Secondary abdominal pregnancies are by far the most common and result from tubal abortion or rupture or, less often, from subsequent implantation within the abdomen after uterine rupture. The incidence of abdominal pregnancy varies from 1 in 372 to 1 in 9,714 live births (211). Abdominal pregnancy is associated with high morbidity and mortality, with the risk for death 7 to 8 times greater than from tubal ectopic pregnancy and 90 times greater than from intrauterine pregnancy. There are scattered reports of term abdominal pregnancies. When this occurs, perinatal morbidity and mortality are high, usually as a result of growth restriction and congenital anomalies such as fetal pulmonary hypoplasia, pressure deformities, and facial and limb asymmetry. The incidence of congenital anomalies ranges from 20% to 40% (212).
The presentation of patients with an abdominal pregnancy varies and depends on the gestational age. In the first and early second trimester, the symptoms may be the same as with tubal ectopic gestation; in advanced abdominal pregnancy, the clinical presentation is more variable. The patient may complain of painful fetal movement, fetal movements high in the abdomen, or sudden cessation of movements. Physical examination may disclose persistent abnormal fetal lies, abdominal tenderness, and a diffuse, distended, tender uterine contour, easy palpation of the uterus separate from fetal parts, and edema of the abdominal wall. The diagnosis may be suspected when there are no uterine contractions after oxytocin infusion. Other diagnostic aids include abdominal x-ray, abdominal ultrasound, computed tomography scanning, and magnetic resonance imaging (213,214).

Because the pregnancy can continue to term, the potential maternal morbidity and mortality are very high. As a result, surgical intervention is recommended when an abdominal pregnancy is diagnosed. At surgery, the placenta can be removed if its vascular supply can be identified and ligated, but hemorrhage can occur, requiring abdominal packing that is left in place and removed after 24 to 48 hours. Angiographic arterial embolization has been described (215). If the vascular supply cannot be identified, the cord is ligated near the placental base, and the placenta is left in place. Placental involution can be monitored using serial ultrasonography and hCG levels. Potential complications of leaving the placenta in place include bowel obstruction, fistula formation, and sepsis as the tissue degenerates. Methotrexate treatment appears to be contraindicated because a high rate of complications has been reported, including sepsis and death, believed to be a result of rapid tissue necrosis (216).

Interrital Pregnancy

Interstitial pregnancies represent about 1% of ectopic pregnancies. These patients tend to present later in gestation than those with tubal pregnancies. Interstitial pregnancies often are associated with uterine rupture; therefore, they represent a disproportionately large percentage of fatalities from ectopic pregnancy. Treatment is caudal resection by laparotomy, although laparoscopic management has also been described (217).

Intergemination Pregnancy

Intergemination is a rare form of ectopic pregnancy that occurs in about 1 in 100 to 1 in 30,000 pregnancies (218). An intergemination pregnancy usually results from trophoblastic penetration of a tubal pregnancy through the tubal serosa and into the mesosalpinx, with secondary implantation beyond the original site of the broad ligament. It can also occur if a uterine fistula develops between the endometrial cavity and the retroperitoneal space. As with an abdominal pregnancy, the placenta may be adherent to the uterus, bladder, and pelvic sidewalls. If possible, the placenta should be removed; when this is not possible, it can be left in situ and allowed to resorb. As in abdominal pregnancy, there are reported cases of live birth with this type ectopic gestation (219).

Heterotropic Pregnancy

Heterotropic pregnancy occurs when there are coexisting intratubal and ectopic pregnancies. The reported incidence varies widely from 1 in 100 to 1 in 30,000 pregnancies (219). Patients who have undergone ovulation induction have a much higher incidence of heterotopic pregnancy than those who have a spontaneous conception. An intrauterine pregnancy is seen during ultrasound examination, and an extratubal pregnancy may be overlooked easily. Serial hCG levels are often not helpful because the intratubal pregnancy causes the hCG level to rise appropriately.

The treatment of the ectopic pregnancy is operative; once the ectopic pregnancy has been removed, intrauterine pregnancy continues in most patients. It may be possible to use nonchemothromapeutic medical treatment such as KCl by transvaginal or laparoscopically directed injection for treatment of the ectopic pregnancy.

Multiple Ectopic Gestations

Twin or multiple ectopic gestations occur less frequently than heterotopic gestations and may appear in a variety of locations and combinations. About 250 twin ectopic gestations have been reported (220). Although most reports are confined to twin tubal gestations, ovarian, interstitial, and abdominal twin pregnancies have been reported. Twin and triplet gestations have been reported following partial salpingectomy (221) and IVF (222). Management is similar to that for other types of ectopic pregnancy and is somewhat dependent on the location of the pregnancy.

Pregnancy After Hysterectomy

The most unusual form of ectopic pregnancy is one that occurs after either vaginal or abdominal hysterectomy (223,224). Such a pregnancy may occur after supracervical hysterectomy because the patient has a cervical canal that may provide intraperitoneal access. Pregnancy may occur in the peroperative period with implantation of the fertilized ovum in the fallopian tube. Pregnancy after total hysterectomy probably occurs secondary to a vaginal mucosal defect that allows sperm into the abdominal cavity.

References

Diagnosis and management of common benign breast conditions, particularly those that mimic malignancy, and an appreciation of treatment options are essential for the practicing gynecologist (1). Benign breast disease is a complex entity of its own with a range of physiologic changes and clinical manifestations that have an impact on a woman's health independent of breast cancer risk (2).

**Detection**

**History**

Evaluation of a new breast complaint begins with symptom assessment by a thorough clinical history (3). The history should include questions regarding current symptoms, duration of the condition, fluctuation of the signs and symptoms, and factors that aggravate or relieve the complaint. Specific questions should address the following points:

- Nipple discharge
  - Characteristics of discharge (appearance, spontaneous or nonspontaneous, unilateral or bilateral, single or multiple duct involvement)
  - Breast mass (size and change in size, density, or texture)
  - Breast pain (cyclic versus continuous)
  - Association of symptoms with menstrual cycle
  - Change in breast shape, size, or texture
  - Previous breast biopsies.

The patient should be questioned about risk factors:

- Age of menarche
- Age of first pregnancy
- Age of menopause
- Family history of breast cancer
- Number of first-degree relatives with breast cancer and their ages when diagnosed
- Other malignancies (ovary, colon, and prostate)
- Pathology of previous breast biopsy.

It is important to obtain a thorough list of medications taken, including hormone therapy and herbal medications such as phytoestrogens. The gestational history should take into consideration the possibility of a current pregnancy. A personal history of exposure to radiation, especially in the treatment of childhood malignancies, is associated with a higher incidence of developing breast cancer (4). The goal of breast evaluation is to determine clearly if the complaint represents a benign breast condition or is suggestive of a neoplastic process.

**Physical Examination**

Breast tumors, particularly cancerous ones, usually are asymptomatic and are discovered only by physical examination or screening mammography. Typically, the breast changes slightly during the menstrual cycle. During the premenstrual phase, most women have increased innocuous nodularity and mild engorgement of the breast. Rarely, this can obscure an underlying lesion and make examination difficult. Findings should be carefully documented in the medical record to serve as a baseline for future reference.

**Inspection**

Inspection is done initially while the patient is seated comfortably with her arms relaxed at her sides. The breasts are compared for symmetry, contour, and skin appearance. Edema or erythema is identified easily, and skin dimpling or nipple retraction is shown by having the patient raise her arms above her head and then press her hands on her hips, thereby contracting the pectoralis muscles (Fig. 18.1). Palpable and even nonpalpable tumors that distort Cooper's ligaments may lead to skin dimpling with these maneuvers.
To establish a baseline breast mammogram and reevaluate patients at yearly intervals to diagnose a potentially curable breast cancer before it has been covered. A pendulous breast can be palpated by placing one hand between the breast and the chest wall and gently palpating the breast between both examining hands. The axillary and supraclavicular areas should be palpated for enlarged lymph nodes. The entire axilla, the upper outer quadrant of the breast, and the axillary tail of Spence are palpated for possible masses.

While the patient is seated, each breast should be palpated methodically. Some physicians recommend palpating the breast in long strips, but the exact palpation technique used is probably not as important as the thoroughness of its application over the entire breast. One very effective method is to palpate the breast in enlarging concentric circles until the entire breast has been covered. A pendulous breast can be palpated by placing one hand between the breast and the chest wall and gently palpating the breast between both examining hands. The axillary and supraclavicular areas should be palpated for enlarged lymph nodes. The entire axilla, the upper outer quadrant of the breast, and the axillary tail of Spence are palpated for possible masses.

The major features to be identified on palpation of the breast are temperature, texture and thickness of skin, generalized or focal tenderness, nodularity, density, asymmetry, dominant masses, and nipple discharge. Most premenopausal patients have normally nodular breast parenchyma. The nodularity is diffuse but predominantly in the upper outer quadrants where there is more breast tissue. These benign parenchymal nodules are small, similar in size, and indistinct. By comparison, breast cancer is usually a nontender, firm mass with irregular margins. This mass feels distinctly different from the surrounding nodularity. A malignant mass may be fixed to the skin or to the underlying fascia. A suspicious mass is usually unilateral. Similar findings in both breasts are unlikely to represent malignant disease.

Breast Self-examination

Breast self-examination (BSE) increases early detection of cancer and may improve the survival of patients with breast carcinoma (67 and 8). In fact, most breast cancers are detected first by the patient rather than by the physician. Although young women have a low incidence of breast cancer, it is important to teach self-examination early so that it becomes habitual. Organizations such as the American Cancer Society sponsor courses in BSE. Reassurance, support, and patient education may encourage women to overcome psychological barriers to routine BSE (9). One study evaluated three different methods of instruction to determine compliance with BSE (19). The first arm evaluated the impact of physician message alone, the second arm assessed physician message in conjunction with a BSE class, and the third arm added follow-up reinforcement by phone or postcard to physician message and BSE class. The third produced the highest percentage of women doing BSE and is the ideal method of engaging patients to perform BSE.

The woman should inspect her breasts while standing or sitting before a mirror, looking for any asymmetry, skin dimpling, or nipple retraction. Elevating her arms over her head or pressing her hands against her hips to contract the pectoralis muscles will highlight any skin dimpling. While standing or sitting, she should carefully palpate her breasts with the fingers of the opposite hand. This may be performed while showering, because soap and water may increase the sensitivity of palpation. Finally, she should lie down and again palpate each quadrant of the breast, as well as the axilla.

Premenopausal women should examine their breasts monthly during the week after menses. It is helpful for all women to examine their breasts at the same time each month to develop a routine. All women should be instructed to report any abnormalities or changes to their physicians. If the physician cannot confirm the patient’s findings, the examination should be repeated in 1 month or after her next menstrual period.

Breast Imaging

Mammography and ultrasonography are the most reliable and common imaging techniques for early detection of breast lesions (11,12). Full-field digital mammography is a modification of screen-film mammography, which records mammographic images on a computer (13). The U.S. Food and Drug Administration (FDA) approved a digital mammography system in March 2000 (14). This technology is still considered investigational and is not widely available (15). Some proposed advantages include lower radiation exposure, ability to manipulate a computerized image for optimal viewing, and distance consultations through telemammography (16). Magnetic resonance imaging (MRI) may be valuable for assessing breast lesions of an indeterminate nature detected by clinical and mammographic examination or occurring in patients who have implants (17). MRI and positron emission tomography (PET) have been used to identify occult lesions (18,19). Novel developments in breast imaging can be anticipated that will use functional imaging and molecular biology to create better methods to quantify the extent of disease as well as response to therapeutic interventions (20-21). A promising new approach uses technetium-99m (99mTc) sestamibi to detect breast cancer, especially in women with dense breast tissue (22).

Mammography

Slowly growing breast cancers can be identified by mammography at least 2 years before the mass reaches a size detectable by palpation (23). In fact, mammography is the only reproducible method of detecting nonpalpable breast cancer. However, its accurate use requires state-of-the-art equipment and a skilled radiologist. Vigorous compression of the breast is necessary to obtain good images, and patients should be forewarned that breast compression is uncomfortable. With a good technique and well-maintained modern equipment, the average mean glandular dose per mammographic image for all facilities in the United States inspected under the Mammography Quality Standards Act in the first one-half of 1997 was 1.6 mGy (160 mrad) (24).

Indications for Mammography

There are several indications for mammography:

1. To screen, at regular intervals, women who are at high risk for developing breast cancer. About one-third of the abnormalities detected on screening mammography prove malignant when biopsy is performed (25).
2. To evaluate a questionable or ill-defined breast mass or other suspicious change in the breast.
3. To establish a baseline breast mammogram and reevaluate patients at yearly intervals to diagnose a potentially curable breast cancer before it has been diagnosed clinically.
4. To search for occult breast cancer in a patient with metastatic disease in axillary nodes or elsewhere from an unknown primary origin.
5. To screen for unsuspected cancer prior to cosmetic operations or biopsy of a mass.
6. To monitor breast cancer patients who have been treated with a breast-conserving operation and radiation.

Screening

Figure 18.1 Raising the arm reveals retraction of the skin of the lower outer quadrant caused by a small palpable carcinoma. (From Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. Practical gynecologic oncology, 3rd ed. Baltimore: Lippincott Williams & Wilkins, 2000:640, with permission.)
Approximately 35% to 50% of early breast cancers can be discovered only by mammography, and about 20% can be detected only by palpation. Mass screening programs to evaluate asymptomatic, healthy women combine physical examination with mammographic screening to identify breast abnormalities. During the past 25 years, there has been an increase in mammography, mammographic screening, and public awareness. The cancer detection rate for screening mammograms is 5 per 1,000 screening examinations (26). It is 11-fold higher for diagnostic mammograms at 55 per 1,000 diagnostic mammographic examinations (26). The mean diameter of breast cancers at diagnosis has decreased from 3 cm from 1979 to 1983 to 2 cm from 1989 to 1993, and this downward trend appears to be continuing (27,28). As the mean maximal diameter of breast cancers has decreased, there has been a simultaneous decrease in the number of positive axillary lymph nodes (28). Detecting breast cancer before it has spread to the axillary nodes greatly increases the chance of survival; about 85% of such women will survive at least 5 years (28).

Mammography’s lack of sensitivity in dense breast tissue has led to questions concerning its screening value in women 40 to 50 years of age. In February 1993, the National Cancer Institute (NCI) held an international workshop on screening for breast cancer (29). The purpose of this workshop was to undertake a critical review of recent clinical screening trials. The participants examined only randomized studies and focused on clinical evidence related to the efficacy of breast cancer screening in various age groups. Of the eight randomized trials identified, only the Health Insurance Plan (HIP) project demonstrated a beneficial effect of screening for women between 40 and 49 years of age. This benefit was seen 10 to 18 years after entry into the study and resulted in a 25% decrease in deaths from breast cancer. Several Swedish trials showed a 13% decrease in breast cancer mortality for women in this age group after 12 years of follow-up; however, this decrease was not statistically significant (29,30). In a metaanalysis of five randomized trials, the breast cancer rates were independent of screening in women aged 40 to 49 years (31). The beneficial effect of screening in women aged 50 to 69 years was confirmed by all clinical trials. The efficacy of screening in women older than 70 years of age was inconclusive because of the small sample size.

This topic was once again revisited in 1997. The American Cancer Society (ACS) convened a workshop on breast cancer screening in 1997 to establish guidelines for early detection of breast cancer (32). The ACS recommends monthly BSE and clinical breast examination every 3 years between ages 18 and 39. They recommend a baseline mammogram at age 40 and annual mammography for women beginning at age 40 with no upper age limit (32). This recommendation has been adopted by the American Medical Association, American College of Radiology, American Society of Clinical Oncology, and the American College of Obstetricians and Gynecologists (33,34). In contrast, the NCI also met in 1997 to discuss, debate, and reach a consensus statement for breast cancer screening (35). They concluded that a beneficial effect was seen in women over 50 years of age, but a 17% reduction in breast cancer deaths in the 40- to 49-year age group with screening was not felt to be significant enough to mandate annual mammography examinations. The NCI recommendations for women with an average risk of breast cancer is screening mammography every 1 to 2 years for women between ages 40 and 49. Women with higher risk should seek the advice of a physician and have their individual risk assessed. In an overview of breast cancer screening, Koppans condemns the arbitrary categorization of women into two age groups (<50 and ≥50 years) (35). There is not an abrupt change in screening parameters at this age cutoff, and breast cancer in the younger woman is no less a serious a problem, with potential years of life lost. He concludes that screening should begin at age 40 and continue on an annual basis to reduce breast cancer mortality by 24%.

There is a consensus that annual physical and mammographic examinations should be performed for women 50 years of age and older. Screening of women older than 70 years of age should be performed after consideration of the patient’s comorbid conditions and her overall state of health. Recent reports evaluating the use of mammography in the older population revealed significantly smaller lesions and earlier stage of disease (36), with a 40% reduction in breast cancer mortality at 10 years (37) and a lower incidence of metastatic disease at time of breast cancer diagnosis (39).

**Mammographic Abnormalities**

A mammographic abnormality includes a mass (solid versus cystic), microcalcifications (benign, indeterminate, suspicious), asymmetric density, architectural distortion, and appearance of a new density. Mammographic abnormalities should be identified on two views and triangulate to the same location on those two views. Examples of mammographic abnormalities can be reviewed in several internet radiology libraries (40). Califications can be macrocalcifications, which are coarse and usually represent benign degenerative breast conditions. In breast cancer, the most common diagnostic mammographic abnormalities are clustered pleomorphic microcalcifications (41). Typically, five to eight or more califications are aggregated in one part of the breast. These califications may be associated with a mammographic mass density. A mass density may appear without evidence of califications. It can represent a cyst, benign tumor, or a malignancy. A malignant density usually has irregular or ill-defined borders and may lead to architectural distortion, which may be subtle and difficult to detect in a dense breast. Other mammographic findings suggesting breast cancer are architectural distortion, asymmetric density, skin thickening or retraction, or nipple retraction.

**Mammographic Reports**

The American College of Radiology has recommended the Breast Imaging Reporting and Data System (BI-RADS) as a standardized scheme for describing mammographic lesions (42). There are eight morphologic categories (42):

1. Calcification distribution
2. Number of calcification
3. Description of calcification
4. Mass margin
5. Shape of mass
6. Density of mass
7. Associated findings
8. Special cases.

In the BI-RADS system, there are six categories for mammographic findings (43):

1. 0 is incomplete, needs further imaging
2. 1 is negative
3. 2 is a benign finding
4. 3 is probably benign, short-interval follow-up recommended
5. 4 is a suspicious finding and biopsy should be considered
6. 5 is highly suggestive of malignancy and appropriate action should be undertaken.

The patient should be referred to a surgeon if the report identifies a lesion as a category 4 or 5 (44). A category 0 indicates incomplete evaluation and further diagnostic studies are required. A category 3 is a finding which is most likely benign and a short-interval follow-up is recommended.

**Biopsy must be performed on patients with a dominant or suspicious mass despite absence of mammographic findings** (45). Mammography should be performed before biopsy so other suspicious areas can be noted and the contralateral breast can be checked (Fig. 18.2).
Correlation of Findings

Mammography is never a substitute for biopsy because it may not reveal clinical cancer, especially when it occurs in the dense breast tissue of young women with fibrocystic changes. In fact, the sensitivity of mammography varies from approximately 60% to 90%, depending on the patient's age (breast density) and the size, location, and mammographic appearance of the tumor.

Mammography is less sensitive in young women with dense breast tissue than in older women, who tend to have fatty breasts in which mammography can detect at least 90% of malignancies. Small tumors, particularly those without calcifications, are more difficult to detect, especially in women with dense breasts. The specificity of mammography is about 30% to 40% for nonpalpable mammographic abnormalities and 85% to 90% for clinically evident malignancies (46).

Ultrasoundography

Reliable, portable computer-enhanced ultrasonography with high-frequency transducers and improved imaging is now available to evaluate and treat problems of the breast (47). It is a sensitive, minimally invasive technique that is being used more frequently in evaluating some breast symptoms, especially in younger women with dense breast tissue (48). There are some lesions that can be detected only with ultrasonography (49). It is the preferred modality to distinguish a solid from a cystic mass (47). Screening breast ultrasonography identifies many irregularities and hypoechoic areas; the significance of these findings must be validated in prospective randomized studies (50). Most experts advise against screening ultrasonography. However, the role of ultrasonography to identify breast cancer is continuing to undergo evaluation (51, 52).

Ultrasonography may be especially useful if the patient feels a mass, but the physician cannot detect an abnormality and the mammogram does not disclose one. Ultrasonography cannot reliably detect microlcalcifications, and it is not as useful as mammography for fatty breasts. Ultrasonography may be useful in identifying noncalcified cancers in the dense breast tissue of premenopausal women, but it is usually used to distinguish a benign cyst from a solid tumor.

Handheld or real-time ultrasonography is 95% to 100% accurate in differentiating solid masses from cysts (53). However, this is of limited clinical value because a dominant mass should be evaluated by biopsy, and a cystic mass can be studied by needle aspiration, which is far less expensive than ultrasonography. The primary role of handheld ultrasonography is in the evaluation of a benign-appearing, nonpalpable density identified by mammography. If such a lesion proves to be a simple cyst, no further workup is necessary. Rarely, ultrasonography may identify a small cancer within a cyst—an intracystic carcinoma. These complex cysts warrant surgical biopsy.

Magnetic Resonance Imaging

MRI is increasing in popularity as a means of imaging the breast (17, 54). It tends to be highly sensitive but not very specific, leading to biopsies of many benign lesions. Image enhancement with gadolinium can discriminate between benign and malignant lesions with varying degrees of accuracy.

Several roles have been proposed for breast MRI. Its lack of radiation exposure makes MRI ideal for mass screening of healthy women, although such widespread use is probably too costly. There may be a role for MRI in evaluation of specific conditions such as (a) focal, asymmetric areas detected mammographically, (b) postoperative scar, and (c) exclusion of silicone leak with implants. Focal asymmetry is usually benign but can represent a malignancy, and MRI may help identify patients in whom focal asymmetric areas should undergo biopsy. Usually, a scar can easily be distinguished from recurrent tumor based on the evaluation and diminution of the scar over time. Some scars, however, do not diminish rapidly and are confused with cancer or, more commonly, with recurrent cancer after breast-conserving operation and radiation. Ideally, such cases are evaluated with MRI; sometimes obviating the need for biopsy. MRI is extremely useful in identifying silicone released by a ruptured breast implant in patients with augmented breasts (Fig. 18.3). In patients with implants, MRI with gadolinium may be performed to detect breast cancer, even if free silicone is not suspected.

Figure 18.3 Mammography shows implant and extracapsular free silicone (arrow).

The International Cooperative Magnetic Resonance Mammography Study that is currently under way will help identify the advantages and limitations of MRI. At present, MRI should be considered only after conventional imaging is performed; it should be used neither as a screening tool nor a substitute for mammography or biopsy.

Technetium-99m Sestamibi Scan

Technetium-99m sestamibi is an agent approved for coronary imaging. It is metabolized in the mitochondria. Evaluation of patients using physical examination, mammography, ultrasonography, and sestamibi scan indicate an 88% positive predictive value and a 93% negative predictive value with a sensitivity of 84% and a specificity of 95% (55). In a multicenter prospective cohort clinical trial comparing mammography to sestamibi, a positive scintimammogram increases the ability to predict the presence of malignant disease (56). This modality is still undergoing evaluation.

Positive Emission Tomography Scan

PET is a diagnostic modality that assesses the metabolic activity of tumors. Radioactive fluorodeoxyglucose (FDG) is an analog of glucose that is metabolized by tissues of high metabolic rates. In two prospective trials comparing PET to mammography, primary breast lesions were correctly identified and lymph node status was determined with a high degree of sensitivity using PET (57, 58). PET has been used to identify occult breast lesions with positive axillary lymph nodes (59).

Breast Biopsy

The diagnosis of breast cancer depends ultimately on examination of tissue removed by biopsy. Because cancer is found in the minority of patients who require biopsy for diagnosis of a breast mass, treatment should never be undertaken without an unequivocal histologic diagnosis of cancer.

The safest course is biopsy examination of all dominant masses found on physical examination and, in the absence of a mass, of suspicious lesions.
shown by mammography. About 30% of lesions suspected to be cancer prove on biopsy to be benign, and about 15% of lesions believed to be benign prove to be malignant (25). Dominant masses or suspicious nonpalpable mammographic findings must be evaluated by biopsy (44,45). Histologic diagnosis should be obtained before conservation management to monitor breast mass. An exception may be a premenopausal woman with a nonsuspicious mass presumed to be fibrocystic disease. However, an apparently fibrocystic lesion that does not completely resolve within several menstrual cycles should be sampled for biopsy. Any mass in a postmenopausal woman who is not taking estrogen replacement should be presumed to be malignant. Figure 18.4 and Figure 18.5 present algorithms for management of breast masses in premenopausal and postmenopausal patients. Simultaneous evaluation of a breast mass using clinical breast examination, radiography, and fine-needle aspiration biopsy can lower the risk of missing cancer to only 1%, effectively reducing the rate of diagnostic failure and increasing the quality of patient care (69). Ultrasonography is frequently used in addition to these techniques; although not studied, it most likely further reduces the risk of failure to diagnose cancer.

If the presence of breast cancer is strongly suggested by physical examination, the diagnosis can be confirmed by fine-needle cytologic assessment or core biopsy, and the patient may be counseled regarding treatment. Treatment should not be determined based on results of physical examination and mammography alone, in the absence of biopsy results. The most reasonable approach to the diagnosis and treatment of breast cancer is outpatient biopsy (either needle or excision), followed by definitive surgery at a later date if needed. This two-step approach allows patients to adjust to the diagnosis of cancer, carefully consider alternative forms of therapy, and seek a second opinion if they wish. Studies have shown no adverse effect from the 1- to 2-week delay associated with the two-step procedure (61). However, the two-step procedure should be reexamined in view of the increasing popularity of lumpectomy. Suspicious lesions may best be excised as the definitive lumpectomy specimen even if biopsy has not shown malignancy. The lumpectomy is, in essence, a biopsy that ensures a rim of normal tissue around the mass. It is better performed with the mass removed in its entirety than after a prior excisional biopsy.

**Fine-needle Aspiration**

Fine-needle aspiration cytology is a useful technique whereby cells from a breast tumor are aspirated with a small (usually 22-gauge) needle and examined by a pathologist. Precise guidelines for this technique are available (62). It can be performed easily, with no morbidity, and is much less expensive than excisional or open biopsy. However, it requires the availability of a pathologist skilled in the cytologic diagnosis of breast cancer to interpret the results, and it is subject to sampling problems, particularly when lesions are deep. Cytologic diagnoses must be correlated with clinical and imaging findings to achieve triple-test concordance and to decrease the false-negative rate (63). The triple test, comprising fine-needle aspiration, physical examination, and mammography, is the foundation of breast evaluation. The triple-test results are more powerful than each modality alone (84). The incidence of false-positive diagnoses was 0% to 0.3%, and the rate of false-negative diagnoses was 1.4% to 2.3% in several recent studies (64,65).

Most experienced clinicians will not leave a dominant mass in the breast even when fine-needle aspiration cytology results are negative. Some clinicians will monitor a mass when results of the clinical diagnosis, breast imaging studies, and cytologic studies are all in agreement. However, occasionally a malignancy will be diagnosed later, and such cases require periodic follow-up.

**Core Biopsy**

A core of tissue can be obtained from palpable lesions using a large cutting needle (66). Image-guided large-core needle biopsy is a reliable diagnostic alternative to surgical excision of suspicious nonpalpable breast lesions (67). As in the case of any needle biopsy, the main drawback is false-negative findings caused by improper positioning of the needle. False-negative findings may be reduced if core biopsy is performed with ultrasonographic direction.

**Open Biopsy**

Open biopsy with local anesthesia as a separate procedure prior to deciding on definitive treatment is the most reliable means of diagnosis. It is required when the results of needle biopsy are nondiagnostic or equivocal.

**Histologic Analysis**

Histologic evaluation with hematoxylin and eosin (H & E) staining confirms benign or malignant disease. Images of benign and malignant breast lesions can be viewed through the Internet Pathology Laboratory for Medical Education (68). The estrogen, progesterone, her-2/neu receptor status, and proliferative indices of the tumor should be determined during initial biopsy. This assessment is performed on paraffin-fixed tissue by immunohistochemistry (69). Her-2/neu assessment in breast cancer by immunohistochemistry (IHC) is appropriate for patients with tumors that score 3+. Fluorescence in situ hybridization (FISH) is recommended for 2+ IHC to more accurately assess her-2/neu amplification and provide better prognostic information (70).
Cyto logical examination of nipple discharge or cyst fluid is rarely performed. Mammography (or ductography) and breast biopsy may be performed when nipple discharge or cyst fluid is bloody or cytologically questionable. However, excision and examination of the involved ductal system is the preferred method of diagnosis, and cytologic assessment should not be relied on for diagnosis.

Ductal lavage using a microcatheter is a new modality that has recently been investigated in high-risk women (71). Patients undergo gentle nipple suction to elicit nipple fluid. A duct that yields fluid is then cannulated with a microcatheter and 10 to 20 ml of saline are introduced in 2- to 4-ml increments. The cytologic assessment of a sample obtained by ductal lavage is more sensitive than that of nipple aspiration. Ductal lavage is a better modality to obtain a large number of cells for cytological evaluation. It is safe and well tolerated (71).

Benign Breast Conditions
Benign breast disorders account for a significant number of breast complaints. These conditions are frequently considered in relation to the possibility of excluding breast cancer and are often not recognized for their own associated morbidity (72). In order to provide appropriate management, it is important to consider benign breast disorders from four aspects, (a) clinical picture, (b) medical significance, (c) treatment intervention, (d) and pathologic etiology (73).

Hughes has described a conceptual framework to understanding benign breast problems that is called Aberrations of Normal Development and Involution (ANDI) (2,72,73). It includes symptomatology, histology, endocrine state, and pathogenesis in a progression from a normal to a disease state. Most benign breast conditions arise from normal changes in breast development, hormone cycling, and reproductive evolution (73).

There are three life cycles that reflect different reproductive phases in a woman’s life and are associated with unique breast manifestations.

1. During the early reproductive period (15 to 25 years) there is lobule and stromal formation. The ANDI conditions associated with this period are fibroedema (mass) and juvenile hypertrophy (excessive breast development). In this first stage the progression from ANDI to a disease state results in the formation of giant fibroadenomas and multiple fibroadenomas.

2. During the mature reproductive period (25 to 40 years) cyclic hormonal changes affect glandular tissue and stroma. In this second period the ANDI is an exaggeration of these cyclic effects, such as cyclic mastalgia and generalized nodularity.

3. The third phase is involution of lobules and ducts or epithelia turnover, which occurs during ages 35 to 55 years. The ANDI associated with lobular involution are macrocysts (lumps) and sclerosing lesions (mammographic abnormalities). Those associated with ductal involution are duct dilatation (nipple discharge) and periductal fibrosis (nipple retraction), and those with epithelial turnover are mild hyperplasia (pathologic description).

With ductal involution, progression to disease states occurs in periductal mastitis with bacterial infections and abscess formation. Disease conditions with increased epithelial turnover are epithelial hyperplasias with atypia. Hughes feels that this framework allows the clinician to understand the pathogenesis of these conditions and to understand that these disorders are aberrations of a normal process that does not usually require any specific treatment (72).

Fibrocystic Change
Fibrocystic change, the most common lesion of the breast, is an imprecise term that covers a spectrum of clinical signs and symptoms and histologic changes (69). Macroscopic cysts occur in approximately 7% of women and microscopic, nonpalpable cysts in close to 40% of women (74). The term refers to a histologic picture of fibrosis, cyst formation, and epithelial hyperplasia (73). It is common in women 35 to 55 years of age but rare in postmenopausal women not taking hormone replacement therapy. The presence of estrogen seems necessary for the clinical symptoms to occur. This is supported by the observation that it is present bilaterally, increased in the perimenopausal age group, and responsive to endocrine therapy (75). In essence, a diagnosis of fibrocystic change is of little clinical significance as long as malignancy is excluded. These lesions are always associated with benign changes in the breast epithelium.

Cysts arise from the breast lobules and are an aberration of normal breast involution. The potassium-to-sodium ratio is a convenient marker to distinguish cyst subtypes (76). Cysts are either lined by apocrine epithelium with a high potassium-to-sodium ratio and a higher hormone or steroid concentration (type I); or by flattened lobule epithelium with a low potassium-to-sodium ratio and a higher concentration of albumin, CEA, CA125, and steroid hormone-binding globulin (type II) (75,77). A recent study has demonstrated that apocrine cysts produce and secrete large amounts of prostate-specific antigen (PSA) (78). The role of this serine protease in proliferative breast disease is not fully understood.

Clinical Findings
Fibrocystic changes may produce an asymptomatic mass but more often are accompanied by pain or tenderness and sometimes nipple discharge. In many cases, discomfort coincides with the premenstrual phase of the cycle, when the cysts tend to enlarge. Fluctuation in size and rapid appearance or disappearance of a breast mass are common. Multiple or bilateral masses appear frequently, and many patients have a history of a transient mass in the breast or cyclic breast pain. Cyclic breast pain is the most common symptom of fibrocystic changes.

Differential Diagnosis
Pain, fluctuation in size, and multiplicity of lesions are the features most helpful for differentiation from carcinoma. If a dominant mass is present, however, the diagnosis of cancer should be suspected until it is disproved by biopsy. Final diagnosis of the mass usually depends on biopsy.

Diagnostic Tests
Patients with cystic disease may have a discrete fibrocystic mass that is frequently indistinguishable from carcinoma on the basis of clinical findings. Mammography may be helpful, but there are no mammographic signs diagnostic of fibrocystic change. Ultrasonography is useful in differentiating a cyst from a solid mass. The finding of a simple cyst rules out carcinoma. Any suspicious lesion should be biopsied. Microscopic findings include cysts (gross and microscopic), papillomatosis, adenosis, fibrosis, and ductal epithelial hyperplasia (79).

When the diagnosis of fibrocystic change has been established by previous biopsy or is practically certain because the history is classic, aspiration of a discrete mass suggestive of a cyst is indicated. Aspiration may be performed with ultrasonographic guidance, but this usually is not necessary (80). Cystic fluid is straw colored to dark green to brownish and does not need to be submitted for cytologic evaluation (5). The patient is reexamined at intervals thereafter. Further cysts will occur in 30% of patients, cause anxiety, and require repeated evaluations (74). Biopsy should be performed if no cyst fluid is obtained, if the fluid is bloody, if a mass persists after aspiration, or if at any time during follow-up a persistent mass is noted. Even if a needle biopsy is performed and results are negative for malignancy, a suspicious mass that does not resolve over several months should be excised. Surgery should be conservative, because the primary objective is to exclude cancer. Simple mastectomy or extensive removal of breast tissue is rarely, if ever, indicated for fibrocystic disease. Most patients do not require treatment.

Mastalgia
Mastalgia is a recognized organic condition (81,82). Approximately 70% of women experience severe breast pain at some time in their lives (83). More than 30% of women seen in surgical breast clinics suffer from mastalgia (84). In 15% of the patients the mastalgia is so severe that it alters lifestyle and requires treatment (83). Mastalgia interferes with sexual (48%), physical (37%), social (12%), and work or school activities (8%) (85).

Cyclic mastalgia is related to exaggerated premenstrual symptoms associated with breast engorgement, pain, and tenderness (86). Noncyclic mastalgia is independent of menstrual cycles and more difficult to treat. Breast pain associated with generalized fibrocystic changes is best treated by avoiding trauma and by wearing (night and day) a brassiere that gives good support and protection (87). Hormone therapy is not advisable because it does not relieve symptoms and has undesirable side effects. Recognized treatments include bromocriptine, danazol, evening primrose oil, and tamoxifen, although tamoxifen is not approved for this use (88,89,90 and 91). A survey of surgeons in Great Britain revealed that 75% prescribed danazol as first-line therapy (81). Other treatments included analgesia (21%),...
diuretics (18%), local excision (18%), bromocriptine (15%), evening primrose oil (13%), tamoxifen (9%), a well-fitting bra (3%), and no treatment (10%) (81). In this study, breast specialists were more likely to initiate therapy with evening primrose oil, tamoxifen, vitamin B6, and analgesia. In another study the first-line therapy was evening primrose oil containing essential fatty acids (g-linolenic acid [GLA]), with danazol and bromocriptine reserved for second-line treatment (83). In a prospective mastalgia trial, women were given eight capsules of evening primrose oil daily for 4 months (320 mg GLA) (92). Those who responded had a lower level of essential fatty acids, all of whom improved when combined with response to therapy suggesting that evening primrose oil increases essential fatty acids and that this increase may be associated with the improvement in symptoms in the responders. Danazol (100 to 200 mg twice daily orally), a synthetic androgen, has been used for patients with severe pain (89). This treatment suppresses pituitary gonadotropins, and its androgenic effects (acne, edema, hirsutism) are usually intolerable; therefore, it probably should not be used. A recent study was conducted to evaluate the response to administration of danazol (200 mg daily) during the luteal phase (93). This approach to therapy reduces the premenstrual mastalgia with virtually no side effects. In one study, taking progesterone agents for birth control reduced cyclic breast pain to 2.3% of women compared with 4.9% who did not take such medication (84). Further studies may be warranted to see whether medroxyprogesterone acetate suppresses cyclic mastalgia in reproductive-age women. Bromocriptine (2.5 mg twice daily) given for 3 to 6 months was effective in women with an abnormal thyroid hormone (TRH) level (95). Patients who have normal TRH levels or are resistant to bromocriptine responded favorably to progesterone and systemic nonsteroidal antiinflammatory drugs.

Fibrocystic Change and Cancer

Fibrocystic change is not associated with an increased risk of breast cancer unless there is histologic evidence of epithelial proliferative changes, with or without atypia (104,105,106,107,108 and 109). The common coincidence of fibrocystic disease and malignancy in the same breast reflects that one in every nine women will develop breast cancer, and as many as 80% of biopsies show fibrocystic changes. Page and Dupont (107) evaluated the relationship between fibrocystic change and breast cancer in 10,366 women who underwent biopsy from 1950 until 1968 and were followed for a median of 17 years. Approximately 70% of the biopsies showed nonproliferative breast disease, whereas 30% showed proliferative breast disease. Cytologic atypia were present in 3.6% of cases. Women with nonproliferative disease had no increased risk of breast cancer, whereas women with proliferative breast disease and no atypical hyperplasia had a twofold higher risk of breast cancer. Patients whose biopsy results showed atypical ductal or lobular hyperplasia had an approximately fivefold higher risk than women with nonproliferative disease to develop invasive breast cancer in either breast. Patients with carcinoma in situ have an 8- to 10-fold risk of developing breast cancer. This risk is bilateral for lobular lesions and local for ductal lesions. A family history of breast cancer added little risk for women with nonproliferative disease, but family history plus atypia increased breast cancer risk 11-fold. The presence of cysts alone did not increase the risk of breast cancer, but cysts combined with a family history of breast cancer increased the risk 12-fold (88,89). Women with these risk factors (family history of breast cancer and at least one cyst) have a 2.5-fold higher risk of breast cancer than women without these risk factors (88,89). Similar to Page and Dupont (107), a recent study by Shah et al. (110) assessed the risk of breast cancer with at least one cyst in a large cohort of women. The authors found that the presence of cysts alone did not increase the risk of breast cancer, but cysts combined with a family history of breast cancer increased the risk 11-fold (110). Women with these risk factors have a 2.5-fold higher risk of breast cancer than women without these risk factors. It is important to note that these risk factors are not mutually exclusive, and multiple risk factors can increase the risk of breast cancer. Therefore, it is crucial to consider the presence of at least one cyst in patients with a family history of breast cancer.

Benign Tumors

Fibroadenoma

Fibroadenomas are the most common benign tumors of the breast. In one series, they account for 50% of all breast biopsies (110). They usually occur in young women (age 20 to 35 years) and may occur in teenagers (111). In women younger than 25 years, fibroadenomas are more common than cysts. They rarely occur after menopause, although occasionally they are found, often calcified, in postmenopausal women. For this reason, it is postulated that fibroadenomas are responsive to estrogen stimulation. A recent study reports the de novo occurrence of fibroadenoma in 51 women over age 35 years, who had no evidence of a palpable or mammographic visualized lesion in well-documented prior visits (112). Although the presence of a fibroadenoma does not increase the risk of breast carcinoma, this subject still generates controversy (113). Because transformation of a fibroadenoma into cancer is rare and regression is frequent, current management recommendations are conservative (110).

On gross examination, fibroadenomas appear encapsulated and sharply delineated from the surrounding breast parenchyma. Microscopically, they have an epithelial and a stromal component. In longstanding lesions and in postmenopausal patients, calcifications may be observed within the stroma. Fibroadenomas may appear in multiples. Clinically, a young patient usually notices a mass while showering or dressing. Most masses are 2 to 3 cm in diameter when detected, but they can become extremely large (i.e., the giant fibroadenoma). On physical examination, they are firm, smooth, and rubbery. They do not elicit an inflammatory reaction, are freely mobile, and cause no dimpling of the skin or nipple retraction. They are often bilobed, and a groove can be palpated on examination. Mammographically, they have extremely large (i.e., the giant fibroadenoma). On physical examination, they are firm, smooth, and rubbery. They do not elicit an inflammatory reaction, are freely mobile, and cause no dimpling of the skin or nipple retraction. They are often bilobed, and a groove can be palpated on examination. Mammographically, they have an appearance consistent with benign fibrous tissue, and they are often well-circumscribed. The differential diagnosis of fibroadenomas includes fibrocystic change, phyllodes tumor, and fibrocystic carcinoma.

Phyllodes Tumor

Cystosarcoma phyllodes, which is perhaps best referred to as a phyllodes tumor, may occur at any age but tends to be more common in women who are in their late thirties, forties, and fifties (120,121,122 and 123). These lesions are rarely bilateral and usually appear as isolated masses that are difficult to distinguish clinically from a fibroadenoma. Patients often relate a long history of a previously stable nodule that suddenly increases in size. Size is not a diagnostic criterion, although phyllodes tumors tend to be larger than fibroadenomas, probably because of their rapid growth. There are no good clinical criteria by which to distinguish a phyllodes tumor from a fibroadenoma.

The histologic distinction between fibroadenoma, benign phyllodes tumor, and malignant phyllodes tumor can be very difficult (124). Tumors judged by the pathologist to be benign tend to recur locally in up to 10% of patients (121,122 and 123). Malignant phyllodes tumors tend to recur locally and usually metastasize to the lung, although brain, pelvic, and bone metastases have also been reported (121,123). The stromal component of the tumor is malignant and metastasizes, behaving like a sarcoma. Axillary involvement is extremely unusual. Often, the appearance of metastasis is the first sign that a phyllodes tumor is malignant.

Treatment is wide local excision (120,121,122 and 123). Primary excision or reexcision with normal breast margins is recommended (122). Massive tumors, or large tumors in relatively small breasts, may require mastectomy; otherwise, mastectomy should be avoided and axillary lymph node dissection is not indicated. Typically, a patient will undergo excisional biopsy of a mass believed to be fibroadenoma, but histologic examination will reveal a phyllodes tumor. When the pathologist diagnoses a phyllodes tumor, complete excision of the tumor must be undertaken so that the prior biopsy site and any residual tumor are removed. Recurrence is associated with margin involvement, whereas death correlates with size and grade (126). Chemotherapy for metastatic phyllodes tumors should be based on regimens for sarcoma, not adrenocortical (122). Radiation therapy has generally not been used in the treatment of phyllodes tumors. When there is bulky
Breast Conditions Requiring Evaluation

Nipple Discharge

Nipple discharge is the breast symptom in 4.8% of patients seeking medical evaluation of a breast complaint, with 2.6% spontaneous and 2.2% provoked (128). Nipple discharge is infrequently found to be associated with carcinoma, with only 4 of 104 cases (3.8%) being due to malignancy (129). The most common causes of nipple discharge in nonlactating women are solitary intraductal papilloma, carcinoma, papillomatosis, and fibrocystic change with ectasia of the ducts (130). Following are the important characteristics of the discharge and other factors to be evaluated by history and physical examination (130).

1. Nature of discharge (serous, bloody, or milky)
2. Association with a mass
3. Unilateral or bilateral
4. Single or multiple ducts
5. Discharge that is spontaneous (persistent or intermittent) or expressed by pressure at a single site or on entire breast
6. Relation to menses
7. Cesarean section and postmenopausal
8. Hormonal medication (contraceptive pills or estrogen).

Unilateral, spontaneous, bloody, or serosanguinous discharge from a single duct is usually caused by an intraductal papilloma or, rarely, by an intraductal carcinoma. In either case, a mass may not be palpable. The involved duct may be identified by pressure at different sites around the nipple and at the margin of the areola. Bloody discharge is more suggestive of cancer but is usually caused by a benign papilloma in the duct. Cytologic examination is usually of no value but may identify malignant cells (129). Negative findings do not rule out cancer, which is more likely in women over 50 years of age. In any case, the involved duct—and a mass, if present—should be excised (129,130 and 131). Although ductography may identify a filling defect prior to excision of the duct system, this study is of little value (129). A new technology, fiberoptic ductoscopy, is emerging to evaluate patients with nipple discharge (132). In 259 patients with nipple discharge, it successfully detected intraductal papillomatous lesions in 92 patients (46%). Further experience and understanding of this technology may guide breast surgery for nipple discharge, and is being used for the assessment of margins in breast cancer value.

In premenopausal women, spontaneous multiple-duct discharge, unilateral or bilateral, is most marked just before menstruation. It often is caused by fibrocystic change. Discharge may be green or brownish. Papillomatosis and ductal ectasia are usually seen on biopsy. If a mass is present, it should be removed. Milky discharge from multiple ducts in nonlactating women presumably reflects increased secretion of pituitary prolactin; serum prolactin and thyroid-stimulating hormone levels should be evaluated to detect a pituitary tumor or hypothyroidism. Hypothyroidism may cause galactorrhea. Alternatively, phenothiazines may cause milky discharge that disappears when medication is discontinued. Oral contraceptive agents may cause clear, serous, or milky discharge from multiple ducts or, less often, from a single duct. The discharge is more evident just before menstruation and disappears when the medication is stopped. If discharge does not stop and is from a single duct, surgical exploration should be performed.

When localization is not possible and no mass is palpable, the patient should be reexamined every week for 1 month. When unilateral discharge persists, even without definite localization or tumor, surgical exploration must be considered. The alternative is careful follow-up at intervals of 1 to 3 months. Mammography should be performed. Chronic unilateral nipple discharge, especially if it is bloody, is an indication for resection of the involved ducts. Purulent discharge may originate in a subareolar abscess and requires excision of the abscess and related lactiferous sinus (133).

Erosive Adenomatosis of the Nipple

Erosive adenomatosis is a rare benign condition of the nipple that mimics Paget's disease (134). Patients seek treatment for pruritus, burning, and pain. On clinical examination the nipple can appear ulcerated, crusting, scaling, indurated, and erythematous. The nipple can be enlarged and more prominent during menstrual cycles (135). The differential diagnosis includes squamous cell carcinoma, psoriasis, contact dermatitis, seborrheic keratosis, adenoarcinoma metastatic to the skin, and unusual primary tumors of the nipple (134). Biopsy should be performed to diagnose the lesion. Local excision is curative (134).

Fat Necrosis

Fat necrosis of the breast is rare but clinically important because it produces a mass, often accompanied by skin or nipple retraction, which is indistinguishable from carcinoma. Trauma is presumed to be the cause, although only about one-half of patients have a history of injury to the breast. Ecchymosis is occasionally seen near the tumor. Tenderness may or may not be present. If untreated, the mass associated with fat necrosis gradually disappears. Fat necrosis often has a confusing clinical picture. Diagnostic imaging studies are usually insufficient (136). As a rule, the safest course is needle core or excisional biopsy of the entire mass to rule out carcinoma (136). Fat necrosis is common after segmental resection and radiation therapy or transverse rectus abdominis musclecaulocutaneous (TRAM) flap (137).

Breast Abscess

Lactational Abscesses

Infection in the breast is rare unless the patient is lactating. During lactation, an area of redness, tenderness, and induration frequently develops in the breast. The organism most commonly found in these abscesses is Staphylococcus aureus (135). In its early stages, the infection can often be reversed while nursing is continued from that breast by administering an antibiotic such as dicloxacillin 250 mg times daily, or oxacillin 500 mg 4 times daily for 7 to 10 days. If the lesion progresses to a localized mass with local and systemic signs of infection, an abscess is present. It should be drained, and nursing should be discontinued.

Nonlactational Abscesses

Rarely, infections or abscesses may develop in young or middle-aged women who are not lactating (139). In 259 patients with nipple discharge, it successfully detected intraductal papillomatous lesions in 92 patients (46%). Further experience and understanding of this technology may guide breast surgery for nipple discharge, and is being used for the assessment of margins in breast cancer value.

Disorders of Breast Augmentation

Estimates indicate that nearly 4 million women in the United States have undergone augmentation mammoplasty. Breast implants are usually placed under the pectoralis muscle or, less desirably, in the subcutaneous tissue of the breast. Most implants are made of an outer silicone shell filled with a silicone gel or saline.

The complications of breast implantation are significant. About 15% to 25% of patients develop capsule contraction or scarring around the implant, leading to a firmness and distortion of the breast that can be painful and sometimes requires removal of the implant and capsule. Implant rupture may occur in as many as 5% to 10% of women, and bleeding of gel through the capsule is even more common (143). In April 1992, the FDA concluded that the safety and effectiveness of silicone gel breast implants had not been established and called for additional preclinical and clinical studies (144). The FDA advised symptomatic women with ruptured implants to discuss the need for surgical removal with their physicians. When there is no evidence of associated symptoms or rupture, implant removal is generally not indicated because the risks of removal are probably greater than those of retention. If screening ultrasonography shows no rupture, the probability of rupture is...
The preoperative medical history should include any significant medical illnesses that might be aggravated by surgery or anesthesia.

1. Inquiry should be made regarding medications currently being taken as well as those discontinued within the months prior to surgery. This inquiry should include notation of nonprescription drugs being taken and the use of oral contraceptives, which many patients consider a routine part of their lives rather than a medication. In addition, information on the use of alternative therapies, herbs, and vitamins should be elicited. Specific instructions must be given to the patient regarding the need to discontinue any medications prior to surgery (e.g., aspirin or oral contraceptives) as well as those medications that should be continued (e.g., cardiac or antihypertensive medications).

2. The patient should be questioned regarding known allergies to medications (e.g., sulfa and penicillin), foods, or environmental agents. A history of sensitivity to shellfish may be the only clue to an iodine sensitivity, which may be significant because iodinated intravenous contrast material is used for intravenous pyelography (IVP), enhanced computed tomography (CT) scanning, and venography and arteriography. A history of hypersensitivity to intravenously administered iodine-containing compounds or shellfish should be clearly noted, and the patient should not be exposed to iodine-containing compounds unless such exposure is absolutely mandatory. When intravenous contrast material must be used, administration of a glucocorticoid preparation may prevent life-threatening anaphylactic reactions.

3. Previous surgical procedures, and the patient’s course following those surgical procedures, should be reviewed to identify complications of previous operations that might be avoided. Pertinent medical records from prior surgery should be obtained and reviewed. Reactions and response to anesthetic techniques should be evaluated with the anesthesiologist in charge. The patient should be asked about specific complications, such as excessive bleeding, wound infection, deep vein thrombosis, peritonitis, or bowel obstruction. A history of pelvic surgery should alert the gynecologist to the possibility of distorted surgical anatomy and possible preexisting injury to adjacent organ systems, such as small bowel adhesions in the pelvis or ureteral stenosis from previous periureteral scarring. Intravenous pyelography may be helpful in such cases to establish ureteral anatomy and patency and to identify any preexisting abnormality. Many patients may not be entirely clear about the extent of the previous surgical procedure or the details of intraoperative findings. Therefore, operative notes from previous pelvic operations should be obtained and reviewed to determine the details of the procedure and findings. This is particularly important in patients who have had surgery for pelvic inflammatory disease, pelvic abscess, endometriosis, or pelvic malignancy.

4. Family history may identify familial traits that might complicate planned surgery. A family history of excessive intraoperative or postoperative bleeding, malignant hyperthermia, and other potentially inherited conditions should be sought. A general review of systems should also be included in the questioning in an effort to identify any coexisting medical or surgical conditions. Inquiry about gastrointestinal and urologic function is particularly important before undertaking pelvic surgery, and many gynecologic diseases also involve adjacent nongynecologic viscera.

5. Although many women undergoing gynecologic surgical procedures are otherwise healthy, with pathology identified only on pelvic examination, other major organ systems should not be neglected in the physical examination. Identification of abnormalities such as a heart murmur or pulmonary compromise should lead the surgeon to obtain additional testing and consultation in order to minimize intraoperative and postoperative complications. Decisions regarding additional testing or consultation should be made in conjunction with the anesthesiologist.

The selection of appropriate preoperative laboratory studies will depend on the extent of the anticipated surgical procedure and the patient's medical status.

1. For patients undergoing general anesthesia, a blood count, including hematocrit, white blood cell count, and platelet count, should be obtained routinely.

2. The results of serum chemistry and liver function tests are rarely abnormal in asymptomatic patients who have no significant factors in their medical history and who are not taking medications.
3. Coagulation studies are of little value unless the patient has a significant risk factor in her medical history (1).
4. In women under 40 years of age, a chest radiograph and electrocardiography are of very low yield in identifying asymptomatic cardiopulmonary disease and thus may not be necessary (2,3). However, women over 40 years of age and those undergoing major gynecologic surgical procedures should have a chest radiograph, electrocardiography, and serum electrolyte analysis preoperatively. If the results of these studies are normal, they will serve as baseline data for comparison to other studies that may be required in the evaluation of a postoperative complication.

Radiographic evaluation of adjacent organ systems should be undertaken based on patients' needs.

1. Intravenous pyelography is helpful to delineate ureteral patency and course, especially in the presence of a pelvic mass, gynecologic cancer, or congenital müllerian anomaly. However, an IVP is not of significant value in the evaluation of most patients undergoing pelvic surgery (4).
2. A barium enema or upper gastrointestinal studies with small bowel assessment may be of significant value in evaluating some patients before pelvic surgery.
3. Other imaging studies, including ultrasonography, CT scanning, or magnetic resonance imaging (MRI), are useful only in selected patients.

A barium enema or upper gastrointestinal studies with small bowel assessment may be of significant value in evaluating some patients before pelvic surgery. Because of the proximity of the female genital tract to the lower gastrointestinal tract, the rectum and sigmoid colon may be involved with benign (endometriosis or gastrointestinal disease) or malignant gynecologic conditions. Conversely, a pelvic mass could have a gastrointestinal origin such as a diverticular abscess or a mass of inflamed small intestines (Cohn's disease). Clearly, any patient with gastrointestinal symptoms should be further evaluated.

3. Other imaging studies, including ultrasonography, CT scanning, or magnetic resonance imaging (MRI), are useful only in selected patients.

Preoperative Discussion and Informed Consent

The verbal and nonverbal rapport and trust that exist between the patient and her gynecologist begin on the initial office visit and should be built on during each subsequent visit. During the initial discussion, the physician should explain in sufficient detail to the patient the findings of the examination, the results of testing, the natural history of the disease process, and the goals of the surgical procedure. Because most gynecologic surgery is elective, the gynecologist has the opportunity to evaluate the patient from a medical point of view, as well as to allow the patient to develop psychological coping mechanisms and to answer questions that may not have been discussed initially. The surgeon should be available to discuss in person or by phone any questions that arise before actual hospital admission.

The goals of the preoperative discussion are to allay the patient's anxiety and fears and to answer any questions. The discussion should serve as the basis to expand further on issues relative to the surgery, its expected outcome, and risks as well as to obtain signed informed consent (5). Informed consent is an educational process for the patient and her family and fulfills the physician's need to convey information in understandable terms. The following items should be discussed and, after each item, the patient and family should be invited to ask questions:

1. The nature and extent of the disease process
2. The extent of the actual operation proposed and the potential modifications of the operation, depending on intraoperative findings
3. The anticipated benefits of the operation, with a conservative estimate of successful outcome
4. The risks and potential complications of the surgery
5. Alternative methods of therapy and the risks and results of those alternative methods of therapy
6. The risks likely if the patient is not treated

A discussion of the nature and the extent of the disease process should include an explanation in lay terms of the significance of the disease. Is it life-threatening, or will it likely result in significant disability or dysfunction? To what extent does the disease process alter the patient's daily living? If untreated, could the disease resolve spontaneously, or could it potentially worsen? What is the time course and natural history of the disease?

The goals of surgery should be discussed in detail. Some gynecologic surgical procedures are performed purely for diagnostic purposes (e.g., dilation and curettage, cold knife conization, a diagnostic laparoscopy, or staging laparotomy), while most are clearly aimed at correcting an anatomic defect or a specific disease process. The extent of the surgery should be outlined, including which organs will be removed. Most patients like to be informed regarding the type of surgical incision and the estimated duration of anesthesia.

The expected outcome of the surgical procedure should be explained. If the procedure is being performed for diagnostic purposes, the outcome will depend on surgical or pathologic findings that are not known before surgery. When treating anatomic deformity or disease, the expected success of the operation should be discussed, as well as the potential for failure of the operation. This discussion should include the probability of failure (i.e., failure of tubal sterilization or the possibility that stress urinary incontinence may not be alleviated). When treating cancer, the possibility of finding more advanced disease and the potential need for adjunctive therapy (e.g., postoperative radiation therapy or chemotherapy) should be mentioned. Other issues of importance to the patient include discussion of loss of fertility or loss of ovarian function. These issues should be raised by the physician to ensure that the patient adequately understands the pathophysiology that may result from the surgery and to allow her to express her feelings regarding these emotionally charged issues.

The risks and potential complications of the surgical procedure should be discussed with the patient, including the most frequent complications of the particular procedure. For most major gynecologic surgery, the risks include intraoperative and postoperative hemorrhage, postoperative infection, venous thrombosis, and injury to adjacent viscera. If the patient has a preexisting medical problem, what additional risks might be encountered? Unanticipated findings at the time of surgery should also be mentioned. For example, if the ovaries are found unexpectedly to be diseased, it may be the best surgical judgment that they should be removed.

The usual postoperative course should be discussed in enough detail to allow the patient to understand what to expect in the days following surgery.

Information regarding the need for a suprapubic catheter or prolonged central venous monitoring helps the patient accept her postoperative course and avoids surprises to the patient that may be very disconcerting. The expected duration of the recovery period, both in and out of the hospital, should be noted.

Alternative methods of therapy should be mentioned as part of the preoperative discussion. Other medical management or surgical approaches should be discussed, along with their potential benefits and complications. Finally, the patient should have an understanding of the outcome of the disease if nothing is done. Following this discussion, it should be clear to the patient why the proposed surgery is the appropriate next step in her care. The preoperative discussion and signing of the consent form should include witnesses—a family member and another member of the health care team. The informed consent discussion detailing the information given to the patient should be documented in the patient's chart.

The anesthesiologist responsible for the surgical procedure should also have the opportunity to examine the patient, review her laboratory findings, and discuss the proposed anesthetic method with the patient. In many institutions, the consent to the administration of anesthetic is included in the surgical consent form, whereas in other institutions it is a separate form that should be obtained by the anesthesiologist after appropriate preoperative discussion.

General Considerations

Nutrition

In general, patients undergoing elective gynecologic surgery have adequate nutritional stores and, for the most part, do not require nutritional support. However, all patients should have a nutritional assessment, especially those undergoing surgery for gynecologic cancer and other major gynecologic procedures in which a prolonged postoperative recovery is expected. Reassessment of nutritional status should also be performed at regular intervals postoperatively until the patient has successfully returned to a regular diet.

A nutritional assessment includes a careful history and physical examination, which are the most useful, reliable, and cost-effective methods of assessing a patient's nutritional status. In particular, information about recent weight loss as well as the patient's dietary history should be noted. Evidence of malnutrition that can be detected on physical examination includes temporal wasting, muscle wasting, ascites, and edema. Accurate height and weight measurements should be obtained and an ideal body weight, percent ideal body weight, and percent usual body weight may be calculated. Patients who have lost less than 6% of their ideal body weight do not need preoperative nutritional intervention. However, patients who have lost more than 12% of their ideal body weight should be considered for preoperative intervention. Patients who have lost between 6% and 12% of their body weight should undergo further studies to determine if preoperative intervention is needed. In addition to routine preoperative laboratory tests, data on albumin, transferrin, zinc, lipids, and liver function may be obtained. In selected patients,
A variety of techniques have been developed to determine nutritional state, including isotope dilution, g neutron activation, and anthropometric measurements. Anthropometric measurements of skin-fold thickness and arm-muscle circumference provide an estimate of total body fat and lean muscle mass. Isotope dilution techniques have been used to determine the ratio of exchangeable sodium and potassium, which can determine body cell mass and thus give another parameter for chronic malnutrition. Whole body counters that can measure radioactive intracellular calcium can also be used to determine skeletal muscle mass. More recently, g neutron activation has been used to measure total body nitrogen, which is currently considered the state-of-the-art method for the determination of total body protein (8,7). Unfortunately, these measurements have not been reproducible and traditionally have been poor predictors of nutritional status and clinical outcome (8,9).

The degree of malnutrition can in part be determined by serum concentrations of albumin, transferrin, prealbumin, and retinal binding protein (RBP). The levels of these serum proteins are greatly influenced by the patient’s level of hydration. Prealbumin and RBP have the shortest half-lives, and levels are depressed very early in comparison with other serum transferrin and albumin, which have half-lives of 8 and 20 days, respectively (10). A quick assessment of malnutrition can be performed based on the patient’s weight, appetite, and serum albumin levels. An unintentional weight loss of 5 pounds over 3 weeks, anorexia, or a serum albumin level <3.5 g/dl are indicative of malnutrition. Serum albumin was determined to be a decent substitute for the Prognostic Nutritional Index (PNI), which is a time-consuming calculation, in assessing malnutrition in women with gynecologic malignancies (11).

No single test accurately predicts the outcome in malnourished surgical patients. A number of formulas incorporating a variety of nutritional indices have been proposed to assess the perioperative risk secondary to malnutrition. Mullen and co-workers have prospectively evaluated a model that incorporates albumin (ALB), triceps skin-fold thickness (TSF), transferrin (TFN), and delayed hypersensitivity (DH). By a step-wise regression analysis, a linear predictive model called the PNI was developed to relate these factors. It is calculated as follows:

\[ \text{PNI (g/dl)} = 158 - 16.4(\text{ALB}) - 0.75(\text{TSF}) - 0.28(\text{TFN}) + 5.8(\text{DH}) \]

This model was tested on 100 patients undergoing elective surgery and was shown to be valid (12).

Despite the variety of tests and calculations, the decisions regarding the need for nutritional support should be based on several individualized factors. These factors include the patient’s prior nutritional state, the anticipated length of time in which the patient will not be able to eat, the severity of surgery, and the likelihood of complications. The nutritional assessment should also determine whether the cause of the malnutrition is increased enteral loss (malabsorption, intestinal fistula), decreased oral intake, increased nutritional requirements as a result of hypermetabolism (sepsis, malignancy), or a combination of these factors. Moderate to severe malnutrition occurs either as a consequence of the patient’s diagnosis or possibly from the therapeutic modality used to treat her disease (13,14). Severe malnutrition, if not corrected, can contribute to further postoperative complications by causing altered immune function, chronic anemia, impaired wound healing and, eventually, multiple organ system failure and death.

The patient’s nutritional requirements are also increased by surgery. Indices of nutrition were abnormal in 50% of patients who were hospitalized for more than 1 week after surgery (14). Surgery increases the nutritional requirements for several reasons. First, there is a period following surgery during which oral intake is not allowed or is very limited. In addition, the operation itself causes increased protein catabolism, increased energy requirements, and a negative nitrogen balance. If the surgery is uncomplicated and the patient is without food for less than 7 days, this response is limited and patients usually recover without the need for nutritional support. An adequate diet is defined as providing 75% of estimated caloric and protein needs. Thus, if an adequate oral diet is not expected for 7 to 10 days, peroperative nutritional support may be required to avoid progressive malnutrition and its associated complications. Perioperative nutritional support can reduce operative morbidity and decrease hospitalization when it is commenced early in the postoperative course. Therefore, in patients with either normal nutritional indices or mild or moderate malnutrition who will be undergoing surgery, the surgeon is likely to require a prolonged catabolic period of more than 7 to 10 days, total parenteral nutrition (TPN) should be instituted in the early postoperative period as soon as the patient is hemodynamically stable. This type of management should be strongly considered in patients undergoing pelvic exenterations, urinary diversions, or multiple enterectomies (15).

Preoperative nutritional support is indicated for patients who have significant preexisting malnutrition or who require major elective surgery. Preoperative nutritional support is recommended for at least 5 to 7 days prior to surgery to correct electrolyte imbalances and nutritional deficits. Starker and others recommended the following markers to determine adequate nutritional support: weight, fluid status, and serum albumin. In this study patients who exhibited weight loss, diuresis, and a rise in serum albumin after initiation of TPN had an extremely low risk of postoperative morbidity. In contrast, patients who exhibited additional fluid retention, weight gain, and a decline in serum albumin had a significantly higher risk of postoperative complications. In this group of patients, an additional 5 to 7 days of TPN was recommended before proceeding with surgical interventions (16). Nutritional support should be tapered and stopped at midnight prior to surgery and then restarted 24 to 72 hours after the procedure and continued until the patient is able to meet nutritional requirements.

### Calculation of Caloric Requirements

The most precise method for calculating a patient’s daily caloric requirements is indirect calorimetry. This method is very costly, however, and is not used routinely in clinical practice. Caloric requirements can be calculated based on Long’s modification of the Harrison-Benedict formula for actual energy expenditure (AEE) (17). This is the most accurate available method to calculate an individual’s AEE.

- **Activity factor:** confined to bed (1.2), out of bed (1.3)
- **Injury factor:** minor surgery (1.2), skeletal trauma (1.3), major sepsis (1.6), severe burn (2.1)

1. The daily caloric requirements can be met by providing 1,000 calories more than the patient’s basal energy expenditure. Alternatively, daily caloric requirements can be met by giving the patient 35 kcal/kg per day for maintenance and 45 kcal/kg per day for anabolic states. Daily nitrogen requirements may be met by providing 1 g of nitrogen (6.25 g of protein) for every 125 to 150 calories.
2. The maximal rate of glucose oxidation in adults is approximately 7 g/kg per day. Patients with very high caloric requirements or diabetes mellitus should receive calories in excess of this in the form of lipids. Insulin should be used to maintain serum glucose concentration between 150 and 250 mg/dl, and it may be added directly to the TPN solution. Glucose administration in excess of the caloric requirements can lead to fatty infiltration of the liver and other metabolic complications.
3. Lipid in a 10% to 20% emulsion can be given as further caloric supplement. More calories can be given in the form of free fatty acids, which are the major source of energy for most peripheral tissues. When lipids are used as a major source of calories, a minimum of 50 to 150 g/day of glycerol should also be given daily to supply 150 to 300 g of carbohydrate per day for the central nervous system, which cannot metabolize free fatty acids. Most patients require about 1 g of fat/kg per day for the first week after surgery, with the requirement gradually decreasing to 0.5 to 0.8 g/kg per day per week.

### Route of Administration

After the decision has been made that nutritional support is required, the appropriate route of administration must be determined. Enteral nutrition should be considered primarily because it is easy to deliver, associated with the fewest complications, linked to enhanced wound healing, and relatively inexpensive (18). Contraindications to this route of delivery include intestinal obstruction, gastrointestinal bleeding, and diarrhea. Many different types are commercially available and can be chosen based on their caloric content, fat content, protein content, osmolality, viscosity, and price. Depending on the patient's problem, the route of delivery may be through a Dohob feeding tube, a gastrostomy tube, or a feeding jejunostomy tube. If the gastrointestinal tract is unusable for more than 7 days postoperatively, TPN should be implemented.
Total parenteral nutrition must be delivered through a central vein and has gained wide acceptance as a means of providing nutritional support for surgically ill patients. It must be delivered through a subclavian or internal jugular vein, and the catheter must be placed using meticulous sterile surgical technique. Proper daily care is required to avoid infectious complications, and a eutonic state may be obtained if multivitamins (including folic acid and B complex) and trace metals (cobalt, iodine, manganese, and zinc) are used to supplement the 2 to 3 L/day of TPN solution. Essential fatty acids are supplied weekly, and iron may be added if hypoferritemia is prolonged and bone marrow stores have become depleted. Appropriately administered TPN can be safely used in patients with liver, renal, or cardiac dysfunction. When managed by an experienced team, the most frequent complication, infection, can be reduced to a very reasonable level (5% to 10%) (19).

Postoperative Outcome

A number of retrospective clinical studies, mostly from the general surgical literature, have demonstrated that nutritional support improves postoperative outcome in a variety of categories, including surgical complications, sepsis, wound infections, and mortality. A number of prospective randomized trials, however, have failed to demonstrate that the widespread use of preoperative TPN improves clinical outcome (20,21,22,23 and 24). The largest, most carefully executed, prospective, randomized trial evaluating perioperative TPN use was reported by the Veterans Affairs Total Parenteral Nutrition Cooperative Study Group (25). The study evaluated a series of 395 malnourished patients who were randomly assigned to receive TPN for 7 to 15 days before surgery and 3 days postoperatively (treatment arm) or no perioperative TPN (control arm). The patients were then followed for 90 days after the surgery and were evaluated in terms of morbidity and mortality. Major complications, excluding death, during the first 30 days, as well as the overall 90-day mortality rates, were then analyzed and were similar in both the treated and control arms. However, in a small group of patients with extremely severe malnutrition, the incidence of nonfected complications was significantly less common in the group given TPN. In this study, severe malnutrition was defined as a nutritional risk index score of less than 83. The authors of that study concluded that preoperative TPN should be limited to patients who were severely malnourished unless there were other specific indications.

The effect of postoperative TPN on outcome was evaluated in patients undergoing major surgery, regardless of their nutritional status. Three hundred patients were randomized to either TPN or a postoperative glucose administration for up to 15 days. There were no significant differences among the two groups with respect to mortality rate or complications. Sixty percent of patients were tolerating enteral intake by 8 to 9 days after surgery, signifying that the majority of patients do not require nutritional support. However, 20% of patients in the glucose-only arm were unable to tolerate oral intake within 15 days of their operations. For these patients, institution of TPN represented a life-saving effort. Unfortunately, a method of preoperative identification of this group has not been established. Interestingly 20% of the TPN-only arm could not tolerate the nutritional therapy and required treatment modifications. This group had a higher mortality rate than the glucose arm that subsequently required parenteral nutrition (36% versus 21%, P < 0.10). Therefore, suboptimal nutrition includes not only too little nutrition, but also too much nutritional support (25).

In summary, clinical trials have demonstrated that TPN can improve nutritional status as measured by biochemical assays, immune function, and nitrogen balance. The effect of TPN on clinical outcome, however, is less well established. Despite what would seem reasonable based on common sense as well as preoperative nutritional parameters, the data do not support TPN for mild to moderately malnourished patients. With severe malnutrition, preoperative TPN would seem to be beneficial and should be instituted.

Fluid and Electrolytes

Water constitutes approximately 50% to 55% of the body weight of the average woman. Two-thirds of this water is contained in the intracellular compartment. One-third is contained in the extracellular compartment, of which one-fourth is contained in plasma, and the remaining three-fourths is in the interstitium.

Osmolarity, or tonicity, is a property derived from the number of particles in a solution. Sodium and chloride are the primary electrolytes contributing to the osmolarity of the extracellular compartment. Potassium and, to a lesser extent, magnesium and phosphate are the major intracellular electrolytes. Water flows freely between the intracellular and the extracellular spaces to maintain osmotic neutrality throughout the body. Any shifts in osmolarity in any fluid spaces within the body are accompanied by corresponding shifts in free water from spaces of lower to higher osmolarity, thus maintaining equilibrium.

The average adult daily fluid maintenance requirement is approximately 30 mI/kg per day, or 2,000 to 3,000 mI/day (26). This is offset partially by insensible losses of 1,200 mI/day, which includes losses from the lungs (600 mI), skin (400 mI), and gastrointestinal tract (200 mI). Urinary output from the kidney will provide the remainder of the fluid loss, and this output will vary depending on total body intake of water and sodium. Approximately 600 to 800 mOsm of solute are excreted by the kidney per day. Healthy kidneys can concentrate urine up to approximately 1,200 mOsm and, therefore, the minimum output can range between 500 and 700 mI/day. The maximal urine output of the kidney can be as high as 20 L/day, as seen in patients with diabetes insipidus. In healthy individuals, the kidney adjusts output commensurate with daily fluid intake.

The major extracellular buffer used in the acid-base balance is the bicarbonate-carbonic acid system: CO\textsubscript{2} + H\textsubscript{2}O → H\textsubscript{2}CO\textsubscript{3} → H\textsuperscript{+} + HCO\textsubscript{3} (27). Typically, the body will maintain a bicarbonate-to-carbonic acid ratio of 20:1 in order to maintain an extracellular pH of 7.4. Both the lung and the kidney play integral roles in the maintenance of normal extracellular pH via retention or excretion of carbon dioxide and bicarbonate. Under conditions of alkalis, minute ventilation decreases and renal excretion of bicarbonate increases to restore the normal ratio of bicarbonate to carbonic acid. The opposite occurs with acidosis.

Ultimately, the kidney plays the most important role in fluid and electrolyte balance through excretion and retention of water and solute. Circulating antidiuretic hormone and aldosterone help modulate the process. Serum osmolality affects hypothalamic release of antidiuretic hormone and aldosterone secretion in response to renal perfusion. Under states of dehydration or hypovolemia, serum antidiuretic hormone levels increase, leading to increased resorption of water in the distal tubule of the kidney. In addition, increased aldosterone release promotes increased sodium and water retention. The opposite occurs in states of fluid excess. As a result, individuals with normal renal function and circulating antidiuretic hormone and aldosterone levels maintain normal serum osmolality and electrolyte composition, despite daily fluctuations of fluid and electrolyte intake.

Various disease states can alter the normal fluid and electrolyte homeostatic mechanisms, making perioperative fluid and electrolyte management more difficult. Patients with intrinsic renal disease are unable to excrete solute and to maintain acid-base balance. In patients undergoing the stress of chronic starvation or severe illness, there may be an inappropriately high level of circulating antidiuretic hormone and aldosterone, resulting in fluid and sodium retention. With severe cardiac disease, secondary renal hyperperfusion can lead to increased aldosterone synthesis and, therefore, increased sodium and water retention by the kidney. Finally, patients with severe diabetes can have significant osmotic diuresis as well as acid-base dysfunction secondary to circulating ketoacids. Correction and optimization of renal, cardiac, or endocrine disorders preoperatively are imperative and will often rectify fluid and electrolyte abnormalities.

Fluid and electrolyte management in the preoperative and perioperative periods requires knowledge of the daily fluid and electrolyte requirements for maintenance, replacement of ongoing fluid and electrolyte losses, as well as correction of any existing abnormalities.

**Fluid and Electrolyte Maintenance Requirements**

The body adjusts to higher and lower volumes of intake by changes in plasma tonicity. Alterations in plasma tonicity induce adjustments in circulating antidiuretic hormone levels, which ultimately regulate the amount of water retained in the distal tubule of the kidney. In the preoperative and the early postoperative periods, it is usually only necessary to replace sodium and potassium. Chloride is automatically replaced, coexistent with sodium and potassium, because chloride is the usual anion used to balance sodium and potassium in electrolyte solutions. There are various commercially available solutions containing 40 mEq of sodium chloride, with smaller amounts of potassium, calcium, and magnesium designed to meet the requirements of a patient who is receiving 3 L of intravenous fluids per day. The daily requirement, however, can be met by any combination of intravenous fluids. For example, 2 liters of DS (5% dextrose)0.45 normal saline (7 mEq sodium chloride each), supplemented with 20 mEq of potassium chloride, followed by 1 liter of DSW (5% dextrose in water) with 20 mEq of potassium chloride, would suffice.

**Fluid and Electrolyte Replacement**

Fluid and electrolyte losses beyond the daily average may be replaced by appropriate solutions. The choice of solutions for replacement depends on the composition of the fluids lost. Often, it is difficult to measure free water loss, particularly in patients who have high losses from the lungs, skin, or the gastrointestinal tract. Weighing these patients daily can be very useful. Up to 300 g of weight loss daily can be attributable to weight loss from catabolism of protein and fat in the patient
who is taking nothing by mouth (26). Anything beyond this, however, would be due to fluid loss and should be replaced accordingly.

Patients with a high fever can have increased pulmonary and skin loss of free water, sometimes in excess of 2 to 3 L/day. These losses should be replaced with free water in the form of D5W. Perspiration typically has one-third the osmolarity of plasma and can be replaced with D5W or, if excessive, with D5/0.25 normal saline.

The patient with acute blood loss needs replacement with appropriate isotonic fluid or blood or both. There are a wide range of plasma volume expanders, including albumin, dextran, and hetastarch solutions, which contain large-molecular-weight particles (>50,000 molecular weight). These particles are slow to exit the intravascular space, and about one-half of the particles remain after 24 hours. These solutions are expensive, however, and for most cases, simple replacement with 0.9 normal saline or lactated Ringer’s solution will suffice. One-third of the volume of lactated Ringer’s solution or normal saline typically will remain in the intravascular space, and the remainder goes to the interstitium.

Appropriate replacement of gastrointestinal fluid loss depends on the source of fluid loss in the gastrointestinal tract. Gastrointestinal secretions beyond the stomach and up to the colon are typically isotonic with plasma, with similar amounts of sodium, slightly lower amounts of chloride, slightly alkaline pH, and more potassium (in the range of 10 to 20 mEq/L). Under normal conditions, stool is hypotonic. However, under conditions of increased flow (i.e., severe diarrhea), stool contents are isotonic with a composition similar to that of the small bowel contents. Gastric contents are typically hypotonic, with one-third the sodium of plasma, increased amounts of hydrogen ion, and low pH.

In patients who have gastric outlet obstruction, nausea, and vomiting, or who undergo nasogastric suction, appropriate replacement of gastric secretions can be achieved with a solution such as 20 mEq/L of potassium chloride. Perspiration typically has one-third the osmolarity of plasma and can be replaced with D5W or, if excessive, with D5/0.25 normal saline. Perspiration typically has one-third the osmolarity of plasma and can be replaced with D5W or, if excessive, with D5/0.25 normal saline.

In patients with bowel obstruction, 1 to 5 liters of fluid can be sequestered daily in the gastrointestinal tract. This fluid should be replaced with isotonic saline or lactated Ringer’s solution. Similarly, patients with enterocutaneous fistulas or new ileostomies should receive replacement with isotonic fluids.

Correction of Existing Fluid and Electrolyte Abnormalities

Patients who have fluid or electrolyte abnormalities preoperatively can pose a diagnostic challenge. The correct diagnosis and therapy is contingent on a correct assessment of total body fluid and electrolyte status. The management of hyponatremia, for example, may be either fluid restriction or fluid replacement. The choice of treatment depends on whether there is overall extracellular fluid excess and normal body sodium stores or decreased overall total body sodium stores and extracellular fluid. A detailed history is necessary to disclose any underlying medical illness and to assess the amount and duration of any abnormal fluid losses or intake. Initial evaluation should include an assessment of hemodynamic, clinical, and urinary parameters in order to determine the overall level of hydration as well as the fluid status of the extracellular fluid compartment. The patient who has good skin turgor, moist mucosa, stable vital signs, and good urinary output is well hydrated. Nonpitting edema is indicative of extracellular fluid excess, whereas patients with orthostasis, sunken eyes, parched mouth, and decreased skin turgor clearly have extracellular volume contraction. A patient’s overall extracellular fluid status does not always reflect the hydration status of the intravascular compartment, however. A patient can have increased intravascular fluid and yet be intravasically dry, requiring replacement with isotonic fluid.

The laboratory workup for patients who may have preexisting fluid problems should include assessment of blood hematocrit, serum chemistry, glucose, blood urea nitrogen (BUN) and creatinine, urine osmolality, and urine electrolyte levels. Serum osmolality is mainly a function of the concentration of sodium and is given by the following equation:

\[
2 \times [Na^+] + \text{glucose (mg/dl)/18} + \text{BUN (mg/dl)/2.8}.
\]

Normal serum osmolality is typically 280 to 300 mOsm. Blood hematocrit will rise or fall inversely at a rate of 1% per 500-mL alteration of extracellular fluid volume. The BUN-to-creatinine ratio is typically 10:1 but will rise to a ratio of greater than 20:1 under conditions of extracellular fluid contraction. Under conditions of extracellular fluid deficit, urine osmolality will typically be high (>400 mOsm), whereas urine sodium concentration is low (<15 mEq/L) indicative of an attempt by the kidney to conserve sodium. Under conditions of extracellular fluid excess or in cases of renal disease in which the kidney has impaired ability to retain sodium and water, urine osmolality will be low and urine sodium will be high (>30 mEq/L). Finally, changes in sodium can give insight into the degree of extracellular fluid excess or deficit. In the average person, the sodium serum rises by 3 mEq/L for every liter of water deficit and falls by 3 mEq/L for each liter of water excess. One must be careful in making these estimates, however, because patients with prolonged water and electrolyte loss can have low serum sodium levels and marked water deficits.

Specific Electrolyte Disorders

Hyponatremia

Because sodium is the major extracellular cation, shifts in serum sodium levels are usually inversely correlated with the hydration state of the extracellular fluid compartment. The pathophysiology of hyponatremia, then, is usually expansion of body fluids leading to excess total body water (27,28). Symptomatic hyponatremia usually does not occur until the serum sodium is below 120 to 125 mEq/L. The severity of the symptoms (nausea, vomiting, lethargy, seizures) is related more to the rate of change of serum sodium than to the actual serum sodium level.

Hyponatremia in the form of extracellular fluid excess can be seen in patients with renal or cardiac failure as well as in conditions such as nephrotic syndrome, in which both total body salt and water are increased, with a relatively greater increase in the latter. Administration of hypertonic salt to correct the hyponatremia would be inappropriate in this setting. The treatment associated with hyponatremia includes fluid restriction, diuretic therapy, and administration of hypertonic saline to increase sodium levels. Inappropriate secretion of antidiuretic hormone (ADH) can occur with head trauma, pulmonary or cerebral tumors, and states of stress. The abnormally elevated ADH results in excess water retention. Treatment includes water restriction and, if possible, correction of the underlying cause. Demeclocycline has been shown to be effective in this disorder via its action in the kidney.

Inappropriate replacement of body salt losses with water alone will result in hyponatremia. This will typically occur in patients losing large amounts of electrolytes secondary to vomiting, nasogastric suction, diarrhea, or gastrointestinal fistulas, and who received replacement with hypotonic solutions. Simple replacement with isotonic fluids and potassium will usually correct the abnormality. Rarely, rapid fluids correction of the hyponatremia is necessary, in which case hypertonic saline (3%) can be administered. Hypertonic saline should be administered very cautiously in order to avoid a rapid shift in serum sodium, which will induce central nervous system dysfunction.

Hypernatremia

Hypernatremia is an uncommon condition that can be life-threatening if severe (serum sodium >160 mEq/L). The pathophysiology is extracellular fluid deficit. The resultant hyperosmolar state leads to decreased water volume in cells in the central nervous system, which, if severe, can cause disorientation, seizures, intracranial bleeding, and death. The causes include excessive extrarenal water loss, which can occur in patients who have a high fever, have undergone tracheostomy in a dry environment, or have extensive thermal injuries; who have diabetes insipidus, either central or nephrogenic; and who have iatrogenic salt loading. The treatment involves correction of the underlying cause (correction of fever, humidification of the tracheostomy, administration of pitressin for control of central diabetes insipidus) and replacement with free water either by the oral route or intravenously with D5W. As with severe hyponatremia, marked hypernatremia should be corrected slowly.

P-Hypokalemia

Hypokalemia may be encountered preoperatively in patients with significant gastrointestinal fluid loss (prolonged emesis, diarrhea, nasogastric suction, intestinal fistulas) and marked urinary potassium loss secondary to renal tubular disorders (renal tubular acidosis, acute tubular necrosis, hyperaldosteronism, prolonged diuretic use). It can also arise from prolonged administration of potassium-free parenteral fluids in patients who are restricted from ingesting anything by mouth. The symptoms associated with hypokalemia include neuromuscular disturbances, ranging from muscle weakness to fascicul paralysis, and cardiovascular abnormalities, including hypotension, bradycardia, arrhythmias, and enhancement of digitalis toxicity. These symptoms rarely occur unless the

In patients who have gastric outlet obstruction, nausea, and vomiting, who undergo nasogastric suction, appropriate replacement of gastric secretions can be achieved with a solution such as 20 mEq/L of potassium chloride.
serum potassium is <3 mEq/L. The treatment is potassium replacement. Oral therapy is preferable in patients who are on an oral diet. If necessary, potassium replacement can be given intravenously in doses that should not exceed 10 mEq/hr.

Hyperkalemia

Hyperkalemia is encountered infrequently in preoperative patients. It is usually associated with renal impairment but can also be seen in patients who have adrenal insufficiency, are taking potassium-sparing diuretics, and have marked tissue breakdown such as that occurring with crush injuries, massive gastrointestinal bleeding, or hemolysis. The clinical manifestations are mainly cardiovascular. Marked hyperkalemia (potassium >7 mEq/L) can result in bradycardia, ventricular fibrillation, and cardiac arrest. The treatment chosen depends on the severity of the hyperkalemia and whether there are associated cardiac abnormalities detected with electrocardiography. Calcium gluconate (10 ml of a 10% solution), given intravenously, can offset the toxic effects of hyperkalemia on the heart. One ampule each of sodium bicarbonate and D50, with or without insulin, will cause a rapid shift of potassium into cells. Over the longer term, cation exchange resins such as sodium polystyrene sulfonate (Kayexalate), taken orally or by enema, will bind and decrease total body potassium. Hemodialysis is reserved for emergent conditions in which other measures are not sufficient or have failed.

Postoperative Fluid and Electrolyte Management

Several hormonal and physiologic alterations in the postoperative period may complicate fluid and electrolyte management. The stress of surgery induces an inappropriately high level of circulating ADH. Circulating aldosterone levels also are increased, especially if sustained episodes of hypotension have occurred either intraoperatively or postoperatively. The elevated levels of circulating ADH and aldosterone make patients prone to sodium and water retention postoperatively.

Total body fluid volume may be altered significantly postoperatively. First, 1 ml of free water is released for each gram of fat or tissue that is catabolized and, in the postoperative period, several hundred milliliters of free water is released daily from tissue breakdown, particularly in the patient who has undergone extensive intraabdominal dissection and who is restricted from ingesting food and fluids by mouth. This free water is often retained in response to the altered levels of ADH and aldosterone. Second, fluid retention is further enhanced by third spacing, or sequestration of fluid in the surgical field. The development of an ileus may result in an additional 1 to 3 liters of fluid per day being sequestered in the bowel lumen, bowel wall, and peritoneal cavity.

In contrast to renal sodium homeostasis, the kidney lacks the capacity for retention of potassium. In the postoperative period, the kidneys will continue to excrete a minimum of 30 to 60 mEq/L of potassium daily, irrespective of the serum potassium level and total body potassium stores (27). If this potassium loss is not replaced, hypokalemia may develop. Tissue damage and catabolism during the first postoperative day usually result in the release of sufficient intracellular potassium to meet the daily requirements. However, beyond the first postoperative day, potassium supplementation is necessary.

Correct maintenance of fluid and electrolyte balance in the postoperative period starts with the preoperative assessment, with emphasis on establishing normal fluid and electrolyte parameters prior to surgery. Postoperatively, close monitoring of daily weight, urine output, serum hematoctrit, serum electrolytes, and hemodynamic parameters will yield the necessary information to make correct adjustments in crystalloid replacement. The normal daily fluid and electrolyte requirements must be met, and any unusual fluid and electrolyte losses, such as from the gastrointestinal tract, lungs, or skin, must be replaced. After the first few postoperative days, third-space fluid begins to mobilize back into the intravascular space, and ADH and aldosterone levels revert to normal. The excess fluid retained postoperatively is thus mobilized and excreted through the kidneys, and exogenous fluid requirements decrease. The patient with inadequate cardiovascular or renal reserve is prone to fluid overload during this time of third-space reabsorption, especially if intravenous fluids are not appropriately reduced.

The most common fluid and electrolyte disorder in the postoperative period is fluid overload. The fluid excess can occur concomitant with normal or decreased serum sodium. Large amounts of isotonic fluids are usually infused intraoperatively and postoperatively to maintain blood pressure and urine output. Because the infused fluid is often isotonic with plasma, it will remain in the extracellular space. Under such conditions, serum sodium will remain within normal limits. Fluid excess with hypotonicity (decreased serum sodium) can occur if large amounts of isotonic fluid losses (e.g., blood and gastrointestinal tract) are inappropriately replaced with hypotonic fluids. Again, the prediposition toward retention of free water in the immediate postoperative period compounds the problem. An increase in body weight occurs concomitant with the fluid expansion. In the patient who is not allowed anything by mouth, catabolism should induce a daily weight loss as great as 300 g/day. Clearly, the patient who is gaining weight in excess of 150 g/day is in a state of fluid expansion. Simple fluid restriction will correct the abnormality. When necessary, diuretics can be used to increase urinary water excretion.

States of fluid dehydration are uncommon but will occur in patients who have large daily fluid losses that are not replaced. Gastrointestinal losses should be replaced with the appropriate fluids. Patients with high fevers should be given appropriate free water replacement, because up to 2 L/day of free water can be lost through perspiration and hyperventilation. Although these increased losses are difficult to monitor, a reliable estimate can be obtained by monitoring body weight.

Postoperative Acid-base Disorders

A variety of metabolic, respiratory, and electrolyte abnormalities in the postoperative period can result in an imbalance in normal acid-base homeostasis, leading to alkalosis or acidosis. Changes in the respiratory rate will directly affect the amount of carbon dioxide that is exhaled. Respiratory acidosis will result from carbon dioxide retention in patients who have hyperventilation from central nervous system depression. This condition can result from oversedation with narcotics, particularly in the presence of concurrent severe chronic obstructive pulmonary disease. Respiratory alkalosis can result from hyperventilation caused by excitation of the central nervous system by drugs, pain, or excess ventilator support. Numerous metabolic derangements can result in alkalosis or acidosis. Proper fluid and electrolyte replacement as well as maintenance of adequate tissue perfusion will help prevent most acid-base disorders that occur during the postoperative period.

Alkalosis

The most common acid-base disorder encountered in the postoperative period is alkalosis (27). Alkalosis is usually of no clinical significance and resolves spontaneously. Several etiologic factors may include hyperventilation associated with pain; posttraumatic transient hyperaldosteronism, which results in decreased renal bicarbonate excretion; nasogastric suction, which removes hydrogen ions; infusion of bicarbonate during blood transfusions in the form of citrate, which is converted to bicarbonates; administration of exogenous alkali; and use of diuretics. Alkalosis can usually be corrected easily with removal of the inciting cause, whether it is an acidifying agent or not.

Marked alkalosis, with serum pH higher than 7.55, can result in serious cardiac arrhythmias or central nervous system seizures. Myocardial excitability is particularly pronounced with concurrent hypokalemia. Under such conditions, fluid and electrolyte replacement may not be sufficient to correct the alkalosis rapidly. Acetazolamide (250 to 500 mg), orally or intravenously, can be given 2 to 4 times daily to induce renal bicarbonate diuresis. Treatment with an acidifying agent is rarely necessary and should be reserved for acutely symptomatic patients (i.e., those with cardiac or central nervous system dysfunction) or for patients with

advanced renal disease. Under such conditions, HCl (5 to 10 mEq/hr of a 100-mmol solution) can be given via a central intravenous line. Ammonium chloride can also be given orally or intravenously but should not be given to patients with hepatic disease.

**Acidosis**

*Metabolic acidosis* is less common than alkalosis during the postoperative period, but acidosis can potentially be serious because of its effect on the cardiovascular system. Under conditions of acidosis, there are decreased myocardial contractility, a propensity for vasodilatation of the peripheral vasculature leading to hypotension, and refractoriness of the fibrillating heart to defibrillation (27). These effects promote decompensation of the cardiovascular system and can hinder attempts at resuscitation.

Metabolic acidosis results from a decrease in serum bicarbonate levels caused by the consumption and replacement of bicarbonate by circulating acids or the replacement by other anions such as chloride. The proper workup includes a measurement of the anion gap:

\[
\text{Anion gap} = (\text{Na}^+ + K^+) - (\text{Cl}^- + \text{HCO}_3^-) = 10 \text{ to } 14 \text{ mEq/L (normal)}
\]

The anion gap is also composed of circulating protein, sulfate, phosphate, citrate, and lactate (29).

With metabolic acidosis, the anion gap can be increased or normal. An increase in circulating acids will consume and replace bicarbonate ion, thus increasing the anion gap. The causes include an increase in circulating lactic acid secondary to anaerobic glycolysis, such as that seen under conditions of poor tissue perfusion; increased ketoacids, as with cases of severe diabetes or starvation; exogenous toxins; and renal dysfunction, which leads to increased circulating sulfates and phosphates (30). The diagnosis can be established via a thorough history and measurement of serum lactate (normal <2 mmol/L), serum glucose, and renal function parameters. Metabolic acidosis in the face of a normal anion gap is usually the result of an imbalance of the ions chloride and bicarbonate, which occurs under conditions leading to excess chloride and decreased bicarbonate. Hyperchloremic acidosis can be seen in patients who have undergone saline loading. Bicarbonate loss will be seen in patients with small bowel fistulas, new ileostomies, severe diarrhea, or renal tubular acidosis. Finally, in patients with marked extracellular volume expansion, which often occurs postoperatively, the relative decrease in serum sodium and bicarbonate will result in a mild acidosis. A summary of the various causes of metabolic acidosis is shown in Table 19.2.

Table 19.2. Causes of Metabolic Acidosis

The treatment of metabolic acidosis depends on the cause. In patients with lactic acidosis, restoration of tissue perfusion is imperative. This can be accomplished through cardiovascular and pulmonary support as needed, oxygen therapy, and aggressive treatment of systemic infection wherever appropriate. Ketosis from diabetes can be corrected gradually with insulin therapy. Ketosis resulting from chronic starvation or from lack of caloric support postoperatively can be corrected with nutrition. In patients with normal anion gap acidosis, bicarbonate losses from the gastrointestinal tract should be replaced, excess chloride administration can be curtailed and, where necessary, a loop diuretic can be used to induce renal clearance of chloride. Dilutional acidosis can be corrected with mild fluid restriction.

Bicarbonates should not be given unless serum pH is lower than 7.2 or severe cardiac complications secondary to acidosis are present. Furthermore, close monitoring of serum potassium levels is mandatory. Under states of acidosis, potassium will exit the cell and enter the circulation. The patient with a normal potassium concentration and metabolic acidosis is actually depleted of intracellular potassium. Treatment of the acidosis without potassium replacement will result in severe hypokalemia with its associated risks. A summary of the various acid-base abnormalities and associated therapies is shown in Table 19.3.

Table 19.3. Acid-Base Disorders and Their Treatment

**Perioperative Pain Management**

Although satisfactory analgesia is easily achievable with currently available methods, patients continue to suffer unnecessarily from postoperative pain. Studies have consistently shown that 30% to 40% of patients suffer moderate to severe pain in the postoperative period (31). There are several reasons for the existing inadequacies in pain management. First, patient expectations of pain relief are low and they are not aware of the extent of analgesia that they should expect. In a study of the perception of pain relief after surgery, 86% of patients had moderate to severe pain after surgery, but 70% felt that the pain was as severe as they had expected (32). Second, there is a lack of formal physician training in pain management. This lack is epitomized by the commonly written order prescribing a range of narcotic to be given intramuscularly every 3 to 4 hours as needed, leaving pain management decisions to the nursing staff, with no attempt made to titrate the dose of the prescribed narcotic commensurate with individual patient requirements. Third, attitudes continue to be influenced by the common misconception that the use of narcotics in the postoperative period can result in opioid dependence. In one review, 20% of nurses responding to a staff questionnaire expressed concern that the use of opioid analgesics during the postoperative period could cause addiction (32). Studies have confirmed that nurses will administer less than one-fourth of the total dose of narcotic that is prescribed on an as-needed basis. In order to facilitate acute pain management and reduce the number of adverse outcomes, the American Society of Anesthesiologists has established practice guidelines for acute pain management (33).

*Minimal effective analgesic concentration (MEAC)* refers to the serum concentration of a drug below which very little analgesia is achieved. At the MEAC, receptor and plasma concentrations of a drug are in equilibrium. Steady-state drug concentrations above the MEAC are difficult to achieve with intramuscular depot injection (34). In one study, patients receiving intramuscular injections with meperidine hydrochloride (Demerol) every 4 hours experienced marked intra- and interpatient variations in narcotic drug peak concentrations as well as in the time required to reach these peaks. As a result, serum concentrations of drug were above the MEAC an average of only 35% of each 4-hour dosing interval (35). Variable pain control following intermittent intramuscular injections is the result of inadequate, highly variable, and unpredictable blood concentrations (36). Adequate analgesia can be achieved through intramuscular or subcutaneous modes of administration,
but unpredictable absorption can make titration difficult. Small intravenous boluses can be more easily titrated but may be shorter acting, requiring more frequent injections and thus intensive nursing care, whereas larger intravenous boluses may be associated with a higher incidence of central nervous system and respiratory depression. The patient-controlled analgesia (PCA) technique, which allows patients to self-administer small doses of narcotic on demand, allows titration of measured boluses of narcotic as needed to relieve pain and can provide a more thorough analgesia with maintenance of steady-state drug concentrations above the MEAC.

Irrespective of the route of administration, anesthetics must be front loaded in order to provide prompt analgesia from the start. Without front loading, attainment of the MEAC will not occur for at least three elimination half-lives of the narcotic agent that is used. After front loading, additional small boluses of narcotic can be administered until analgesia is achieved. From the total dose of drug required to achieve analgesia, maintenance drug dosages can then be determined and administered either as a continuous infusion or on a scheduled basis, so that the dose of drug administered offsets the amount that is cleared (Table 19.4). Thereafter, prescribed doses of narcotic can be adjusted as needed.

Carefully supervised regimens using continuous infusions, on-demand intramuscular therapy, or fixed dosage schedules (every-4-hour dosing) with on-demand supplementation can have analogical efficacy comparable with PCA. Nonetheless, the type of dose supervision required to achieve adequate on-demand analgesia without PCA is difficult to maintain. Use of PCA shortens the time between the onset of pain and the administration of pain medication, provides more continuous access to analgesics, and allows for an overall steadier state of pain control.

Epidural and Spinal Analgesia
Anesthetics and narcotics administered either in the epidural space or intrathecally are among the most potent analgesic agents available; the efficacy of these agents is greater than that provided by intravenous PCA techniques. These drugs can be administered in one of several ways, including a single-shot dose given by epidural or intrathecal injection, intermittent injection given either on schedule or on demand, and continuous infusion.

Because of the risk of central nervous system infections and headaches, intrathecal administration is usually limited to a single dose of narcotic, local anesthetic, or both. In comparison with epidural administration, duration of action for a single dose is increased via the intrathecal route as a result of the high concentrations of drug attained in the cerebrospinal fluid. However, the risk of central nervous system and respiratory depression, as well as systemic hypotension, also is increased.

Even the low doses of opioids required for intrathecal analgesia have been associated with an increased risk of respiratory depression (39). Therefore, some investigators have warned against the use of intrathecal spinal analgesia outside the intensive care setting.

Epidural administration is the preferred approach and provides extended (>24 hours) pain control during the postoperative period. Relative contraindications are the presence of coagulopathy, sepsis, and hypotension. Both anesthetic and narcotic agents have been used with excellent efficacy. Among the anesthetic agents, bupivacaine has been the most popular, providing excellent analgesia with minimal toxicity. Epidural analgesia is most suited for pain control in the lower abdomen and extremities. Potential adverse effects of epidural anesthetic agents include urinary retention, motor weakness, hypotension, and central nervous system and cardiac depression. In contrast to anesthetic agents, opioids offer excellent analgesia without accompanying sympathetic blockade. Epidural opioids tend to have a much longer duration of action, and hypotension is a rare complication. Compared with epidural anesthetics, however, there is a higher incidence of nausea and vomiting, respiratory depression, and pruritus (39).

Compared with anesthetics administered intramuscularly or intravenously, epidural analgesia has been shown to be associated with improved pulmonary function postoperatively, a lower incidence of pulmonary complications, a decrease in postoperative venous thromboembolic complications (most likely secondary to earlier ambulation), fewer gastrointestinal side effects, a lower incidence of central nervous system depression, and shorter convalescence (39). Severe respiratory depression is the most serious potential complication, seen in fewer than 1% of patients. A lower incidence of respiratory depression is seen with the more lipophilic drugs such as fentanyl, which is quickly absorbed through the spinal cord and is therefore less likely to diffuse to the central nervous system respiratory control centers. Pruritus, nausea, and urinary retention are common but can be easily managed and are usually of little clinical significance. Cost is perhaps the main and most limiting drawback of epidural analgesia.

Close monitoring by nursing staff is required for safe administration of epidural analgesia. However, an intensive care setting is not necessary. Epidural analgesics can be administered safely in a hospital ward setting under close nursing supervision, using respiratory monitoring with hourly ventilatory checks during the first 8 hours of epidural analgesia.

Nonsteroidal Antiinflammatory Drugs
Nonsteroidal antiinflammatory drugs (NSAIDs) are becoming increasingly popular for the postoperative treatment of pain in patients undergoing major and minor surgical procedures. The NSAID ketorolac is a potent drug that can be given intravenously or intramuscularly. K etorolac has a slightly slower onset of activity than fentanyl but has an analgesic potency comparable to morphine. The theorectical advantages of NSAIDs over opioids include absence of respiratory depression, lack of abuse potential, decreased sedative effects, decreased nausea, early return of bowel function, and faster recovery. In clinical studies, ketorolac has been found to have analgesic effects similar to those of morphine in postoperative orthopedic patients and, when used in conjunction with PCA, significantly reduced opioid requirements (40,41). Studies in gynecologic populations have been less positive. One study found no differences in pain scores, morphine consumption, or side effects between patients given ketorolac intravenously compared with placebo following hysterectomy (42). Because of the potential advantages, many advocate the addition of NSAIDs to opioid therapy for perioperative pain management.
Potential adverse effects associated with the use of NSAIDs include an increased risk of renal compromise (particularly in patients suffering from acute hypovolemia), gastrointestinal side effects, hypersensitivity reactions, and bleeding. Although NSAIDs cause a modest increase in bleeding time, this does not appear to be clinically significant. Controlled prospective studies have not demonstrated a significant increase in blood loss in patients who receive NSAIDs perioperatively. These agents should be used with extreme care, if at all, in patients with asthma, because 5% to 10% of adult patients with asthma are sensitive to aspirin and other NSAID preparations. Ketorolac is active when administered both intravenously and orally, making it easy to administer in the perioperative setting for patients undergoing minor procedures.

**Antibiotic Prophylaxis**

Infection at the operative site is a common cause of morbidity in patients undergoing gynecologic surgery. Procedures such as vaginal hysterectomy, abdominal hysterectomy, surgical drainage of pelvic abscesses, selected cases of pregnancy termination, and radical surgery for gynecologic malignancy carry a significant risk of postoperative infection. Other risk factors for the development of wound infection include prolonged operative time, prolonged preoperative admission, concurrent infection, and presence of malignancy. Such infections result in considerable morbidity as well as prolonged hospitalization, increased rates of readmission, and substantial cost. Prophylactic antibiotics have been used in an effort to reduce these problems.

Pathogens that can cause contamination during gynecologic surgery are organisms indigenous to the vaginal tract, including gram-positive and gram-negative aerobes and anaerobes (Table 19.5). The primary pathogenic bacteria include coliforms, streptococci, fusobacteria, and *Bacteroides*.

**Table 19.5. Bacteria Indigenous to the Lower Genital Tract**

Prophylactic antibiotic use in patients undergoing vaginal hysterectomy is highly effective and widely accepted as the standard of care. A review of the placebo-controlled trials in the literature regarding antibiotic prophylaxis in vaginal and abdominal hysterectomy included 48 studies of 5,524 patients who underwent vaginal hysterectomy and 30 studies of 3,752 patients who underwent abdominal hysterectomy (43). In vaginal hysterectomy, prophylactic antibiotics decreased febrile morbidity from 40% in control patients to 15% in treated patients and lowered pelvic infection rates from 25% in control patients to 5% in treated patients. In this analysis, the benefits of prophylaxis were less pronounced with abdominal hysterectomy; prophylactic antibiotics reduced febrile morbidity from 28% in control patients to 16% in treated patients, pelvic infections from 10% to 5%, and wound infections from 8% to 3%. More recently, a metaanalysis of 25 randomized controlled trials revealed that use of antibiotic prophylaxis reduced the incidence of serious infections after abdominal hysterectomy from 21.1% (372 of 1,768) to 9% (166 of 1,836) (45). The authors concluded that because prophylactic antibiotics are highly effective in prevention of serious infections associated with total abdominal hysterectomy, they should be used routinely.

The antibiotic chosen for prophylaxis for gynecologic surgery should have activity against the broad range of vaginal organisms. The first- and second-generation cephalosporins are well suited for this purpose because of their activity against gram-positive, gram-negative, and anaerobic organisms. Most classes of antibiotics (including *penicillin*, *tetracycline*, *sulfonamide*, broad-spectrum *penicillin*, and cephalosporins) and anaerobic drugs (clindamycin, *metronidazole*) have been shown to be effective prophylactically, but none has been shown to be consistently more effective than first-generation cephalosporins (45,46,47 and 49).

The timing of administration of the prophylactic antibiotic agent is important. Antibiotics given for prophylaxis are most active if present in tissues prior to the start of surgery. The importance of good surgical technique must be emphasized. Delicate handling of tissues, good hemostasis, adequate drainage, and avoidance of unnecessarily large pedicles in ligatures promote healing and lower the risk of complications.

**Postoperative Infections**

Infections are a major source of morbidity in the postoperative period. Risk factors for infectious morbidity include the absence of perioperative antibiotic prophylaxis, contamination of the surgical field from infected tissues or from spillage of large bowel contents, an immunocompromised host, poor nutrition, chronic and debilitating illness, poor surgical technique, and preexisting or systemic infection. Sources of postoperative infection can include the lung, urinary tract, surgical site, pelvic side wall, vaginal cuff, abdominal wound, and sites of indwelling intravenous catheters. Early identification and treatment of infection will result in the best outcome from these potentially serious complications.

Although infectious morbidity is an inevitable complication of surgery, the incidence of infections can be decreased by the appropriate use of simple preventive measures. In cases that involve transaction of the large bowel, spillage of fecal contents inevitably occurs. A thorough preoperative mechanical and antibiotic bowel preparation in combination with systemic antibiotic prophylaxis will help decrease the incidence of postoperative pelvic and abdominal infections in these patients. The surgeon can further decrease the risk of postoperative infections by using meticulous surgical technique. Blood and necrotic tissue are excellent media for the growth of aerobic and anaerobic organisms. In cases in which there is higher-than-usual potential for serum and blood to collect in spaces that have been contaminated by bacterial spill, closed-suction drainage may reduce the risk of infection. Antibiotic therapy, rather than prophylaxis, should be initiated during surgery in patients who have frank intra-abdominal infection or pus.

Elective surgical procedures should be postponed in patients who have infections preoperatively. In an epidemiologic study conducted by the Centers for Disease Control and Prevention, the incidence of nosocomial surgical infections ranged from 4.3% in community hospitals to 7% in municipal hospitals (53). Urinary tract infections accounted for approximately 40% of these nosocomial infections. Infections of the skin and wound accounted for approximately one-third of the infections, and respiratory tract infections accounted for approximately 16%. In patients who had any type of infection prior to surgery, the risk of infection at the surgical wound site was increased fourfold. Rates of infection were higher in older patients, in patients with increased length of surgery, and in those with increased length of hospital stay prior to surgery. The relative risk was 3 times higher in patients with a community-acquired infection prior to surgery. These community-acquired infections included infections of the urinary and respiratory tracts.

Historically, the standard definition of febrile morbidity for surgical patients has been the presence of a temperature higher than or equal to 100.4°F (38°C) on two occasions at least 4 hours apart during the postoperative period, excluding the first 24 hours. However, other sources have defined fever as two consecutive
Intravenous catheter–related infections are common; the reported incidence is from 25% to 35% (54,55). Febrile morbidity has been estimated to occur in as many as one-half of patients; however, it is often self-limited, resolving without therapy, and is usually noninfectious in origin (56). Overzealous evaluations of postoperative fever, especially during the early postoperative period, are time consuming, expensive, and sometimes uncomfortable for the patient (55). The value of 101.0°F is more useful than 100.4°F to distinguish an infectious cause from an inconsequential postoperative fever.

The assessment of a febrile surgical patient should include a review of the patient's history with regard to risk factors. Both the history and the physical examination should focus on the potential sites of infection (Table 19.6). The examination should include inspection of the pharynx, a thorough pulmonary examination, percussion of the kidneys to assess for costovertebral angle tenderness, inspection and palpation of the abdominal incision, examination of sites of intravenous catheters, and an examination of the extremities for evidence of deep venous thrombosis or thrombophlebitis. In gynecologic patients, an appropriate workup may also include inspection and palpation of the vaginal cuff for signs of induration, tenderness, or purulent drainage. A pelvic examination should also be performed in order to identify a mass consistent with a pelvic hematoma or abscess and to look for signs of pelvic cellulitis.

### Urinary Tract Infections

Historically, the urinary tract has been the most common site of infection in surgical patients (53). However, the incidence reported in the more recent gynecologic literature has been less than 4% (56,57). This decrease in urinary tract infections is most likely the result of increased perioperative use of prophylactic antibiotics. The incidence of postoperative urinary tract infection in gynecologic surgical patients not receiving prophylactic antibiotics has been confirmed to be as high as 40% (58), ed even a single dose of perioperative prophylactic antibiotic has been shown to decrease the incidence of postoperative urinary tract infection from 35% to 4% (59).

Symptoms of a urinary tract infection may include urinary frequency, urgency, and dysuria. In patients with pyelonephritis, other symptoms include headache, malaise, nausea, and vomiting. A urinary tract infection is diagnosed on the basis of microbiology and has been defined as the growth of 10³ organisms/ml of urine cultured. Most infections are caused by coliform bacteria, with *Escherichia coli* being the most frequent pathogen. Other pathogens include * Klebsiella, Proteus, and Enterobacter* species. *Staphylococcus* organisms are the causative bacteria in fewer than 10% of cases.

Despite the high incidence of urinary tract infections in the postoperative period, few of these infections are serious. Most are confined to the lower urinary tract, and pyelonephritis is a rare complication (59). Catheterization of the urinary tract, either intermittently or continuously with the use of an indwelling catheter, has been implicated as a main cause of urinary tract contamination (61). In fact, more than 1 million catheter-associated urinary tract infections occur yearly in the United States, and *catheter-associated bacteria remains the most common etiology of gram-negative bacteremia in hospitalized patients*. Bacteria adhere to the surface of urinary catheters and grow within bile films, which appear to protect embedded bacteria from antibiotics, making treatment less effective. Therefore, the use of urinary tract catheters should be minimized. An indwelling catheter should be removed or replaced in a patient undergoing treatment for catheter-related infections.

The treatment of urinary tract infection includes hydration and antibiotic therapy. Commonly prescribed and effective antibiotics include penicillin, sulfonamides, cephalexins, furoquinolones, and nitrofurantoin. The choice of antibiotic should be based on knowledge of the susceptibility of organisms cultured at a particular institution. In some institutions, for example, more than 40% of *E. coli* strains are resistant to ampicillin. For uncomplicated urinary tract infections, an antibiotic that has good activity against *E. coli* should be given in the interim while awaiting results of the urine culture and sensitivity data.

Patients who have a history of recurrent urinary tract infections, those with chronic indwelling catheters (Foley catheters or urethral stents), and those who have urinary conduits should be treated with antibiotics that will be effective against the less common urinary pathogens such as * Klebsiella* and *Pseudomonas*. Chronic use of the furoquinolones for prophylaxis is not advised, because these agents are notorious for inducing antibiotic-resistant strains of bacteria.

The respiratory tract is an uncommon site for infectious complications in gynecologic surgical patients. Hernslet noted only six cases of pneumonia in more than 4,000 women who underwent elective hysterectomy (60). This low incidence is probably a reflection of the young age and good health status of gynecologic patients in general. In acute care facilities, pneumonia is a frequent hospital-acquired infection, particularly in elderly patients (62). Risk factors include extensive or prolonged atelectasis, preexistent chronic obstructive pulmonary disease, severe or debilitating illness, central neurologic disease causing an inability to clear oropharyngeal secretions effectively, and nasogastric suction (62). In surgical patients, early ambulation and aggressive management of atelectasis are the most important preventive measures. The role of prophylactic antibiotics remains unclear.

A significant proportion (40% to 50%) of hospital-acquired pneumonias are caused by gram-negative organisms. These organisms gain access to the respiratory tract from the oral pharynx. Gram-negative colonization of the oral pharynx has been shown to be increased in patients in acute care facilities and has been associated with the presence of nasogastric tubes, preexistent respiratory disease, mechanical ventilation, tracheal intubation, and paralytic ileus, as a result of microbial overgrowth in the stomach (63). Interestingly, the use of antimicrobial drugs seems to significantly increase the frequency of colonization of the oral pharynx with gram-negative bacteria.

A thorough lung examination should be included in the assessment of all febrile surgical patients. In the absence of significant lung findings, a chest radiograph is probably of little benefit in patients at low risk for postoperative pulmonary complications. In patients with pulmonary findings or with risk factors for pulmonary complications, a chest radiograph should be obtained. A sputum sample should also be obtained for Gram stain and culture. The treatment should include postural drainage, aggressive pulmonary toilet, and antibiotics. The antibiotic chosen should be effective against both gram-positive and gram-negative organisms, and in patients who are receiving assisted ventilation, the antibiotic spectrum should include drugs that are active against *Pseudomonas* organisms.

### Phlebitis

Intravenous catheter–related infections are common; the reported incidence is from 25% to 35% (64). The intravenous site should be inspected daily, and the catheter
should be removed if there is any associated pain, redness, or induration. Unfortunately, phlebitis can occur even with close surveillance of the intravenous site. In one study, more than 50% of the cases of phlebitis became evident more than 12 hours after discontinuation of intravenous catheters (65). In addition, fewer than one-third of patients had symptoms related to the intravenous catheter site 24 hours prior to the diagnosis of phlebitis.

Intravenous catheters should be inserted using sterile technique, and they should be changed frequently. The institution of intravenous therapy teams has decreased the incidence of phlebitis by as much as 50% (64). This decrease is related not so much to surveillance of the intravenous catheter site as it is to frequent changing of intravenous catheters. The incidence of catheter-related phlebitis increases significantly after 72 hours. Therefore, intravenous catheters should be changed at least every 3 days.

Phlebitis can be diagnosed based on the presence of fever, pain, redness, induration, or palpable venous cord. Occasionally, suppuration will present. Phlebitis is usually self-limited and resolves within 3 to 4 days. The treatment includes application of warm, moist compresses and prompt removal of any catheters from the infected vein. Antibiotic therapy with antimicrobial agents should be instituted for catheter-related sepsis. Excision or drainage of an infected vein is rarely necessary.

**Wound Infections**

The results of a prospective study of more than 62,000 wounds were revealing in regard to the epidemiology of wound infections (66). The wound infection rate varied markedly, depending on the extent of contamination of the surgical field. The wound infection rate for clean surgical cases (infection not present in the surgical field, no break in aseptic technique, no viscus entered) was lower than 2%, whereas the incidence of wound infections with dirty, infected cases was 40% or higher. Preoperative showers with hexachlorophene slightly lowered the infection rate for clean wounds, whereas preoperative shaving of the wound site with a razor increased the rate of infection. A 5-minute warm-water soak of the wound site was as effective as preoperative shaving. The infection rate can be further decreased with the addition of a 10- to 15-minute warm-water intraoperative rinse of the wound site. Postoperative administration of antibiotics can be administered in patients undergoing clean surgical procedures. The study concluded that the incidence of wound infections could be decreased by short preoperative hospital stays, hexachlorophene showers prior to surgery, minimizing shaving of the wound site, use of meticulous surgical technique, decreasing operative time as much as possible, bringing drains out through sites other than the wound, and dissemination of information to surgeons regarding their wound infection rates. A program instituting these conclusions led to a fall in the clean wound infection rate from 2.5% to 0.6% over an 8-year period. The wound infection rate in most gynecologic services has been lower than 5%, reflective of the clean nature of most gynecologic operations.

The symptoms of wound infection often occur late in the postoperative period, usually after the fourth postoperative day, and may include fever, erythema, tenderness, induration, and purulent drainage. Wound infections which occur on postoperative days 1 through 3 are generally caused by streptococcal and 

**Intraabdominal and Pelvic Abscess**

The development of an abscess in the surgical field or elsewhere in the abdominal cavity is an uncommon complication after a gynecologic surgery. It is most likely to occur in contaminated cases in which the surgical site is not adequately drained or as a secondary complication of hematomas. The causative pathogens in patients who have intraabdominal abscesses are usually polymicrobial in nature. The aerobes most commonly identified include E. coli, Klebsiella, Streptococcus, Proteus, and Enterobacter. Anaerobic isolates are also common, usually from the Bacteroides group. These pathogens arise mainly from the vaginal tract but also can be derived from the gastrointestinal tract, particularly when the colon has been entered at the time of surgery.

Intraabdominal abscess is sometimes difficult to diagnose. The evolving clinical picture is often one of persistent febrile episodes with a rising white blood cell count. Findings on abdominal examination may be equivocal. If an abscess is located deep in the pelvis, it may be palpable by pelvic or rectal examination. For abscesses above the pelvis, the diagnosis will depend on radiologic confirmation. Ultrasonography can occasionally delineate fluid collections in the upper abdomen as well as in the pelvis. However, bowel gas interference makes visualization of fluid collections or abscesses in the midabdomen difficult to distinguish. CT scanning is therefore much more sensitive and specific for diagnosing intraabdominal abscesses and often is the radiologic procedure of choice. Occasionally, if conventional radiologic methods fail to identify an abscess and the index of suspicion for an abscess remains high, labeled leukocyte scanning may be useful for localizing the infected focus.

The standard therapy for intraabdominal abscess is evacuation and drainage combined with appropriate parental administration of antibiotics. Abscesses located low in the pelvis, particularly in the area of the vaginal cuff, can often be reached through a vaginal approach. In many patients, the ability to drain an abscess by placement of a drain percutaneously under CT guidance has obviated the need for surgical exploration. With CT guidance, a pigtail catheter is placed into an abscess cavity via either transperineal, transrectal, or transvaginal approaches. The catheter is left in place until drainage decreases. Transperineal and transrectal drainage of pelvic abscesses has been successful in 90% to 95% of patients, obviating the need for surgical management (68,69). For those patients in whom radiographic drainage is not successful, however, surgical exploration and evacuation are indicated. The gold standard of initial antibiotic therapy has been the combination of ampicillin, gentamicin, and clindamycin. Adequate treatment can also be achieved with currently available broad-spectrum single agents (including the broad-spectrum penicillins), second- and third-generation cephalosporins, levofloxacin and metronidazole, and the sulfadimethoxine-containing preparations (70,71,72 and 73).

**Necrotizing Fasciitis**

Necrotizing fasciitis is an uncommon infectious disorder; approximately 1,000 cases occur annually in the United States (74). The disorder is characterized by a rapidly progressive bacterial infection that involves the subcutaneous tissues and fascia while characteristically sparing underlying muscle. Systemic toxicity is a frequent feature of this disease, as manifested by the presence of dehydration, septic shock, DIC, and multiple organ system failure.

The pathogenesis of necrotizing fasciitis involves a polymicrobial infection of the dermis and subcutaneous tissue. Hemolytic streptococcus was initially believed to be the primary pathogen responsible for the infection in necrotizing fasciitis (75). However, it is now evident that numerous other organisms are often cultured in addition to streptococcus, including other gram-positive organisms, coagulase-positive, and anaerobes (75,76,77,78 and 79). Bacterial enzymes such as hyaluronidase and lipase released in the subcutaneous space destroy the fascia and adipose tissue and induce a liquefactive necrosis. In addition, noninflammatory intravascular coagulation or thrombosis subsequently occurs. Intravascular coagulation results in ischemia and necrosis of the subcutaneous tissues and skin (70,73). Late in the course of the infection, destruction of the superficial nerves produces anesthesia in the involved skin. The release of bacteria and bacterial toxins into the systemic circulation can
cause septic shock, acid-base disturbances, and multiple organ impairment.

The diagnostic criteria for necrotizing fasciitis include extensive necrosis of the superficial fascia and subcutaneous tissue with peripheral undermining of the normal skin, a moderate to severe systemic toxic reaction, the absence of muscle involvement, Clostridium in wound and blood culture and major vascular occlusion, intensive leukocyte infiltration, and necrosis of subcutaneous tissue (83).

Most patients with necrotizing fasciitis suffer pain, which in the early stages of the disease is often disproportionately greater than that expected from the degree of cellulitis present. Late in the course of the infection, the involved skin may actually be anesthetized secondary to necrosis of superficial tissues. Temperature abnormalities, both hyperthermia and hypothermia, are common concomitant with the release of bacterial toxins as well as with bacterial sepsis, which is present in up to 40% of patients (81). The involved skin is initially tender, erythematous, and warm. Edema develops and the erythema spreads diffusely, fading into normal skin, characteristically without distinct margins or induration. Subcutaneous microvascular thrombosis induces ischemia in the skin, which becomes cyanotic and blistered. Eventually, as necrosis develops, the skin becomes gangrenous and may slough spontaneously. Most patients will have leukocytosis and acid-base abnormalities. Fibrin subcutaneous may develop, which may be identified by palpation and by radiograph. The finding of subcutaneous gas by radiograph is often indicative of clostridial infection, although it is not a specific finding and may be caused by other organisms. These organisms include Enterobacter, Pseudomonas, anaerobic streptococci, and Bacteroides (82) which, unlike clostridial infections, spare the muscles underlying the affected area. A tissue biopsy specimen for Gram stain and aerobic and anaerobic culture should be obtained from the necrotic center of the lesion in order to identify the etiologic organisms (77). Although necrotizing fasciitis is often diagnosed during surgery, a high index of suspicion as well as liberal use of frozen-section biopsy can often provide an early life-saving diagnosis and minimize morbidity (83).

Predisposing risk factors for necrotizing fasciitis include diabetes mellitus, alcoholism, an immunocompromised state, hypertension, peripheral vascular disease, intravenous drug abuse, and obesity (74,75,78,82,84). The most frequent site of infection has been in the extremities (77), but the infection can occur anywhere in the subcutaneous tissues, including the head and neck, trunk, and perineum. Necrotizing fasciitis has been known to occur after trauma, surgery, burns, and lacerations; as a secondary complication in perirectal infections or Bartholin duct abscesses; and de novo (74,75,76,77,83). Increased age, delay in diagnosis, inadequate debridement during initial surgery, extensive disease at the time of diagnosis, and the presence of diabetes mellitus are all factors that have been associated with an increased likelihood of mortality from necrotizing fasciitis (74,81). Clearly, early diagnosis and aggressive management of this lethal disease have led to improved survival. In an earlier series, the mortality rate was consistently higher than 30%; in more recent series, the mortality rate has decreased to less than 10% (82,85,86).

Successful management of necrotizing fasciitis involves early recognition, immediate initiation of resuscitative measures (including correction of fluid, acid-base, electrolyte, and hematologic abnormalities), aggressive surgical debridement and rederbainment as necessary, and broad-spectrum antibiotic therapy. Many patients will benefit from central venous monitoring, as well as from high-caloric nutritional support.

During surgery, the incision should be made through the infected tissue down to the fascia. An ability to undermine the skin and subcutaneous tissues with digital palpation often will confirm the diagnosis. Multiple incisions can be made sequentially toward the periphery of the affected tissue until well-vascularized, healthy, resistant tissue is reached at all margins. The remaining affected tissue must be excised. The wound can then be packed and sequentially debrided on a daily basis as necessary until healthy tissue is displayed at all margins.

Hyperbaric oxygen therapy may be of some benefit, particularly in patients for whom culture results are positive for anaerobic organisms. Retrospective nonrandomized studies (74,87) have demonstrated that the addition of hyperbaric oxygen therapy to surgical debridement and antimicrobial therapy appears to significantly decrease both wound morbidity and overall mortality in patients with necrotizing fasciitis. The demonstrated benefit of hyperbaric therapy in one study (74) was remarkable, given that patients receiving hyperbaric oxygen were sicker and had a higher incidence of diabetes mellitus, leukocytosis, and shock.

After the initial resuscitative efforts and surgical debridement, the primary concern is the management of the open wound. Allograft and xenograft skin can be used to cover open wounds, thus decreasing heat and evaporative water loss. Interestingly, temporary biologic closure of open wounds also seems to decrease bacterial growth (88). Amniotic membranes have also been shown to be an effective wound covering in patients with necrotizing fasciitis (84). Recently a new technology has been developed to expedite wound healing. The vacuum-assisted closure (VAC) method is a subatmospheric pressure technique that has been demonstrated in laboratory and clinical studies to significantly improve wound healing. The VAC device as a method for wound control has demonstrated significant promotion of wound healing in laboratory and clinical studies (89,90). In situations in which spontaneous closure is not likely, the VAC device may allow for the development of a suitable granulation bed and prepare the tissue for graft placement, thereby increasing the probability of graft survival. Finally, skin flaps can be mobilized to help cover open wounds once the infections have resolved and granulation has begun.

**Gastrointestinal Preparation**

Preparation of the lower gastrointestinal tract prior to elective gynecologic surgery has several goals. In most gynecologic surgery, when the gastrointestinal tract is not involved in the resection of the bowel, preparation of the gastrointestinal tract allows for a more atraumatic surgical procedure. If a rectosigmoid colon enterotomy occurs, the mechanical bowel preparation eliminates formed stool and thus allows for atraumatic gastrointestinal tract manipulation. When compared to atraumatic gastrointestinal tract manipulation, the use of oral antibiotics 24 hours prior to colonic resection has reduced the infection rate from approximately 40%, to 5% to 10%, in randomized trials. Because these oral antibiotics are poorly absorbed and many do little to reduce infection from vaginal contamination, an intravenous antibiotic (first-generation cephalosporin) can be added to the preoperative regimen. Antibiotic bowel prophylaxis should be used.

</table>

High infection rates after colonic surgery have led to investigation of methods aimed at reducing these significant complications. Although mechanical bowel preparation is an essential part of all colonic surgery preparation regimens, it does not reduce the infection rate satisfactorily. Reduction of the number of pathogenic flora in the colon is the primary strategy to reduce infection after colonic surgery. The colon has the greatest concentration of bacteria in the body, including both aerobes and anaerobes. Anaerobes outnumber aerobes by 1,000:1. After reducing the bacterial load by mechanical preparation, the administration of antibiotics can further reduce the bacterial count in the colon. Of the many trials reported, the most widely accepted regimen combines erythromycin base and neomycin administered orally (Table 19.7) (83,84, and 85). Many surgeons substitute metronidazole for the erythromycin; there is no significant difference in infection rates, but patients tolerate metronidazole better than erythromycin. The use of oral antibiotics 24 hours prior to colonic resection has reduced the infection rate from approximately 40%, to 5% to 10%, in randomized trials. Because these oral antibiotics are poorly absorbed and many do little to reduce infection from vaginal contamination, an intravenous antibiotic (first-generation cephalosporin) can be added to the preoperative regimen. Antibiotic bowel prophylaxis should be used.
Ileus
Following abdominal or pelvic surgery, most patients will experience some degree of intestinal ileus. The exact mechanism by which this arrest and disorganization of gastrointestinal motility occurs is unknown, but it appears to be associated with the opening of the peritoneal cavity and is aggravated by manipulation of the intestinal tract and prolonged surgical procedures. Infection, peritonitis, and electrolyte disturbances may also result in ileus. For most patients undergoing common gynecologic operations, the degree of ileus is minimal and gastrointestinal function returns relatively quickly, allowing the resumption of oral intake within a few days of surgery. Patients who have persistently diminished bowel sounds, abdominal distention, and nausea and vomiting require further evaluation and more aggressive management.

Ileus is usually manifested by abdominal distention and should be evaluated initially by physical examination. Pertinent points of the abdominal examination include assessment of the quality of bowel sounds and palpation in search of tenderness or rebound. The possibility that the patient's signs and symptoms may be associated with a more serious intestinal obstruction or other intestinal complication must be considered. Pelvic examination should be performed to evaluate the possibility of a pelvic abscess or hematoma that may contribute to the ileus. Abdominal radiograph to evaluate the abdomen in the flat (supine) position as well as in the upright position usually will aid in the diagnosis of an ileus. The most common radiographic findings include dilated loops of small and large bowel as well as air-fluid layers while the patient is in the upright position. Sometimes, massive distention of the colon or stomach may be noted. The remote possibility of distal colonic obstruction suggested by a dilated cecum should be excluded by rectal examination, proctosigmoidoscopy, or barium enema. In the postoperative gynecology patient, especially in the upright position, the flat plate of the abdomen may also show evidence of free air. This is a common finding following surgery, which lasts 7 to 10 days in some instances and is not indicative of a perforated viscus in most patients.

The initial management of a postoperative ileus is aimed at gastrointestinal tract decompression and maintenance of appropriate intravascular replacement fluids and electrolytes.

1. A nasogastric tube should evacuate the stomach of its fluid and gaseous contents. Prolonged nasogastric suction continues to remove swallowed air, which is the most common source of air in the small bowel. Some clinicians prefer to use a longer small intestinal tube (Cantor or Miller-Abbott tube) (96). This tube, which usually has a mercury-filled bag on its distal tip, may be propelled by peristalsis through the pylorus and into the small bowel, thus allowing a better evacuation of the small bowel. The disadvantage of long tubes is that they take a longer time to become positioned and may not enter the small bowel as a result of the decreased intestinal motility associated with ileus.

2. Fluid and electrolyte replacement must be adequate to keep the patient well perfused. Significant amounts of third-space fluid loss occur in the bowel wall, and the peritoneal cavity. Diarrheal fluid losses from the stomach may lead to a metabolic alkalosis and depletion of other electrolytes as well. Careful monitoring of serum chemistry levels and appropriate replacement are necessary.

3. Most cases of severe ileus will begin to improve over a period of several days. In general, this is recognized by reduction in the abdominal distention, return of normal bowel sounds, and passage of flatus or stool. Follow-up abdominal radiographs should be obtained as necessary for further monitoring.

4. When the gastrointestinal tract function appears to have returned to normal, the nasogastric tube may be removed and a liquid diet may be instituted.

5. If a patient shows no evidence of improvement before the first 48 to 72 hours of medical management, other causes of ileus should be sought. Such cases may include ureteral injury, peritonitis from pelvic infection, unrecognized gastrointestinal tract injury with peritoneal spill, or fluid and electrolyte abnormalities such as hypokalemia. With persistent ileus, the use of water-soluble upper gastrointestinal contrast studies may assist in the resolution, but prospective randomized data regarding this maneuver are lacking.

Small Bowel Obstruction
Obstruction of the small bowel following major gynecologic surgery occurs in approximately 1% to 2% of patients (97). The most common cause of small bowel obstruction is adhesions to the operative site. If the small bowel becomes adherent in a twisted position, partial or complete obstruction may result from distention, ileus, or bowel wall edema. Less common causes of postoperative small bowel obstruction include entrapment of the small bowel into an incisional hernia and an unrecognized defect in the small bowel or large bowel mesentery. Early in its clinical course, a postoperative small bowel obstruction may exhibit signs and symptoms identical to those of ileus. Initial conservative management as outlined for the treatment of ileus is appropriate. Because of the potential for mesenteric vascular occlusion and resulting ischemia or perforation, worsening symptoms of abdominal pain, progressive distention, fever, leukocytosis, or acidosis should be evaluated carefully because immediate surgery may be required.

In most cases of small bowel obstruction following gynecologic surgery, the obstruction is only partial and the symptoms usually resolve with conservative management.

1. Further evaluation after several days of conservative management may be necessary. Evaluation of the gastrointestinal tract with barium enema and an upper gastrointestinal study with small bowel assessment are appropriate. In most cases, complete obstruction is not documented, although a narrowing or tethering of the segment of small bowel may indicate the site of the problem.

2. Further conservative management with nasogastric decompression and intravenous fluid replacement may allow time for bowel wall edema or torsion of the mesentery to resolve.

3. If resolution is prolonged and the patient's nutritional status is marginal, the use of total parenteral nutrition may be necessary.

4. Conservative medical management of postoperative small bowel obstruction usually results in complete resolution. However, if persistent evidence of small bowel obstruction remains after full evaluation and an adequate trial of medical management, exploratory laparotomy may be necessary to surgically evaluate and manage the obstruction. In most cases, lysis of adhesions is all that is required, although a segment of small bowel that is badly damaged or extensively sclerosed from adhesions may require resection and reanastomosis.

Colonic Obstruction
Postoperative colonic obstruction following surgery for most gynecologic conditions is exceedingly rare. It is almost always associated with a pelvic malignancy, which in most cases will have been known at the time of the initial operation. Advanced ovarian carcinoma is the most common cause of colonic obstruction in postoperative gynecologic surgery patients, and it is caused by extrinsic impingement on the colon by the pelvic malignancy. Intrinsic colonic lesions may be undetected, especially in a patient with some other benign gynecologic condition. When colonic obstruction is manifested by abdominal distention and abdominal radiographs reveal a dilated colon and enlarging cecum, further evaluation of the large bowel is required by barium enema or colonoscopy. Dilation of the cecum to more than 10 to 12 cm in diameter as viewed by abdominal radiograph requires immediate evaluation and surgical decompression by performing colectomy or colostomy. Surgery should be performed as soon as the obstruction is documented. Conservative management of colonic obstruction is not appropriate because the complications of colonic perforation has an exceedingly high mortality rate.

Diarrhea
Episodes of diarrhea often occur following abdominal and pelvic surgery as the gastrointestinal tract returns to its normal function and motility. However, prolonged and multiple episodes may represent a pathologic process such as impending small bowel obstruction, colonic obstruction, or pseudomembranous colitis. Excessive amounts of diarrhea should be evaluated by abdominal radiographs and stool samples tested for the presence of ova and parasites, bacterial culture, and Clostridium difficile toxin. Proctoscopy and colonoscopy may also be advisable in severe cases. Evidence of intestinal obstruction should be managed as outlined previously. Infectious causes of diarrhea should be managed with the appropriate antibiotics as well as fluid and electrolyte replacement. C. difficile-associated pseudomembranous colitis may result from exposure to any antibiotic. Discontinuation of these antibiotics (unless they are needed for another severe infection) is advisable, along with the institution of appropriate therapy. Oral metronidazole is a suitable agent for instituting therapy and is less expensive than vancomycin. Therapy should be continued until the diarrhea abates and several weeks of oral metronidazole may be required in order to obtain complete resolution of the pseudomembranous colitis.

for patients who are likely to undergo colorectal surgery (pelvic exenteration, ovarian cancer debulking) and those who are at high risk for rectal injury (such as severe cases of endometriosis or pelvic inflammatory disease).
Fistula

Gastrointestinal fistulas are relatively rare following gynecologic surgery. They are most often associated with malignancy, prior radiation therapy, or surgical injury to the large or small bowel that was improperly repaired or unrecognized. Signs and symptoms of gastrointestinal fistula are often similar to those of small bowel obstruction or enterocutaneous fistula from a previous abdominal surgery. The presence of a fistula is usually associated with new-onset or worsening of patient's symptoms. When the fistula is suspected, postoperatively, evaluation should include early assessment of the gastrointestinal tract to confirm its continuity. When fistula is suspected, the use of water-soluble gastrointestinal contrast material is advised to avoid the complication of barium peritonitis. Evaluation with abdominal pelvic CT scan may also assist in identification of a fistula and associated abscess. Recognition of an intrauterine gastrointestinal leak or fistula formation usually requires immediate surgery, unless the fistula has drained spontaneously through the abdominal wall or vaginal cuff.

An enterocutaneous fistula arising from the small bowel and draining spontaneously through the abdominal incision may be managed successfully with medical therapy. Therapy should include nasogastric decompression, replacement of intraoperative fluids as well as TPN, and appropriate antibiotics to treat an associated medical infection. If the infection is under control and there are no other signs of peritonitis, the surgeon may consider allowing potential resolution of the fistula over a period of up to 2 weeks. Some authors have suggested the use of somatostatin to decrease intestinal tract secretion and allow earlier healing of the fistula. In some cases, the fistula will close spontaneously with this mode of management. If the enterocutaneous fistula does not close with conservative medical management, surgical correction with resection, bypass, or reanastomosis will be necessary.

A rectovaginal fistula that occurs following gynecologic surgery is usually the result of surgical trauma that may have been aggravated by the presence of extensive adhesions in the rectovaginal septum associated with endometriosis, pelvic inflammatory disease, or pelvic malignancy. A small rectovaginal fistula may be managed with a conservative medical approach, in the hope that decreasing the fecal stream will allow closure of the fistula. A small fistula that allows continuity except for an occasional leak of flatus may be managed conservatively until the inflammatory process in the pelvis resolves. At that point, usually several months later, correction of the fistula is appropriate. Large rectovaginal fistulas for which there no hope of spontaneous closure are best managed by performing an initial diverting colostomy followed by repair of the fistula after inflammation has resolved. After the fistula closure is healed and deemed successful, the colostomy can be closed.

Thromboembolism Prophylaxis

Risk Factors

Deep venous thrombosis and pulmonary embolism, although largely preventable, are significant complications in postoperative patients. The magnitude of this problem is relevant to the gynecologist, because 40% of all deaths following gynecologic surgery are directly attributed to pulmonary embolism (99). Pulmonary embolism is also the second leading cause of death in women who undergo a legally induced abortion (99) and the most frequent cause of postoperative death in patients with uterine (100) or cervical carcinoma (101).

The causal factors of venous thrombosis were first proposed by Virchow in 1858 and include the following: a hypercoagulable state, venous stasis, and vessel intima injury. Two prospective studies have evaluated risk factors associated with the postoperative occurrence of deep vein thrombosis in patients undergoing gynecologic surgery. In one study, the risk factors of 124 patients undergoing vaginal and abdominal surgery for benign gynecologic disease were studied (102). Five factors were identified to be associated with postoperative deep venous thrombosis: (a) increasing age, (b) presence of varicose veins, (c) being overweight, (d) prolonged euglobulin lysis time, and (e) presence of serum fibrin-related antigen. In another prospective study, the risk factors associated with venous thromboembolic complications were also assessed in 411 patients undergoing major abdominal and pelvic surgery (103). Preoperative risk factors identified in this study include advanced age; nonwhite race; increasing stage of malignancy; history of deep venous thrombosis, lower extremity edema, or venous stasis changes; presence of varicose veins; being overweight; and a history of radiation therapy. Intraoperative factors associated with postoperative deep venous thrombosis included increased anesthesia time, increased blood loss, and the need for transfusion in the operating room. It is important to recognize these risk factors in order to provide the appropriate level of venous thrombosis prophylaxis.

Prophylactic Methods

During the past 2 decades, a number of prophylactic methods have undergone clinical trials that showed significant reduction in the incidence of deep venous thrombosis, and a few studies have demonstrated a reduction in fatal pulmonary embolism (100,101,102). More than 25 controlled trials have demonstrated that low-dose heparin is effective in reducing the incidence of deep venous thrombosis. The value of low-dose heparin in preventing fatal pulmonary embolism was established by a randomized, controlled, multicenter international trial that showed a significant reduction in fatal postoperative pulmonary embolism in general surgery patients receiving low-dose heparin every 8 hours postoperatively (104). Trials of low-dose heparin use in gynecologic surgery patients are limited, and a clear consensus regarding the value of low-dose heparin in all groups of patients has not been established because of differences in patient selection and length of follow-up. Three randomized controlled studies used the same regimen of low-dose heparin administration: 5,000 units subcutaneously every 2 hours preoperatively and every 12 hours for 7 days postoperatively. Two trials were conducted in patients with benign gynecologic conditions (98%); all patients were older than 40 years of age, and follow-up was discontinued at 6 months after the end of deep venous prophylaxis. Only one of the trials demonstrated a reduction in the incidence of deep venous thrombosis in the patients treated with low-dose heparin (106). This difference was statistically significant (P = 0.05). Although this was a randomized trial, the control group contained a larger number of patients with malignancy and, when the cancer patients were excluded from the trial analysis, there was no significant value to the use of low-dose heparin in patients with benign conditions. In the other study, the nontreated control group had a 29% incidence of deep vein thrombosis compared with a 3.6% incidence in the group treated with low-dose heparin (P = 0.001) (105). A third trial evaluated a larger group of patients receiving treatment in gynecologic oncology unit, only 16% of whom had benign gynecologic conditions; follow-up included the first 6 weeks postoperatively (107). In this trial, there was no difference in the incidence of thromboembolic complications between the control group (12.4%) and the group treated with low-dose heparin (14.8%) (107).

In a subsequent trial (108), two more intense heparin regimens were evaluated in high-risk gynecologic oncology patients. Heparin was given either in a regimen of 5,000 units subcutaneously 2 hours preoperatively and every 8 hours postoperatively, or 5,000 units subcutaneously every 8 hours preoperatively (a minimum of 4 hours) and every 8 hours postoperatively. Both of these prophylaxis regimens were effective in significantly reducing the incidence of postoperative deep venous thrombosis in patients with gynecologic cancers. Although low-dose heparin is considered to have no measurable effect on coagulation, most large series have noted an increase in the bleeding complication rate, especially a higher incidence of wound hematoma. Up to 10% to 15% of otherwise healthy patients develop a transiently prolonged activated partial thromboplastin time (APTT) after 5,000 units of heparin is given subcutaneously (109). Retrospective studies have suggested that low-dose heparin contributed to an increased occurrence of lymphocytosis (110,111). A prospective study demonstrated an increase in retropertitoneal lymph drainage volume in patients treated with low-dose heparin, but was no increased in the incidence of lymphocytosis (109). Although a 2.5-fold increase in the incidence of lymphocytosis has been found in 6% of patients after low-dose heparin for greater than 4 days, it is reasonable to perform a platelet count to assess the possibility of heparin-induced thrombocytopenia.

Low-molecular-weight Heparin

Low-molecular-weight heparin (LMWH) consists of fragments of unfractionated heparin that vary in size from 4,500 to 6,500 daltons. When compared with unfractionated heparin, LMWH has more anti-Xa and less antithrombin activity, leading to less effect on partial thromboplastin time. Decreased platelet inhibition and microvascular bleeding has been noted with LMWH use, which may also lead to fewer bleeding complications (112). An increased half-life of 4 hours (in both intravenous and subcutaneous administrations) leads to increased bioavailability when compared with unfractionated heparin. The increase in half-life of LMWH...
allows the convenience of once-a-day dosing. Several commercially available LMWH preparations are internationally available but only two (i.e., enoxaparin and dalteparin) have been approved by the Food and Drug Administration for deep venous thrombosis prophylaxis in the United States.

Four randomized controlled trials have compared LMWH with unfractionated heparin in patients undergoing gynecologic surgery. All studies showed a similar incidence of deep venous thrombosis. Bleeding complications (115, 114 and 115) were also similar between the unfractionated heparin and LMWH groups. In a trial evaluating LMWH (dalteparin) in a gynecologic cancer population, the LMWH was associated with fewer bleeding complications than would have been expected. The rate of thromboembolism was approximately 2% in this collective group of 521 operative patients, with deep venous thrombosis diagnosed in 7 patients receiving unfractionated heparin and 3 patients receiving LMWH prophylaxis. A recent metaanalysis of patients undergoing general surgery and gynecologic surgery from 32 trials showed that daily LMWH prophylaxis was effective in reducing the rate of deep venous thrombosis, although there was no reduction in deep vein thrombosis in the absence of any diagnostic tests (116). Caution should be maintained in interpretation of assimilated data involving LMWH, because different anti-Xa activities are associated with the different preparations (117). In a comparison of prophylactic methods of deep venous thrombosis treatment, LMWH has been suggested by some investigators to be more cost effective than unfractionated heparin because of the convenience of once-daily dosing (118, 119).

**Mechanical Methods**

Stasis in the veins of the legs while the patient is undergoing surgery has been clearly demonstrated and continues postoperatively for varying lengths of time. Stasis occurring in the capacitance veins of the calf during surgery, in addition to the hypercoagulable state induced by surgery, are the prime factors contributing to the development of acute postoperative deep venous thrombosis. Prospective studies of the natural history of postoperative venous thrombosis have shown that the calf veins are the predominant site of thrombi and that most thrombi develop within 24 hours of surgery (120). Reduction of venous stasis in the perioperative period by various mechanical methods has been less extensively investigated than pharmacologic methods such as low-dose heparin. However, mechanical prophylactic methods may play an important role in the prevention of postoperative deep vein thrombosis.

Although probably of only modest benefit, reduction of stasis by short preoperative hospital stays and early postoperative ambulation should be encouraged for all patients. Elevation of the foot of the bed, raising the calf above heart level, allows gravity to drain the calf veins and should further reduce stasis. More active forms of mechanical prophylaxis include elastic gradient compression stockings and external pneumatic leg compression.

**Elastic Stockings** In a survey of general surgeons in the United States, gradient elastic stockings were second only to low-dose heparin as the prophylactic method of choice in high-risk and moderately high-risk surgical patients (121). The simplicity of elastic stockings and the absence of significant side effects are probably the two most important reasons that they are often included in routine postoperative care. Controlled studies of graduated pressure stockings are limited but do suggest modest benefit when they are carefully fitted (122). Poorly fitted stockings may be hazardous to some patients who develop a tourniquet effect at the knee or midthigh (89). Variations in human anatomy do not allow perfect fit of all patients to available stocking sizes.

**External Pneumatic Compression** The largest body of literature dealing with the reduction of postoperative venous stasis deals with intermittent external compression of the leg by pneumatically inflated sleeves placed around the calf or leg during intraoperative and postoperative periods. Various pneumatic compression devices and leg sleeve designs are available, and currently one method has not been shown to be superior to others. Single-chambered calf compression devices have been studied most extensively in gynecologic surgery and appear to significantly reduce the incidence of deep vein thrombosis on a level similar to that of low-dose heparin. In addition to increasing venous flow and pulsatile emptying of the calf veins, external pneumatic compression also appears to augment endogenous fibrinolysis, which may result in lysis of very early thrombi before they become clinically significant (123).

The duration of postoperative external pneumatic compression has differed in various trials. External pneumatic compression may be effective only when used in the operating room or for the first 24 hours postoperatively (124, 125), although they should remain in use in patients who are not ambulatory.

**Combination Prophylaxis**

Combination therapy using heparin and compression stockings has been utilized in other high-risk surgical patients in an attempt to diminish both the hypercoagulability and venous stasis that can be found in postoperative patients at high risk for thromboembolism. The prophylactic use of low-dose heparin has been compared with low-dose heparin combined with graduated compression stockings in deep vein thrombosis prophylaxis among general surgery patients. Willie-Jorgensen and associates (120), in an investigation involving 245 patients undergoing acute extensive abdominal operations, demonstrated that the rate of postoperative deep vein thrombosis was significantly lower among 79 patients receiving a combination regimen of graduated compression stockings and low-dose heparin (i.e., 5,000 units subcutaneously 1 hour preoperatively and 12 hours postoperatively) than patients receiving only the low-dose heparin regimen (P = 0.013). A statistically significant improvement (P < 0.05) in postoperative deep vein thrombosis was similarly noted by the same investigators in the evaluation of 176 patients undergoing elective abdominal surgery (131). A metaanalysis of six studies involving 898 general surgery patients has shown that combination therapy with low-dose heparin and graduated compression stockings provides significantly better deep vein thrombosis prophylaxis postoperatively than either single modality (odds ratio 0.40; 95% CI 0.27 to 0.59) (132). Recently, a multicenter prospective randomized clinical trial demonstrated that combination prophylaxis consisting of graduated compression stockings and LMWH was more effective in deep vein thrombosis prevention than graduated compression stockings alone (relative risk 0.52; 95% CI 0.17 to 0.95, P = 0.04) (133). Such combination prophylaxis might be considered in the highest risk gynecologic oncology patients, although the efficacy, risks, and costs have not been studied.

**Management of Postoperative Deep Venous Thrombosis and Pulmonary Embolism**

Because pulmonary embolism is the leading cause of deaths following gynecologic surgical procedures, identification of high-risk patients and the use of prophylactic venous thromboembolism regimens is an essential part of management (89,100,101). In addition, the early recognition of deep vein thrombosis and pulmonary embolism and immediate treatment are critical. Although pulmonary emboli arise from the deep venous system of the leg, following gynecologic surgery the pelvic veins are a known source of fatal pulmonary embol as well.

The signs and symptoms of deep venous thrombosis of the lower extremities include pain, edema, erythema, and prominent vascular pattern of the superficial veins. These signs and symptoms are relatively nonspecific; 50% to 80% of patients with these symptoms will not actually have deep vein thrombosis (134). Conversely, approximately 80% of patients with symptomatic pulmonary emboli have no signs or symptoms of thrombosis in the lower extremities (135). Because of the lack of specificity when signs and symptoms are recognized, additional diagnostic tests should be performed to establish the diagnosis of deep vein thrombosis.

**Venography** Although venography has been the gold standard for diagnosis of deep vein thrombosis, other diagnostic studies are accurate when performed by a skilled technologist and, in most patients, may replace the need for routine contrast venography. Venography is moderately uncomfortable, requires the injection of a contract material that may cause allergic reaction or renal injury, and may result in phlebitis in approximately 5% of patients (136). Fortunately, newer diagnostic tests...
have been developed that are less invasive yet have a high accuracy rate in most patients.

**Doppler Ultrasound** B-mode duplex Doppler imaging is currently the most common technique used in the diagnosis of symptomatic venous thrombosis, especially when it arises in the proximal lower extremity. With duplex Doppler imaging, the femoral vein can be visualized and clots may be seen directly. Compression of the vein with the transducer head decreases venous outflow resistance and allows for easier visualization of the clot; the presence of a thrombus diminishes vein wall collapsibility. Doppler imaging is less accurate when evaluating the calf venous system and the pelvic veins.

**Impedance Plethysmography** Impedance plethysmography is a noninvasive study that measures the change in electrical impedance of the lower extremities when venous blood flow and volume are altered by an occlusive cuff on the thigh. This study may be performed at the patient's bedside and repeated as often as necessary without any risk to the patient. Correlation with venography in symptomatic patients approaches 95% (138,139). The test is effective in the identification of deep venous thrombosis in the popliteal, femoral, and external iliac segments. It is less accurate (30%) in identifying calf vein thrombosis and does not identify thrombi occurring in the internal iliac venous system. False-positive results are primarily due to extrinsic venous compression. In gynecology, this might include a large pelvic mass compressing the external iliac or common iliac vein.

**Magnetic Resonance Imaging** MRI has a sensitivity and specificity comparable to venography. In addition, MRI may detect thrombi in pelvic veins which are not imaged by venography (140). The primary drawback to MRI is the time involved in examining the lower extremity and pelvis as well as the expense of this technology.

### Deep Venous Thrombosis

The treatment of postoperative deep venous thrombosis requires the immediate institution of anticoagulant therapy. Treatment may be with either unfractionated heparin or LMWHs, followed by 3 to 6 months of oral anticoagulant therapy with warfarin.

#### Unfractionated Heparin

After venous thromboembolism is diagnosed, unfractionated heparin should be initiated to prevent proximal propagation of the thrombus and allow physiologic thrombolytic pathways to dissolve the clot. After an initial bolus of 5,000 units intravenously, a continuous infusion of 30,000 units per day should be implemented and dosage adjusted to maintain APTT levels at a therapeutic range of 1.5 to 2.5 times the control value. Patients having subtherapeutic APTT levels in the first 24 hours have a risk of recurrent thromboembolism 15 times the risk of patients with appropriate levels. Administration of subcutaneous heparin also results in a higher likelihood of subtherapeutic prophylaxis when compared with continuous intravenous infusion. Thus management should entail aggressive use of intravenous heparin to achieve prompt anticoagulation. Oral anticoagulant (warfarin) should be started on the first day of heparin infusion. International normalized ration (INR) should be monitored daily until a therapeutic level is achieved. The change in the INR resulting from warfarin administration often precedes the anticoagulant effect by approximately 2 days, during which time low protein C levels are associated with a transient hypercoagulable state. Therefore, heparin should be administered until the patient has maintained a therapeutic range at least 2 days, or confirming the proper warfarin dose. Intravenous heparin may be discontinued in 5 days if an adequate INR level has been established. Patients experiencing a thromboembolic event for the first time should take warfarin for approximately 3 to 6 months to prevent recurrent thromboembolism. Longer periods of anticoagulation should be considered in patients experiencing a recurrence. Indefinite anticoagulation has not been shown to decrease the risk of deep venous thrombosis recurrence, and the risks of bleeding are increased in patients who maintain prolonged therapy.

#### Low-molecular-weight Heparin

LMWH has been shown to be effective in the treatment of venous thromboembolism and has a cost-effective advantage over intravenous heparin in that it may be administered in the outpatient setting. The dosages used in treatment of thromboembolism are unique and weight adjusted according to each LMWH preparation. Because LMWH has a minimal effect on APTT, serial laboratory monitoring of APTT levels is not necessary. Similarly, monitoring of anti-Xa activity has not been shown to be of benefit in a dose adjustment of LMWH. The increased bioavailability associated with LMWH allows for once- or twice-daily dosing, potentially making outpatient management for a subset of patients an option. A metaanalysis involving more than 1,000 patients from 19 trials suggests that LMWH is more effective in preventing recurrent thromboembolism, safer, and less costly when compared with unfractionated heparin.

### Pulmonary Embolism

Many of the signs and symptoms of pulmonary embolism are associated with other, more commonly occurring pulmonary complications following surgery. The classic findings of pleuritic chest pain, hemoptysis, shortness of breath, tachycardia, and tachypnea should alert the physician to the possibility of a pulmonary embolism. Many times, however, the signs are much more subtle and may be suggested only by a persistent tachycardia or a slight elevation in the respiratory rate. Patients suspected of pulmonary embolism should be evaluated initially by chest radiography, electrocardiography, and arterial blood gas assessment. Any evidence of abnormality should be further evaluated by ventilation–perfusion lung scan, searching for evidence of decreased perfusions in areas of adequate ventilation. Unfortunately, a high percentage of lung scans may be interpreted as indeterminate. In this setting, careful clinical evaluation and judgment are required to decide whether pulmonary arteriography should be obtained to document or exclude the presence of a pulmonary embolism.

The treatment of pulmonary embolism is as follows:

1. Immediate anticoagulant therapy, identical to that outlined for the treatment of deep vein thrombosis, should be initiated.
2. Supplemental oxygen, including respiratory support, including intubation and mechanical ventilation, may be necessary.
3. Although massive pulmonary emboli are usually quickly fatal, pulmonary embolectomy has been performed successfully on rare occasions.
4. Pulmonary artery catheterization with the administration of thrombolytic agents bears further evaluation and may be important in patients with massive pulmonary embolism.
5. A vena cava interruption may be necessary in situations in which anticoagulant therapy is ineffective in the prevention of rethrombosis and repeated embolization from the lower extremities or pelvis. A vena cava umbrella or filter may be situated percutaneously or a large clip can be used to obstruct the vena cava above the level of the thrombus. In most cases, however, anticoagulant therapy is sufficient to prevent repeat thrombosis and embolism and to allow the patient’s own endogenous thrombolytic mechanisms to lyse the pulmonary embolus.

### Management of Medical Problems

#### Endocrine Disease

The three most frequent endocrine disorders that occur in patients undergoing gynecologic surgery are diabetes mellitus, thyroid disease, and adrenal abnormalities. The pathophysiology of these disorders aids in understanding the effects of surgery on patients with these problems.

#### Diabetes Mellitus

It is estimated that approximately six million people in the United States (2.5% of the population) have diabetes mellitus (DM) and that about one-half of these individuals will undergo surgery at some point in their lives. Approximately 75% of individuals with DM will have surgery after they are 50 years of age. Many of these procedures are a direct result of the complications of DM: retinopathy, nephropathy, large- and small-vessel occlusive disease, and coronary artery disease. It is the direct effect of DM on the end organs that determines the risk of surgery rather than the type or duration or the control of the condition itself.

Diabetes mellitus is a complicated medical disorder of glucose metabolism that is related to a lack of production of or resistance to insulin. Patients with DM experience exaggerated hyperglycemia during surgery. This hyperglycemia is multifactorial in origin and is secondary to increased catecholamine production, which inhibits pancreatic secretion and secretion of growth hormone, and glucagon also enhance gluconeogenesis and glycogenolysis. Goals of the preoperative assessment and perioperative management are to ensure metabolic homeostasis and to anticipate problems arising from preexisting complications.

#### Preoperative Risk Assessment

Large- and small-vessel arterial occlusive disease is the single most important risk factor in the preoperative setting. A careful history and physical examination should be performed to determine the presence or absence of coronary artery or cerebral vascular disease. Assessment of end-organ disease in the retina, kidney, and carotid arteries, or evidence of peripheral vascular disease by the presence of foot ulcers, should alert the clinician to the possibility of small- or large-vessel
Adrenal insufficiency may result in catastrophic postoperative complications, including death. In patients undergoing surgery, insufficiency most often occurs secondary to the exogenous use of glucocorticoids. Therefore, the physician should ascertain whether a patient has used exogenous steroids for asthma, malignant conditions, arthritis, or irritable bowel syndrome. The type of steroid use, the route, the dose, the duration, and the temporal relationship to the timing of the surgical procedure must be determined. The classification of the surgical procedure and its associated stress should also be taken into consideration. High doses of exogenous steroids for prolonged periods can cause circulatory collapse, and they have adverse effects on wound healing and immunocompetence.
The daily replacement dose of cortisol is approximately 5 to 7.5 mg of prednisone. Suppression of the hypothalamic–pituitary–adrenal axis for more than a few weeks may produce relative adrenal insufficiency. When systemic steroids are used for longer periods, adrenal insufficiency may persist for up to 1 year (154). A number of biochemical tests have been recommended to preoperatively evaluate the function of the adrenal gland. The easiest and safest test to assess hypothalamic–pituitary–adrenal function is the cosyntropin stimulation test. Cosyntropin, a synthetic analog of adrenocorticotropic hormone, is given in a dose of 250 μg intravenously, and a blood sample is collected 30 minutes after the injection and assayed for plasma cortisol. A plasma cortisol value of >500 nmol/L (18 to 20 μg/dL) indicates adequate adrenal function (155). If the history regarding exogenous steroid use is unclear, then the cosyntropin stimulation test should be performed preoperatively to determine if the patient will need perioperative glucocorticoid coverage.

Guidelines for perioperative steroid coverage have been recommended by Salem and co-workers based on clinical and research findings (156). The amount of glucocorticoid replacement should be equivalent to the normal physiologic response to surgical stress. In response to major surgical procedures, adults secrete 75 to 150 mg glucocorticoid a day. In contrast, during minor procedures only 50 mg of glucocorticoid is released (156). For minor surgical stress, the glucocorticoid target is approximately 25 mg of hydrocortisone preoperatively and then resume the normal glucocorticoid dose the next day. For moderate surgical stress (i.e., as with abdominal hysterectomy) the glucocorticoid target is 50 to 75 mg of hydrocortisone equivalent per day for 1 to 2 days. The patient should receive her normal daily dose preoperatively, followed by 50 mg of hydrocortisone intravenously administered during surgery. Salem and co-workers recommended that patients should receive 60 mg hydrocortisone (20 mg every 8 hours) intravenously on postoperative day 1 and then return to their preoperative dose, given either enterally or parenterally on postoperative day 2. For major surgical stress, the glucocorticoid target range is 100 to 150 mg hydrocortisone equivalent per day for 2 to 3 days. The patient should receive her normal daily dose within 2 hours preoperatively, followed by 50 mg of hydrocortisone intravenously every 8 hours after the initial dose for the first 2 to 3 days after surgery (155).

Whether patients need even this amount of perioperative steroids is unknown. A randomized blinded trial evaluating perioperative steroid use in patients with secondary adrenal insufficiency was performed at the Veterans Affairs Medical Center. Patients who had been taking at least 7.5 mg of prednisone daily and had secondary adrenal insufficiency were randomized to two groups. The subjects underwent major surgical procedures; one group received perioperative saline injections and the other received cortisol. All patients received their usual daily steroid dose. Two patients had hypotension, one from each group, which was reversible with fluid replacement. When given their daily dose of steroids for surgical procedures, patients with secondary adrenal insufficiency do not experience serious hypotension secondary to insufficient glucocorticoid levels (157). Therefore, perioperative glucocorticoid coverage should be individualized, based on the patient’s preoperative dosage requirements and the type of surgical procedure (156).

Administration of high-dose steroids should be stopped as soon as possible postoperatively because it can inhibit wound healing and promote infection. Hypertension and glucose intolerance also can develop. If it is safe to abruptly discontinue steroid use after a few days of therapy, Addison’s disease is uncommon but should be considered in the differential diagnosis if the patient develops perioperative hypotension. In addition to blood and isotonic fluid replacement, a “stress” dose of steroids should be given if adrenal insufficiency is suspected and sepsis and hypovolemia have been excluded.

When a prolonged or involved procedure is performed and longer steroid use is necessary, careful tapering will be required. The recommended approach is to halve the dose of hydrocortisone on a daily basis until a dose of 25 mg is reached. Eliminating one dose each day until the drug has been stopped is the safest method of withdrawal.

Cardiovascular Diseases

The incidence of perioperative cardiovascular complications has decreased markedly as a result of improvements in preoperative detection of high-risk patients, preoperative preparation, and surgical and anesthetic techniques (158).

Preoperative Evaluation

The goal of a preoperative cardiac evaluation is to determine the presence of heart disease, its severity, and the potential risk to the patient during the perioperative period. Every patient should be questioned about symptoms of cardiac disease including chest pain, dyspnea on exertion, peripheral edema, wheezing, syncope, claudication, or palpitations. Patients with a history of cardiac disease should be evaluated for worsening of symptoms, which indicates progressive or poorly controlled disease. Records of previous treatment should be obtained. Prescriptions for antihypertensive, anticoagulant, antiarrhythmic, antianginal, or anxiolytic medications may be the only indication of cardiac problems. In patients without known heart disease, the presence of DM, hyperlipidemia, hypertension, tobacco use, or a family history of heart disease identifies a group of patients at higher risk for heart disease who should be more carefully screened.

On physical examination, the presence of findings such as hypertension, jugular venous distention, laterally displaced point of maximum impulse, irregular pulse, third heart sound, pulmonary rales, heart murmurs, peripheral edema, or vascular bruises should prompt a more complete evaluation. Laboratory evaluation of patients with known or suspected heart disease should include a blood count and serum chemistry analysis. Patients with heart disease tolerate anemia poorly. Serum sodium and potassium levels should be checked. BUN and creatinine values provide information on renal function and hydration status. Assessment of blood glucose levels may detect undiagnosed DM. Chest radiograph and electrocardiography are mandatory as part of the preoperative evaluation, and the results may be particularly helpful when compared with those of previous studies.

Coronary Artery Disease

Coronary artery disease is a major risk factor for patients undergoing abdominal surgery. In an adult population without a prior history of myocardial infarction, the incidence of myocardial infarction following surgery is 0.1% to 0.7% (159). In patients who have had a prior myocardial infarction, however, the reinfarction rate is 2.8% to 7% (160). The risk of reinfarction is inversely proportional to the length of time between infarction and surgery. At 3 months or less, the risk of reinfarction is 5.7%, and from 3 to 6 months, the rate falls to 2.3%. Six months after myocardial infarction, the reinfarction rate is 1.5% (159). Fortunately, careful perioperative management can lower the reinfarction rate even in patients who have had recent infarctions. Perioperative myocardial infarction is associated with a mortality rate of 26% to 70% (160).

Because of the high mortality and morbidity associated with perioperative myocardial infarction, much effort has been made to predict perioperative cardiac risk. A prospective evaluation of preoperative cardiac risk factors using a multivariate analysis identified independent cardiac risk factors for patients undergoing noncardiac surgery (161). Using these factors, a cardiac risk index was created that placed a patient in one of four risk classes. High-risk clinical factors included age over 70 years, myocardial infarction within 6 months prior to surgery, congestive heart failure, and atrial and ventricular arrhythmias. More recent studies have added to and modified the commonly accepted list of risk factors, which are listed in Table 19.8 (160). Additional risk factors include unstable angina, DM, uncontrolled hypertension, history of stroke, and abnormal electrocardiogram.

*Table 19.8: Risk Factors for Perioperative Cardiovascular Risk* (160)
In addition to clinical predictors, cardiac risk is also determined by the risk level of the proposed operation and the functional capacity of the patient. High-risk procedures include emergent major operations, aortic and vascular procedures, and prolonged surgical procedures associated with large fluid shifts or blood loss. Intermediate-risk procedures include other intraperitoneal operations, whereas low-risk procedures include endoscopic surgery, breast surgery, and superficial procedures. The patient’s functional status is assessed by a thorough history; risk classification is unambiguous in Table 19.9. Patients with poor functional capacity have higher perioperative cardiac risk and should be considered for preoperative cardiac function testing (160).

Table 19.9. Functional Capacity Assessment from Clinical History (160)

In an effort to quantitate preoperative cardiac risk, several tests have been used to assess cardiovascular function. Exercise stress testing prior to surgery can identify patients who have ischemic heart disease not apparent at rest. These patients have been shown to be at increased risk of developing cardiac complications in the perioperative period. In a study of patients undergoing peripheral vascular surgery, a high-risk group of patients was identified who had ischemic electrocardiographic changes when they exercised to less than 75% of their maximal predicted heart rate. In this group, the incidence of perioperative myocardial infarction was 25% and the overall cardiac mortality rate was 18.5%. Conversely, no perioperative infarctions occurred in patients who were able to exercise to more than 75% of their maximal predicted heart rate and who had no electrocardiographic evidence of ischemia (162). However, the prognostic value of stress testing was not supported in another study. It was found that only an abnormal preoperative resting electrocardiogram was an independent risk factor (163). The exercise stress test must be selectively applied to a high-risk population because its predictive value is dependent upon the prevalence of the disease. Therefore, it is not prudent to screen all patients preoperatively; it is preferable to rely on a careful history to identify patients with symptoms of cardiac disease for whom the test would be most predictive.

Exercise stress testing is limited in some patients who cannot exercise because of musculoskeletal disease, pulmonary disease, or severe cardiac disease. Dipyridamole-thallium scanning may be used to overcome the limitations of exercise stress testing. This study has a high degree of sensitivity and specificity, and it relies on the ability of dipyridamole to dilate normal coronary arteries but not stenotic vessels. Normally perfused myocardium readily takes up thallium when it is given intravenously. Conversely, hyperperfused myocardium does not demonstrate good uptake of thallium when scanned 5 minutes after injection. Reperfusion and uptake of thallium 3 hours after injection identify viable but high-risk myocardium. Old infarctions are identified as areas without uptake. Several studies have shown a risk of perioperative myocardial infarction in patients with areas of reperfusion of thallium uptake ranging from 20% to 33% (164,165). The dipyridamole-thallium scan is applicable for patients who are unable to exercise because it uses a medically induced “stress.”

Dobutamine stress echocardiography is another test to evaluate cardiac risk in patients who are unable to exercise. This method identifies regional cardiac wall motion abnormalities after dobutamine infusion to identify patients at high risk for cardiac events. Positive and negative predictive values are similar to those of dipyridamole-thallium testing (166,167).

It is rare for patients who are younger than 50 years and who do not have diabetes, hypertension, hypercholesterolemia, or coronary artery disease to suffer a perioperative myocardial infarction. However, patients with coronary artery disease are at increased risk of myocardial infarction in the postoperative period. Prevention, early recognition, and treatment are important, because myocardial infarctions that occur in the postoperative period have mortality rates of approximately 50% and are more lethal than those that are not associated with surgery.

Nearly two-thirds of postoperative myocardial infarctions occur during the first 3 days postoperatively. Although the pathophysiologic factors are complex, the causes of postoperative myocardial ischemia and infarction are related to decreased myocardial oxygen supply coupled with increased myocardial oxygen requirements. In postoperative patients, conditions that decrease oxygen supply to the myocardium include tachycardia, increased preload, hypotension, anemia, and hypoxia (168). Conditions that increase myocardial oxygen consumption are tachycardia, increased preload, increased afterload, and increased contractility. Tachycardia and increased preload are the most important causes of ischemia, because both conditions decrease oxygen supply to the myocardium while simultaneously increasing myocardial oxygen demand. Tachycardia decreases the diastolic time which, when the coronary arteries are perfused, decreases the volume of oxygen available to the myocardium. Increased preload increases the pressure exerted by the myocardial wall on the arterioles within it, thus decreasing myocardial blood flow.

Other factors associated with perioperative myocardial ischemia include physiologic responses to the stress of intubation, intravenous or intraarterial line placement, emergence from anesthesia, pain, and anxiety. This stress results in catecholamine stimulation of the cardiovascular system, resulting in increased heart rate, blood pressure, and contractility, which may induce or worsen myocardial ischemia. Loss of intravascular volume because of third spacing of fluids or postoperative hemorrhage can also induce ischemia.

Postoperative myocardial infarction is often difficult to diagnose. Chest pain, which is present in 90% of nonsurgical patients with myocardial infarction, may be present in only 50% of patients with postoperative infarction, because of the masking of myocardial pain by coexisting surgical pain and the use of analgesia (159). Thus, it is important to maintain a high level of suspicion for postoperative infarction in patients with coronary artery disease. The presence of arrhythmia, congestive heart failure, hypotension, dyspnea, or elevations of pulmonary artery pressure may indicate infarction and should prompt a thorough cardiac investigation and electrocardiographic monitoring. Measurement of creatinine phosphokinase myocardial band (CPK-MB) isoenzyme and troponin T levels are the most sensitive and specific indicators of myocardial infarction, and assessments should be obtained for all patients suspected of myocardial infarction.

Despite the high incidence of silent myocardial infarction, routine use of postoperative electrocardiography (ECG) for all patients with cardiovascular disease is controversial. Many patients will exhibit P-wave changes that spontaneously resolve and do not represent ischemia or infarction. Conversely, patients with proven myocardial infarctions may show few, if any, ECG abnormalities. If routine screening of asymptomatic patients is desired, ECGs should be obtained 24 hours following surgery, because it has been shown that significant ECG changes that occur immediately postoperatively will persist for 24 hours. It is prudent to continue serial ECG assessments for at least 3 days postoperatively.

Postoperative management of patients with coronary artery disease is based on maximizing delivery of oxygen to the myocardium as well as decreasing myocardial oxygen utilization. Most patients benefit from supplemental oxygen in the postoperative period, although special care should be exercised in patients with chronic obstructive pulmonary disease. Oxygenation can be easily monitored by pulse oximetry. Anemia is detrimental because of loss of oxygen-carrying capacity as well as resultant tachycardia and should, therefore, be carefully corrected in high-risk patients.

Patients with coronary artery disease may benefit from pharmacologic control of hyperadrenergic states that result from increased postoperative catecholamine production. b-Blockers decrease heart rate, myocardial contractility, and systemic blood pressure, all of which are increased by adrenergic stimulation. Perioperative b-blockade with atenolol has been shown to significantly reduce perioperative ischemia, myocardial infarction, and overall mortality caused by cardiac death and congestive heart failure in the perioperative period (169,170). For patients receiving b-blockade therapy prior to surgery, that therapy should be continued in the perioperative period because abrupt withdrawal results in a rebound hyperadrenergic state.

Although prophylactic nitrates have been used in the perioperative period for many years, this practice remains controversial. Nitroglycerin enhances blood flow to ischemic areas, increases collateral flow, increases myocardial oxygenation, and reduces angina (171,172,173,174). The route of administration, dosage, and duration of therapy are controversial; thus, perioperative treatment with nitrates should be initiated in consultation with a cardiologist. Likewise, calcium-channel
Patients with congestive heart failure (CHF) face a substantially increased risk of myocardial infarction during and after surgery (181). The postoperative development of pulmonary edema is a grave prognostic sign and results in death in a high percentage of patients (179). Because patients with heart failure at the time of surgery are significantly more likely to develop pulmonary edema perioperatively, every effort should be made to diagnose and treat CHF before surgery (177). The signs and symptoms of CHF are listed in Table 19.10 and should be assessed based on preoperative history and physical examination. Patients who are able to perform usual daily activities without developing CHF are at limited risk of perioperative heart failure.

To prevent severe postoperative complications, congestive heart failure must be corrected preoperatively. Treatment usually relies on aggressive diuretic therapy, although care must be taken to avoid dehydration, which may result in hypotension during the induction of anesthesia. Hypokalemia can result from diuretic therapy and is especially deleterious to patients who are also taking digitalis. In addition to diuretics and digitalis, treatment often includes the use of preload- and afterload-reducing agents. Optimal use of these drugs and correction of CHF may be aided by consultation with a cardiologist. In general, it is preferable to continue the usual regimen of cardioactive drugs throughout the perioperative period. In patients with severe or intractable CHF, the peroperative measurement of left ventricular filling (wedge) pressure with a pulmonary artery catheter (Swan-Ganz) may be extremely helpful to guide peroperative fluid management.

### Postoperative CHF results most frequently from excessive administration of intravenous fluids and blood products. Other common postoperative causes are myocardial infarction, systemic infection, pulmonary embolism, and cardiac arrhythmias. The cause of postoperative heart failure must be diagnosed because, to be successful, treatment should be directed simultaneously to the underlying cause.

Acute postoperative CHF frequently manifests as pulmonary edema. Treatment of pulmonary edema may include the use of intravenous furosemide, supplemental oxygen, including morphine sulfate, and elevation of the head of the bed. Intravenous aminophylline may be useful if cardiogenic asthma is present. Electrocardiography, in addition to laboratory evaluation, including arterial blood gas, serum electrolyte, and renal function chemistry measurements, should be obtained expeditiously. If the patient's condition does not improve rapidly, she should be transferred to an intensive care unit.

### Arrhythmias

Nearly all arrhythmias found in otherwise healthy patients are asymptomatic and of limited consequence. In patients with underlying cardiac disease, however, even brief episodes of arrhythmias may result in significant cardiac morbidity and mortality.

Preoperative evaluation of arrhythmias by a cardiologist and anesthesiologist is important because many anesthetic agents as well as surgical stress contribute to the development or worsening of arrhythmias. In patients undergoing continuous electrocardiographic monitoring during surgery, a 60% incidence of arrhythmias, excluding sinus tachycardia, has been reported (179). Patients with heart disease have an increased risk of arrhythmias, most commonly ventricular arrhythmias (179). Conversely, patients without cardiac disease are more likely to develop supraventricular arrhythmias during surgery. Patients taking antiarrhythmic medications prior to surgery should continue taking those drugs during the perioperative period. Initiation of antiarrhythmic medications is rarely indicated preoperatively, but consultation with a cardiologist is recommended for patients in whom arrhythmias are detected prior to surgery.

Patients with first-degree atrioventricular (AV) block or asymptomatic Mobitz I (Wenckebach) second-degree AV block require no preoperative therapy. Conversely, a pacemaker is appropriate in patients with symptomatic Mobitz II second- or third-degree AV block before elective surgery (179). In emergency situations, a pacing pulmonary artery catheter can be used. Prior to performing surgery on patients with a permanent pacemaker, the type and location of the pacemaker should be determined because electrocautery units may interfere with demand-type pacemakers (180). When performing gynecologic surgery on patients with pacemakers, it is preferable to place the electrocautery unit ground plate on the leg to minimize interference. In patients with a demand pacemaker in place, the pacemaker should be converted preoperatively to the fixed-rate mode.

Surgery is not contraindicated in patients with bundle branch blocks or hemiblocks. Complete heart block rarely develops during noncardiac surgical procedures in patients with conduction system disease (181, 182 and 183). However, the presence of a left bundle branch block may indicate the presence of aortic stenosis, which can increase surgical mortality if it is severe.

### Valvular Heart Disease

Although there are many forms of valvular heart disease, primarily two types—aortic and mitral stenosis—are associated with significantly increased operative risk (184). Patients with significant aortic stenosis appear to be at greatest risk, which is further increased if atrial fibrillation, congestive heart failure, or coronary artery disease is also present. Significant stenosis of aortic or mitral valves should be repaired prior to elective gynecologic surgery (185).

Severe valvular heart disease is usually evident during physical exertion. Common findings in such patients are listed in Table 19.11. The classic history presented by patients with severe aortic stenosis includes exercise dyspnea, angina, and syncope, whereas symptoms of mitral stenosis are paroxysmal and effort dyspnea, hemoptysis, and orthopnea. Most patients have a remote history of rheumatic fever. Severe stenosis of either valve is considered to be a valvular area of less than 1 cm², and diagnosis can be confirmed by echocardiography or cardiac catheterization.
Patients with valvular abnormalities have been subdivided by the American Heart Association into risk groups for the development of subacute bacterial endocarditis following surgery (185). Patients with prosthetic valves are classified as high risk, whereas patients with mitral valve prolapse with regurgitation, history of rheumatic heart disease, or bicuspid aortic valve are considered at moderate risk. Patients in both high- and moderate-risk groups should receive prophylactic antibiotics immediately preoperatively to prevent subacute bacterial endocarditis. Table 19.12 outlines the American Heart Association recommendations for antibiotic prophylaxis (185).

Table 19.12. Recommendations for Prophylaxis of Bacterial Endocarditis for Genitourinary and Gastrointestinal Procedures (185)

Patients with aortic and mitral stenosis tolerate sinus tachycardia and other tachyarrhythmias poorly. In patients with aortic stenosis, sufficient digitalization should be provided to correct preoperative tachyarrhythmias, and propranolol may be used to control sinus tachycardia. Patients with mitral valve stenosis often have atrial fibrillation and, if present, digitalis should be used to reduce rapid ventricular response.

Patients with mechanical heart valves usually tolerate surgery well (186). Management of these patients requires antibiotic prophylaxis (Table 19.12) and discontinuation of anticoagulant therapy during the perioperative period. Usually, warfarin (Coumadin) is withheld several days prior to surgery and anticoagulation is obtained by intravenous administration of heparin (187). The heparin is discontinued 6 to 8 hours prior to surgery and resumed a few days postoperatively (188). The patient is returned to oral warfarin maintenance therapy. Alternatively, warfarin can be stopped 1 to 3 days perioperatively and restarted several days postoperatively. Perioperative heparinization is indicated in patients who have more thrombogenic valves, such as the Starr-Edwards valve, and valves in the tricuspid position (179). Both methods of management have essentially no risk of thromboembolic complications and bleeding complication rates of approximately 15%.

In the postoperative period, patients with mitral stenosis should be carefully monitored for pulmonary edema because they may not be able to compensate for the amount of intravenous fluid administered during surgery. Patients with mitral stenosis also frequently have pulmonary hypertension and decreased airway compliance. Therefore, they may require more pulmonary support and therapy postoperatively, including prolonged mechanical ventilation.

For patients with significant aortic stenosis, it is imperative that a sinus rhythm be maintained during the postoperative period. Even sinus tachycardia can be deleterious because it shortens the diastolic time. Bradycardia less than 45 beats per minute should be treated with atropine. Supraventricular dysrhythmias may be controlled with verapamil or direct-current cardioversion. Particular attention should be provided to the maintenance of proper fluid status, digoxin levels, electrolyte levels, and blood replacement.

Hypertension

Patients with controlled essential hypertension have no increased risk of perioperative cardiac morbidity or mortality (177). However, patients with concomitant heart disease are at elevated risk and should be completely evaluated by a cardiologist preoperatively. Laboratory studies should include an ECG, chest radiograph, blood count, urinalysis, and serum electrolytes and creatinine measurement. Antihypertensive medications should be continued perioperatively. Of note, b-blockers should be continued, parenterally if necessary, to avoid rebound tachycardia, hypercontractility, and hypertension.

Patients with diastolic pressures higher than 110 mmHg or systolic pressures higher than 180 mmHg should receive medication to control their hypertension prior to surgery. Chronically hypertensive patients are very susceptible to intraoperative hypotension because of impaired autoregulation of blood flow to the brain and, therefore, require a higher mean arterial pressure to maintain adequate perfusion (189). Conversely, during induction of anesthesia episodes of hypertension occur, and such episodes are seen more frequently in patients with baseline hypertension.

Postoperative hypertension is usually treated parenterally because gastrointestinal absorption may be diminished, and transdermal absorption can be erratic in patients who are cold and rewarming. Commonly used parenteral antihypertensives are listed in Table 19.13.

Table 19.13. Common Parenteral Antihypertensives
Hemodynamic Monitoring

Hemodynamic monitoring has become integral to the perioperative management of patients with cardiovascular and pulmonary disease. The major impetus for this advancement resides in the need for the quantitative estimate of cardiac function, resulting in the development of bedside pulmonary artery catheterization. The impact of monitoring of cardiac function is demonstrated by the significant reduction of myocardial infarctions in high-risk patients who are aggressively monitored for 72 to 96 hours postoperatively (190).

Before the development of the pulmonary artery catheter, central venous pressure (CVP) measurement was used to assess intravascular volume status and cardiac function. To measure the CVP, a catheter is placed in the central venous system, most frequently the superior vena cava. A water manometer or a calibrated pressure transducer is connected to the CVP line, thus allowing an estimation of right atrial pressure to be obtained. Right atrial pressure is determined by the balance between cardiac output and venous return. Cardiac output is determined by heart rate, myocardial contractility, preload, and afterload. Thus, if the pulmonary vascularly and left ventricular function are normal, the CVP accurately reflects the left ventricular end-diastolic pressure (LVEDP). The LVEDP reflects cardiac output or systemic perfusion and has been considered the standard estimator of left ventricular pump function. Venous return is determined primarily by the mean systemic pressure, which propels blood toward the heart, balanced against resistance to venous return, which acts in the opposite direction. Thus, if right ventricular function is normal, the CVP accurately reflects intravascular volume.

Left and right ventricular function is frequently abnormal or discordant; therefore, the relationship of CVP to cardiac function and to intravascular volume is not maintained. When this occurs, measurement of pulmonary artery occlusion pressure is required to accurately assess volume status and cardiovascular function. The use of a pulmonary artery catheter also allows detection of changes in cardiovascular function with more sensitivity and rapidity than clinical observation.

The balloon-tipped pulmonary artery catheter (Swan-Ganz catheter) can provide measurement of pulmonary artery and pulmonary artery occlusion pressures (191). The catheter can measure cardiac output, be used to perform intracavitary electrocardiography, and provide temporary cardiac pacing. The standard pulmonary artery occlusion catheter is a 7-French, radiopaque, flexible, polyvinyl chloride, 4-lumen catheter with a 1.5-mm latex balloon at its distal tip. Most often, a right internal jugular cannulation is used for placement of the catheter, because this site provides the most direct access into the right atrium and has fewer complications when compared with a subclavian route of placement. After the catheter is placed into the right atrium, the balloon is inflated and the catheter is pulled by blood flow through the right ventricle into the pulmonary artery. The position of the catheter can be identified and followed by the various pressure waveforms generated by the right atrium, right ventricle, and pulmonary artery. As the catheter passes through increasingly smaller branches of the pulmonary artery, the inflated balloon eventually occludes the pulmonary artery. The distal lumen of the catheter, which is beyond the balloon, measures left atrial pressure (LAP) and, in the absence of mitral valvular disease, LAP approximates LVEDP. Thus, pulmonary–capillary wedge pressure (PCWP) equals the LAP, which equals LVEDP and is normal at 8 to 12 mm Hg. Additionally, because the standard pulmonary artery catheter has an incorporated thermistor, thermodilution studies can be performed to determine cardiac output. This thermodilution method is performed by injecting cold 5% dextrose in water through the proximal port of the catheter, which cools the blood entering the right atrium. The change in temperature measured at the more distal thermometer (4 cm from the catheter tip) generates a curve proportional to cardiac output. Knowledge of the cardiac output is helpful in establishing cardiovascular diagnoses. For example, a patient with hypotension, low-normal wedge pressure, and a cardiac output of 3 L/min is most likely hypovolemic. Conversely, the same patient with a cardiac output of 8 L/min is probably septic with resultant low systemic vascular resistance.

Pulmonary artery catheters are associated with a small but significant complication rate. The complications can be grouped into those occurring during venous cannulation and those resulting from the catheter or its placement. The most common problems encountered during venous access are cannulation of the carotid or subclavian artery and introduction of a pneumothorax. Problems resulting from the catheter itself include dysrythmias, sepsis, and disruption of the pulmonary artery. Pulmonary artery catheters should be placed under the supervision of experienced personnel in a setting in which complications can be rapidly diagnosed and treated.

The effect of pulmonary artery catheter use on patient outcome has become controversial. In 1996 Dalen and Bone recommended a reevaluation of pulmonary artery catheters and initiation of randomized clinical trials to assess their benefit (192). At that time, Connors and others published a large study demonstrating a higher mortality rate in patients who received a pulmonary artery catheter (193). The study was questioned, however, and it was retrospective and not randomized. A recent metaanalysis evaluating 12 randomized clinical trials demonstrated a statistically significant reduction in morbidity (63% versus 74%, P < 0.01) in the pulmonary artery catheter group, but no significant difference in mortality (194). Future large randomized clinical trials comparing pulmonary artery catheters to central venous catheters for the treatment of critical care patients are currently under way, and it is hoped a consensus regarding who will benefit from pulmonary artery catheters will eventually be established.

Hematologic Disorders

The presence of hematologic disorders, although uncommon in gynecologic patients, significantly affects operative morbidity and mortality and therefore should be considered routinely in preoperative evaluation. Preoperative assessment should include consideration of anemia, platelet and coagulation disorders, white blood cell function, and immunity.

Anemia

Moderate anemia is not in itself a contraindication to surgery because it can be corrected by transfusion. If possible, surgery should be postponed until the cause of the anemia can be identified and the anemia corrected without resorting to transfusion. Current anesthetic and surgical practice ideally recommend a hemoglobin level of >10 g/dl or a hematocrit of >30%. Such numbers are only guidelines, and should be applied on an individual basis. Oxygen-carrying capacity and tissue oxygenation is provided by the circulating blood volume. Usually this capacity is reflected by the hemoglobin level and hematocrit. Under certain circumstances, however, this is not the case. After an acute blood loss or before plasma expansion by extracellular fluid has occurred, hematocrit measurements may be normal despite a low circulating blood volume. Conversely, overhydration may result in low hematocrit and hemoglobin levels despite adequate red blood cell mass.

Individual tolerance of anemia depends on overall physical fitness and cardiovascular reserve. The effects of anemia depend on its magnitude, the rate at which it occurs, the oxygen requirement of the patient, and the ability of physiologic mechanisms to compensate (195). Maintenance of adequate tissue perfusion requires an increase in cardiac output as hemoglobin concentration falls (196). A patient with ischemic heart disease will not tolerate anemia as well as a healthy young patient. The presence of cardiac, pulmonary, or other serious illness justifies a more conservative approach to the management of anemia. Conversely, patients with longstanding anemia may have normal blood volume levels and tolerate surgical procedures well. There is no evidence that mild to moderate anemia increases perioperative morbidity or mortality (197).

Patients with normal hematocrit levels may store three or more units of autologous blood preoperatively to reduce the need for allogenic blood transfusion and minimize the risk of infections and immunologic problems (198). Recombinant human erythropoietin may increase collection and reduce preoperative anemia in these patients (199). Further, intraoperative blood collection and homologous transfusion can be employed to limit need for allogenic blood transfusion.

Platelet and Coagulation Disorders

Surgical hemostasis is provided by platelet adhesion to injured vessels, which plugs the opening as the coagulation cascade is activated, resulting in the formation of fibrin clots. Thus, functional platelets and coagulation pathways are necessary to prevent excessive surgical bleeding. Platelet dysfunction is encountered more frequently preoperatively than coagulation disorders.

Platelets may be deficient in both number and function. The normal peripheral blood count is 150,000 to 400,000 per mm 3, and the normal lifespan of a platelet is approximately 10 days. Although there is no clear-cut correlation between the degree of thrombocytopenia and the presence or amount of bleeding, several generalizations can be made. If the platelet count is higher than 100,000/mm 3 the platelets are functioning normally, there is little chance of bleeding during surgical procedures. Patients with a platelet count higher than 75,000/mm 3 almost always have normal bleeding times, and a platelet count higher than 50,000/mm 3 is probably adequate. A platelet count lower than 20,000/mm 3 will often be associated with severe and spontaneous bleeding. Platelet counts higher than 1,000,000/mm 3 are often, paradoxically, associated with bleeding.
If the patient's platelet count is lower than 100,000/mm³, an assessment of bleeding time should be obtained. If the bleeding time is abnormal and surgery must be performed, an attempt should be made to raise the platelet count by administering platelet transfusions immediately before surgery. In patients with immune destruction of platelets, human leukocyte antigen (HLA)-matched donor-specific platelets may be required to prevent rapid destruction of transfused platelets. If surgery can be postponed, a hematologic consultation should be obtained to identify and treat the cause of the platelet abnormality.

Abnormally low platelet counts result from either decreased production or increased consumption of platelets. Although there are numerous causes of thrombocytopenia, most are exceedingly uncommon. Decreased platelet production may be drug induced and has been associated with the use of sulfonamides, cinchona alkaloids, thiazide diuretics, nonsteroidal antiinflammatory drugs (NSAIDs), gold salts, penicillamine, antibiotics, and heparins (203). Decreased platelet count is a feature of several diseases, including vitamin B₁₂, and folate deficiency, aplastic anemia, myeloproliferative disorders, renal failure, and viral infections. Inherited congenital thrombocytopenia is extremely rare. More commonly, thrombocytopenia results from immune destruction of platelets by diseases such as idiopathic thrombocytopenia purpura and collagen vascular diseases. Consummptive thrombocytopenia is a feature of disseminated intravascular coagulation (DIC), which is encountered most frequently in conjunction with sepsis or malignancy in the preoperative population.

Platelet dysfunction is most often acquired, but may be inherited. Occasionally, a patient with von Willebrand's disease, the second most common inherited disorder of coagulation, may be encountered in the preoperative setting. Moreover, however, platelet dysfunction results from the use of drugs (e.g., aspirin and amiodarone), and patients with resulting prolonged bleeding times should have the drug withheld for 7 to 10 days before surgery. Uremia and hepatic diseases can also affect platelet function.

Platelet dysfunction is more difficult to diagnose than abnormalities of platelet count. A history of easy bruising, petechiae, bleeding from mucous membranes, or prolonged bleeding from minor wounds may signify an underlying abnormality of platelet function. Such dysfunction can be identified with the help of a bleeding time, but full characterization of the underlying etiology should be carried out with hematologic consultation. If at all possible, surgery should be postponed until therapy has been instituted.

Similarly, disorders of the coagulation cascade are often diagnosed through a personal or family history of excessive bleeding during minor surgery, childbirth, or menses. Deficiency of factor VIII (hemophilia) and factor IX (Christmas disease) are the most commonly encountered inherited disorders of coagulation. There are few commonly prescribed drugs that affect coagulation factors, the exceptions being warfarin and heparin. Disease states that may be associated with decreased coagulation factor levels are primarily liver disease, vitamin K deficiency (secondary to obstructive biliary disease, intestinal malabsorption, or antibiotic reduction of bowel flora), and DIC.

Preoperative laboratory screening for coagulation deficiencies is controversial. Routine screening in patients without historical evidence of a bleeding problem is not warranted (201). However, patients who are seriously ill or who will be undergoing extensive surgical procedures should undergo testing preoperatively to determine prothrombin time, partial thromboplastin time, fibrinogen level, and platelet count.

White Blood Cells and Immune Function

Abnormally high or low white blood cell counts are not an absolute contraindication to surgery; however, they should be considered relative to the need for surgery. Evaluation of an elevated or decreased white blood cell count should be undertaken prior to elective surgery. Clearly, patients with absolute granulocyte counts lower than 1,000/mm³ are at increased risk of severe infection and perioperative morbidity and mortality, and should undergo surgery only for life-threatening indications (205).

Blood Component Replacement

Most hematologic problems observed in the postoperative period are related to perioperative bleeding and blood component replacement. Although the primary cause of the bleeding is usually lack of surgical hemostasis, other factors, including deranged coagulation, may compound the problem. Such coagulopathy can result from massive transfusion (less than one blood volume) and is thought to be due to dilution of platelets and labile coagulation factors by platelet- and factor-poor packed red blood cells (PRBCs), fibrinolysis, and DIC.

Reports of massive transfusions in soldiers reveal that for those in whom thrombocytopenia developed following red blood cell replacement, bleeding diatheses that responded to infusion of fresh blood but not fresh-frozen plasma (FFP) also developed (203). The investigators concluded that dilutional thrombocytopenia is a major cause of posttransfusion bleeding. However, more recently, in a prospective, randomized, double-blind study, prophylactic platelet administration during massive transfusion was not helpful (204). Although it seems that these studies are contradictory, they demonstrate the need for obtaining platelet counts during transfusion of large amounts of blood. If clinical evidence of excessive bleeding exists and the platelet count is lower than 100,000/mm³, platelets should be transfused, because they are consumed during surgery and higher levels are required to maintain hemostasis following surgery.

Packed red blood cells, which may be stored for several weeks, are used for most postoperative transfusions. Most clotting factors are stable for long periods. The exceptions are factors V and VIII, which decrease to 15% and 50% of normal, respectively. Despite this loss, these factors rarely decrease below levels required for hemostasis. In 1985, a National Institutes of Health consensus conference concluded that there was little or no scientific evidence to support the use of FFP for bleeding diatheses following multiple blood transfusions except in the presence of clinical bleeding, platelet count higher than 100,000/mm³, and a partial thromboplastin time greater than 1.5 times control. A task force of the American Society of Anesthesiologists (205) recently recommended critical values for replacement in patients with massive transfusion and microvascular bleeding:

1. Platelet counts <50,000/mm³ (with intermediate platelet counts, i.e., 50,000/mm³ to 100,000/mm³ the transfusion of platelet concentrates should be based on the risk for more significant bleeding).
2. Elevated (>1.5 times normal) prothrombin or activated partial thromboplastin time values
3. Coagulation factor concentrations less than 30%
4. Fibrinogen concentrations less than 80 to 100 mg/dL.

Donor blood is stored in the presence of citrate, which chelates calcium to prevent clotting, raising the theoretical risk of hypocalcemia following massive transfusion. However, citrate is metabolized at a rate equivalent to 20 units of blood transfused per hour; thus, routine supplementation of calcium is unnecessary. Close monitoring of calcium levels is required in patients with hypothermia, liver disease, or hyperventilation, because citrate metabolism may be slowed. Hepatic metabolism of citrate to bicarbonate can result in metabolic alkalosis following transfusion, resulting in subsequent hypokalemia, despite the high level of extracellular potassium in stored blood.

Pulmonary Disease

In patients undergoing abdominal surgery, several pulmonary physiologic changes occur secondary to immobilization, anesthetic irritation of the airways, and the splitting of breathing that inevitably occurs with incision pain. Pulmonary physiologic changes include a decrease in the functional residual capacity (FRC) and vital capacity (VC), an increase in ventilation–perfusion mismatching, and impaired mucociliary clearance of secrections from the tracheobronchial tree. These changes result in transient hypoxemia and atelectasis that, untreated, can progress to pneumonia in the postoperative period (205-207). Postoperative pulmonary dysfunction is more pronounced in patients with advanced age, preexisting lung disease, obesity, a significant history of smoking, and upper abdominal surgery (208).

Most postoperative pulmonary complications occur in patients who have preexisting pulmonary disease. In these patients, the incidence of pulmonary complications is higher than 70%, as compared with the low incidence (2% to 5%) that occurs in individuals with healthy lungs (206,208). The risk of postoperative pulmonary complications is lower in patients undergoing lower abdominal surgery as compared with upper abdominal surgery and in those undergoing nonthoracic, nonabdominal surgery as compared with abdominal operations. The presence of chronic obstructive pulmonary disease markedly increases the risk (206,209).

Preoperative spirometry is of unproved value in patients undergoing abdominal surgery in whom the risk of postoperative pulmonary complications is low (210,211,212 and 213). In high-risk patients, preoperative spirometry should be performed with and without bronchodilators in order to identify patients who may...
benefit from preoperative treatment with inhaled b₂ agonists and steroids. These patients include those with a history of chronic cough or dyspnea, evidence of pulmonary abnormalities by either physical examination or chest radiograph, and a history of chronic obstructive pulmonary disease, as well as patients with a significant history of smoking. In addition to the preoperative spirometric evaluation, an arterial blood gas assessment should be performed. The spirometric abnormalities most often associated with postoperative atelectasis and pneumonia are shown in Table 19.14.

**Table 19.14. Predictors of Postoperative Pulmonary Complications**

Young, healthy patients rarely have abnormal chest radiographic examination results. Therefore, chest radiographs should not be performed routinely in these patients. Most patients with abnormal chest radiographs have a history or physical examination findings suggestive of pulmonary disease (214). Chest radiographs should be limited to patients older than 40 years, patients with a history of smoking, patients with a history of pulmonary disease, and patients who have evidence of cardiopulmonary disease.

**Asthma**

The prevalence of bronchial asthma is increasing worldwide, and approximately 10% of people have suffered an asthma attack (215). Asthma is a disease that is characterized by a history of episodic wheezing, physiologic evidence of reversible obstruction of the airways, either spontaneously or following bronchodilator therapy, and pathologic evidence of chronic inflammatory changes in the bronchial submucosa. Asthma is not a disease of airway physiology in which hypertherphy and increased contractility of bronchial smooth muscle is the dominant lesion; rather, it is an inflammatory disease affecting the airways that secondarily results in epithelial damage, leukocytic infiltration, and increased sensitivity of the airways to a number of different stimuli. The treatment of asthma is directed toward relaxing the airways and alleviating inflammation with glucocorticoids.

Despite advances in pharmacologic management, morbidity and mortality from asthma have been increasing in recent years (216). This most likely cause has been the result of underdiagnosis and undertreatment of this disease (217). Multiple stimuli have been noted to precipitate or exacerbate asthma, including environmental allergens or pollutants, respiratory tract infections, exercise, cold air, emotional stress, use of b₂-adrenergic blockers, and aspirin (218). Management of asthma includes removal of the inciting stimuli as well as use of appropriate pharmacologic therapy.

The severity of clinical asthma correlates with measurements of the severity of the inflammatory response in the lung (219). Some investigators have referred to asthma as a chronic eosinophilic bronchitis (217). Numerous mediators, including interleukin-3, interleukin-5, granulocyte-macrophage colony-stimulating factors, tumor necrosis factor-a, and interferon-g, are released in the lungs by eosinophils, macrophages, and T cells. The mediators induce microvascular leakage, bronchoconstriction, and epithelial damage, which block the distal airways. The optimal therapy for asthma involves not only managing the acute symptoms but also long-term management of the inflammatory component of the disease.

**Pharmacotherapy of Asthma**

The recognition of asthma as an inflammatory condition that should be treated with antiinflammatory agents has led to the use of glucocorticoids for treatment. Glucocorticoids have become the first-line therapy for chronic asthma because they inhibit mediator release from eosinophils and macrophages, inhibit the late response to allergens, and reduce hyperresponsiveness of the bronchioles (217). Inhaled steroids have greatly reduced the steroid dose required to achieve optimal results. The steroid effect is dose related, but many patients with asthma can achieve control using low-dose inhaled steroids (1,000 g/day). Onset of action is slow (several hours), and up to 3 months of steroid therapy may be required for optimal improvement of bronchial hyperresponsiveness. Even with acute exacerbation of asthma, steroid treatment can enhance the beneficial effect of b₂-adrenergic treatment.

During acute exacerbations of asthma, a short course of oral steroids may be necessary in addition to inhaled steroids. For adults with chronic asthma, however, only a minority will require chronic oral steroid therapy. Patients taking oral steroids should receive intravenous steroid support perioperatively.

Until recently, b₂-adrenergic agonists were considered the first-line drugs for asthma. These drugs, inhaled 4 to 6 times daily, rapidly relax smooth muscle in the airways and are effective for up to 6 hours. Studies of b₂ agonists in chronic asthma, however, have failed to show any influence of these agents on the inflammatory component of asthma. Furthermore, it has been suggested that the long-term use of this class of drugs can lead to a worsening of asthma (217). Thus b₂ agonists are now recommended for use for short-term relief of bronchospasm or as first-line treatment for patients with very infrequent symptoms or symptoms provoked solely by exercise (220).

Methylxanthines, such as theophylline, have been relegated to third-line status in the management of asthma. It is doubtful whether these drugs have any additional benefit in patients who are using maximal inhaler therapy. The xanthines are limited by their narrow therapeutic window. It is necessary to achieve a serum concentration of at least 10 g/ml; at levels higher than 20 g/ml significant toxicity develops, including nausea, tremor, and central nervous system excitation. Xanthines have a limited antiinflammatory effect and no effect on bronchial hyperresponsiveness or eosinophilic degranulation. In addition, plasma concentrations can be altered by drugs or environmental factors, requiring an adjustment in the theophylline dose. Smoking and phenobarbital use, for example, increase clearance of theophylline by the liver, whereas clearance of theophylline is decreased with hepatic diseases and cardiac failure or with the concomitant use of certain drugs, including ciprofloxacin, cimetidine, erythromycin, and troleancomycin.

Anticholinergic agents are weak bronchodilators that work via inhibition of muscarinic receptors in the smooth muscle of the airways. The quaternary derivatives such as ipratropium bromide (Atrovent) are available in an inhaled form that is absorbed systemically. Anticholinergic drugs may provide additional benefit in conjunction with standard steroid and bronchodilator therapy but should not be used as single-agent therapy because they do not inhibit mast cell degranulation, do not have any effect on the late response to allergens, and do not have an antiinflammatory effect.

Cromolyn sodium is highly active in the treatment of seasonal allergic asthma in children and young adults. It is usually not as effective in older patients or in patients in whom asthma is not caused by allergy (220). The drug is taken by inhalation but has a relatively short duration of action (3 to 4 hours). It has a mild antiinflammatory effect but is less effective than inhaled corticosteroids, and its role as a single agent is limited.

**Perioperative Management of Asthma**

In patients with asthma, elective surgery should be postponed whenever possible until pulmonary function and pharmacotherapeutic management are optimized. The preoperative evaluation may include spirometry, exercise testing, and arterial blood gas assessment, depending on the severity of the symptoms and concerns regarding ventilation and oxygenation. Preoperative chest physiotherapy, bronchodilator therapy, systemic hydration, and appropriate antibiotics will improve the reversible components of asthma (221). For mild asthma, the use of inhaled b₂-adrenergic agonists preoperatively may be all that is required. For chronic asthma, optimization of steroid therapy will greatly decrease allergic inflammation and bronchial hyperresponsiveness. Inhaled b₂ agonists should be added to therapy as needed for further control of asthma. Each drug prescribed should be used in maximal dosage before adding an additional agent. For patients undergoing emergent surgery who
have significant bronchoconstriction, a multimodal approach should be instituted, including aggressive bronchodilator inhalation therapy, intravenous aminophylline, as well as steroid therapy. Ideally, steroid therapy can be instituted 3 to 6 days preoperatively. In all patients with asthma, pharmacotherapeutic response can be demonstrated by an improvement in the peak expiratory flow rate based on pulmonary function testing (220).

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is the greatest risk factor for the development of postoperative pulmonary complications. The term COPD has been used to encompass both chronic bronchitis and emphysema, disease entities that often occur in tandem. Cigarette smoke is implicated in the pathogenesis of both, and any treatment plan must include cessation of smoking (222). Chronic bronchitis is defined as the presence of productive cough on most days for at least 3 months of the last 2 years and for at least 2 successive years (223). It is characterized by chronic airway inflammation and excessive mucus production. The histologic changes of emphysema include destruction of alveolar septa and distension of airspaces distal to terminal alveoli. The destruction of alveolar septa is most likely caused by serine elastase, released by neutrophils exposed to cigarette smoke (222). The destruction of alveoli results in air trapping, loss of pulmonary elastic recoil, collapse of the airways in expiration, increased work of breathing, significant ventilation–perfusion mismatching, and an ineffective cough (219). The impaired ability to cough effectively and clear secretions predisposes patients with COPD to atelectasis and pneumonia in the postoperative period.

COPD and a history of heavy smoking account for the majority of postoperative pulmonary complications in gynecologic surgical patients. The severity of COPD can be determined preoperatively via a thorough history, physical examination, pulmonary function tests, and arterial blood gas assessments. Preoperative evaluation should be performed to assess reversible components of COPD, such as bronchospasm or infection. Several studies have suggested that preoperative pulmonary preparation of patients with preexisting lung disease can decrease the incidence of postoperative pulmonary complications by 50% to 70% (224,225,226 and 227).

The severity of COPD can be quantitated with pulmonary function testing (206,208,228). Typically, patients with COPD demonstrate impaired expiratory air flow, manifested by diminished forced expiratory volume (FEV1), forced vital capacity (FVC), FEV1/FVC, and maximal expiratory flow rate (MEFR). In one study, patients with abnormal pulmonary function test results had a 70% incidence of postoperative pulmonary complications, as compared with a 3% incidence of complications in patients who had normal spirometry results (208). In patients considered to be at high risk, the incidence of complications was highest in those undergoing abdominal surgery (92%) or thoracic surgery (78%) and lowest in those undergoing surgery outside the abdomen (26%). Guidelines for preoperative spirometry include the following: lung resection; coronary artery bypass or upper abdominal surgery in a patient with a positive smoking history or dyspnea; lower abdominal surgery in a patient with uncharacterized pulmonary symptoms or history of pulmonary disease without recent spirometry within 60 days, especially if the surgery will be extensive, prolonged, or require strenuous postoperative rehabilitation (220).

Arterial blood gas measurement may show varying degrees of hypoxemia and hypercapnia and can be used for prognostic purposes; PaO2 levels lower than 70 mm Hg and PaCO2 levels higher than 45 mm Hg are associated with an increase in the risk of postoperative pulmonary complications and the need for mechanical ventilation postoperatively (230). PaCO2 levels higher than 50 mm Hg are associated with increased postoperative respiratory failure and should caution against elective surgery (221).

The preoperative preparation of the patient at risk for postoperative pulmonary complications should include cessation of smoking as long as possible preoperatively. Whereas 2 to 3 days of smoking abstinence are sufficient for carboxyhemoglobin levels to return to normal (231), 2 months of smoking abstinence is required to significantly lower the risk of postoperative pulmonary complications (223). Long periods of abstinence can thus be considered in patients undergoing elective surgery.

In patients with severe COPD, maximal improvement in airflow limitation can be achieved with a therapeutic trial of high-dose oral glucocorticoids followed by a 2-week trial of high-dose inhaled steroid (beclomethasone 1.5 mg/day or the equivalent) in addition to inhaled bronchodilator therapy. Ideally, oral and inhaled steroid therapy should be initiated 1 to 2 weeks preoperatively. Inhaled steroids, in particular, address the inflammatory component of COPD. Oral steroid therapy initiated preoperatively should be maintained throughout the perioperative period and tapered postoperatively. b-Adrenergic agonist therapy can be initiated at least 72 hours preoperatively and is beneficial in patients who have demonstrated either clinical or spirometric improvement with bronchodilator therapy.

Patients with COPD and an active bacterial infection, as suggested by purulent sputum, should undergo a full course of antibiotic therapy prior to surgery. The antibiotic used should cover the most likely etiologic organisms, Streptococcus pneumoniae and Haemophilus influenzae. In any patient with acute upper respiratory infection, surgery should be delayed if possible. In the absence of evidence of an acute infection, the use of antibiotics to sterilize the sputum should be avoided because this practice may lead to bacterial resistance.

Instruction in deep breathing maneuvers and chest physical therapy are easily instituted, and these measures can be started the evening before surgery (232). Steps to improve skeletal muscle strength include good nutrition and treatment of hypokalemia (221). Prophylactic measures, such as smoking cessation, pharmacotherapy administration, and aggressive pulmonary toilet, should be instituted preoperatively and continued postoperatively to minimize the incidence of atelectasis and pneumonia.

Postoperative Pulmonary Management

Atelectasis

Atelectasis accounts for more than 90% of all postoperative pulmonary complications. The pathophysiology involves a collapse of the alveoli resulting in ventilation–perfusion mismatching, intrapulmonary venous shunting, and a subsequent drop in the PaO2. Collapse of alveoli results in air trapping, loss of pulmonary elastic recoil, collapse of the airways in expiration, increased work of breathing, significant ventilation–perfusion mismatching, and an ineffective cough (219). The impaired ability to cough effectively and clear secretions predisposes patients with COPD to atelectasis and pneumonia in the postoperative period.

Therapy for atelectasis should be aimed at expanding the alveoli and increasing the functional residual capacity. The most important maneuvers are those that promote maximal inspiratory pressure, which is maintained for as long as possible. This exercise promotes not only an expansion of the alveoli but also secretion of surfactant, which stabilizes alveoli. It can be achieved with aggressive supervised use of incentive spirometry, deep breathing exercises, coughing and, in some cases, the use of positive expiratory pressure with a mask (continuous positive airway pressure). Overinflation should be avoided, and patients should be encouraged to ambulate and change positions frequently. Fiberoptic bronchoscopy for removal of mucopurulent plugs should be reserved for patients who fail to improve with the usual measures.

Cardiogenic (High-pressure) Pulmonary Edema

Cardiogenic pulmonary edema can result from myocardial ischemia, myocardial infarction, or from intravascular volume overload, particularly in patients who have low cardiac reserve orrenal failure. The process usually begins with an increase in the fluid in the alveolar septa and bronchial vascular cuffs, ultimately seeping into the alveoli. Complete filling of the alveoli impairs secretion and production of surfactant. Concomitant with alveolar flooding, there is a decrease in lung compliance, impairment of the oxygen diffusion capacity, and an increase in the arteriole–alveolar oxygen gradient. Ventilation–perfusion mismatching in the lung results in a decrease in the PaO2 resulting eventually in decreased oxygenation of the tissues and impairment of cardiac contractility.

Symptoms may include tachypnea, dyspnea, wheezing, and use of the accessory muscles of respiration. Clinical signs may include distention of the jugular veins, peripheral edema, rates upon auscultation of the lungs, and an enlarged heart. Radiographic findings may include the presence of bronchial cuffing as well as increased interstitial fluid markings extending to the periphery of the lung. The diagnosis can be further confirmed with the use of central hemodynamic monitoring,
which will denote an elevated central venous pressure and, more specifically, an elevation in the pulmonary–capillary wedge pressure.

The patient's volume status should be evaluated thoroughly. In addition, myocardial ischemia or infarction should be ruled out by performing ECG and analyzing cardiac enzyme levels. The management of cardiogenic pulmonary edema includes oxygen support, aggressive diuresis, and afterload reduction to increase the cardiac output. In the absence of myocardial infarction, an inotropic agent may be used. Mechanical ventilation should be reserved for cases of acute respiratory failure.

**Noncardiogenic Pulmonary Edema (Adult Respiratory Distress Syndrome)**

In contrast to cardiogenic pulmonary edema, in which alveolar flooding is a result of an increase in the hydrostatic pressure of the pulmonary capillaries, alveolar flooding in patients with adult respiratory distress syndrome (ARDS) is the result of an increase in pulmonary capillary permeability. The primary pathophysiologic process is one of damage to the capillary side of the alveolar–capillary membrane. This damage results in rapid movement of fluid containing high concentrations of protein from the blood to the alveolar space. As lung compliance decreases and alveolar diffusion capacity is impaired, resulting in hypoxemia, if not managed aggressively, respiratory failure may result. Even if managed aggressively, the mortality rate associated with ARDS is 60% to 70% (221). There are a number of causes as well as several distinct states of ARDS. The causes of ARDS include shock, sepsis, massive nonultrasonic trauma (as from fractures or burns), multiple red blood cell transfusions, aspiration injury, inhalation injury, pneumonia, pancreatitis, DIC, and fat emboli (221). Irrespective of the cause, which should be identified and treated if possible, the evolving clinical findings and management are very similar.

Clinically, ARDS passes through several stages. Initially, patients develop tachypnea and dyspnea with no remarkable findings on clinical evaluation or on chest radiograph. Chest radiographs will eventually reveal bilateral, symmetric patchy pulmonary infiltrates. As lung compliance becomes impaired, functional residual capacity, tidal volume, and vital capacity decrease. The PaO₂ decreases and, characteristically, increases only marginally with oxygen supplementation. An attempt should be made to maintain the arterial oxygen level above 90%. This may be achievable initially by administering oxygen by mask. For patients with severe hypoxemia, endotracheal intubation with positive-pressure ventilation should be instituted. Guidelines for initial ventilatory support are changing, and new lung-protective ventilation strategies are being advocated. One strategy advocates the use of high positive end-expiratory pressure (PEEP), low tidal volume, permissive hypercapnia, and pressure-limited ventilatory modes. The low-tidal-volume strategy may confer a survival advantage, and available data support its use in patients with ARDS (233). Multicenter trials are currently under way to assess differences in PEEP and FIO₂ levels, and the use of glucocorticoids.

Attempts to manage and treat the cause of ARDS also must include aggressive efforts toward hemodynamic and circulatory resuscitation in patients with shock. Nosocomial pneumonia is present in 50% of patients with ARDS, and broad-spectrum antibiotic therapy should be administered as appropriate for patients with suspected pneumonia or sepsis. Patients who have DIC may require replacement with cryoprecipitate or FFP. Other measures for general care should include the placement of a nasogastric tube, gastric acid suppression with H⁺ blockers, and administration of steroids in patients with the fat emboli syndrome.

Hemodynamic monitoring is invalid and should be initiated early in the course of the disease process. Patients with any evidence of fluid overload should receive aggressive diuresis, whereas others may require fluid resuscitation for maintenance of tissue perfusion while the pulmonary–capillary wedge pressure is maintained below 15 mm Hg. Pulmonary wedge pressure may be falsely elevated when PEEP is being applied. The goal of management is to maintain the lowest possible pulmonary–capillary wedge pressure, with acceptable cardiac output and blood pressure. In the presence of hypotension and oliguria, inotropic support with dopamine or dobutamine is helpful.

With aggressive management, particularly if the initiating cause is identified and treated, ARDS can be reversed during the first 48 hours with few sequelae. After the first 48 hours, however, progression of the ARDS will cause lung damage that may leave residual pulmonary fibrosis. With progression beyond 10 days, multiple organ system failure occurs and the mortality rate is higher than 80% (234).

**Renal Disease**

The need for surgical intervention in patients with renal impairment has resulted in the development of a very specialized medical approach to their care. Special precautions are necessary to compensate for the kidney's impaired ability to regulate fluids and electrolytes and excrete metabolic waste products. Equally important are the unique problems that develop in patients with chronic renal impairment, including an increased risk of sepsis, coagulation defects, impaired immune function and wound healing, and a propensity to develop specific acid-base abnormalities. Special consideration must be given to a variety of different medications, anesthetic agents, and numerous hematologic and nutritional factors that are important in the successful surgical care of patients with renal insufficiency.

Management of fluid levels and cardiovascular hemodynamics in patients with acute or chronic renal impairment is paramount. Intravascular fluid volume changes that lead to hypertension or hypotension are very common in these patients and are often difficult to manage secondary to autonomic dysfunction, acidosis, and other problems that are inherent to the underlying kidney disease. Patients undergoing dialysis for whom major abdominal or pelvic surgery is contemplated should be treated using a Swan-Ganz catheter intraoperatively and postoperatively. The results of physical examination and central venous pressure monitoring correlate poorly with left cardiac filling pressures. Swan-Ganz catheter measurements will help guide fluid replacement and avoid volume overload. Invasive hemodynamic monitoring should be continued as needed throughout the first postoperative week because third spacing will occur during this period.

Postoperative dialysis is usually necessary to avoid problems associated with fluid overload and hyperkalemia. Dialysis-dependent patients should undergo dialysis approximately 12 to 24 hours following surgery. A sharp following significant fall in the number of platelets occurs during dialysis, and repletion is used in hemodialysis equipment to prevent clotting. Because of these factors and concerns about postoperative bleeding, dialysis is usually avoided during the first 12 to 24 hours following surgery. Although ischemic heart disease is the most common cause of death in patients with renal insufficiency, it is not a major cause of perioperative mortality (235). A large percentage of perioperative deaths of patients with renal insufficiency are associated with hyperkalemia that is controlled most effectively by dialysis (236).

Patients with chronic renal failure are at an increased risk for postoperative infections resulting from abnormalities in neutrophil and monocyte function (237). Appropriate preoperative antibiotic prophylaxis and an accurate assessment of nutritional status will lower the incidence of postoperative infectious complications.

The major hemotologic concern in patients with chronic renal insufficiency is the increased incidence of bleeding. These bleeding problems are secondary to abnormal bleeding times and, in particular, disorders of platelet function related to a decreased amount of factor VIII and von Willebrand antigen in the serum of uremic patients. Anemia, which is common in patients with renal insufficiency, can contribute to prolonged bleeding times (238).

Abnormalities in arachidonic acid metabolism, acquired platelet storage pool deficiency, and disturbed regulation of platelet calcium content all account for an increased tendency for uremic patients to have significant bleeding during surgery (239). Therefore, the bleeding time should be routinely checked preoperatively in these patients and abnormalities should be corrected before surgery. Options for the correction of bleeding time in uremic patients include infusion of desmopressin or cryoprecipitate, both of which act to increase plasma levels of factor VIII and von Willebrand antigen (240,241).

Normal renal function is essential for maintenance of acid-base balance in the body. Patients with renal insufficiency can have a normal anion gap or an elevated anion gap acidosis. When mild renal insufficiency develops, a normal anion gap can be seen, whereas in more significant and severe renal dysfunction, an elevated anion gap occurs. Hemodialysis corrects metabolic acidosis. If a patient is severely acidic (pH less than 7.15) and emergency surgery is planned, correction of the blood pH to 7.25 using intravenous sodium bicarbonate is indicated. Correction of metabolic acidosis should be carried out slowly, however, because in patients with hypokalemia, correction of the pH can cause an exaggerated kaliuresis, which can precipitate a severe drop in serum potassium. Hypocalcemia, however, should be corrected aggressively, because hypocalcemia is common in patients with renal insufficiency and can contribute to an increased risk of bleeding. Normalization of serum calcium aids in the maintenance of intracellular calcium levels and helps prevent bleeding complications. When severe metabolic acidosis occurs, treatment should be initiated with calcium carbonate (0.125 g per kg per day) and vitamin D. If available, an injectable calcium source such as calcium gluconate or calcium chloride can be used. Calcium administration must be accompanied by adequate vitamin D supplementation to ensure adequate absorption of calcium from the gastrointestinal tract. If the patient has a history of calcium-containing stones, calcium carbonate should be avoided, and a calcium-free Source should be used instead.

Impaired kidney function causes phosphate retention by the kidney and impaired vitamin D metabolism. Therefore, hypocalcemia is common in patients with renal insufficiency, but tetany and other signs of hypocalcemia are relatively uncommon because metabolic acidosis raises the level of ionized calcium. Oral phosphate binders such as aluminum hydroxide (1 to 2 g per meal) and dietary phosphate restriction (1 g per day) is the usual treatment for hypocalcemia-hyperphosphatemia in patients with renal insufficiency. In these situations, because of central nervous system toxicity associated with elevated aluminum levels, it is preferable to treat hypocalcemia-hyperphosphatemia with large doses of calcium carbonate (0 to 12 g per day) rather than with the standard aluminum-containing antacids (242).

Approximately 20% of patients with renal insufficiency will exhibit clinical evidence of protein calorie malnutrition. Vitamin deficiencies, most notably with water-soluble
vitamins, also occur with dialysis. Nutritional disturbances in patients with chronic renal insufficiency arise secondary to deficiencies in protein intake, and studies have shown that, in patients with chronic renal insufficiency, their kidneys are hyperfiltrating (243). Postoperatively, both protein and caloric intake may need to be increased dramatically to meet catabolic demands in surgical patients. As much as 1.5 g/kg of protein and 45 kcal/kg of calories may be needed (243).

Wound healing is impaired in patients with chronic renal failure, and wound dehiscence and evisceration are potential problems. Wound healing is most appropriately aided by nutritional assessment preoperatively and maintenance of adequate caloric and protein intake in the perioperative setting. Antibiotic prophylaxis should be used in these patients, and uraemia should be treated with dialysis as indicated. A running mass-close of the midline vertical incision with continuous monofilament sutures should be used to further decrease the risk of wound dehiscence and evisceration (244).

Patients with chronic renal disease have an altered ability to excrete drugs and are prone to significant metabolic derangements secondary to the altered bioavailability of many commonly used medications. Because of this, as well as the effect of dialysis on drug pharmacokinetics, the gynecologic surgeon and nephrologist must be aware of the lowered metabolism and bioavailability of narcotics, barbiturates, muscle relaxants, antibiotics, and other drugs that require renal clearance. Of particular note is the inability of patients with renal insufficiency to clear the neuromuscular blockade caused by pancuronium (245). Care must be taken with D-tubocurarine, especially if repeated doses are given (246). Midazolam, propofol, vecuronium, and atracurium have been safely used in patients with renal failure (241). Succinylcholine has been reported to cause significant hyperkalemic responses in patients with renal failure (247). Succinylcholine can be safely used in patients with chronic renal insufficiency. Careful monitoring of the serum potassium level is necessary (248).

Perioperative acute renal failure in previously normal patients may be caused by decreased renal perfusion, nephrotoxins, or both. Patients with impaired cardiac function, intravascular volume depletion, sepsis, or hypotension fall under the first category. Nephrotoxic medications such as aminoglycosides, chemotherapeutic agents such as cisplatin, or iodinated contrast agents fall under the second category (249,250 and 251). The risk of renal impairment becomes cumulative if more than one of these factors exist at the same time, and especially if a variety of factors are associated with intravascular volume depletion (252). Several measurements should be used to avoid acute renal failure. All nephrotoxic drugs should be discontinued when possible, when it is not practical to withdraw medication, strict attention should be paid to the pharmacokinetic characteristics of each drug as well as to the regular measurements of the serum creatinine. Patients with diabetes should be given reduced doses of radiocontrast agents and should be well hydrated because they are particularly susceptible to renal injury from these materials (253). Volume repletion is essential to lower the incidence of renal impairment (254).

Liver Disease

Management of perioperative problems in gynecologic patients with liver disease requires a comprehensive understanding of normal liver physiology and the pathophysiology underlying diseases of the liver that may complicate surgery or recovery. Patients with liver disease often have numerous complicated problems involving nutrition, coagulation, wound healing, encephalopathy, and infection.

History and Physical Examination

Patients with a history of alcohol abuse, drug use, hepatitis, jaundice, blood product exposure, or a family member with liver disease should undergo biochemical evaluation. During the physical examination, note should be made of any jaundice, signs of muscle wasting, ascites, right upper quadrant tenderness, or hepatomegaly.

Laboratory Testing

The biochemical profile (alkaline phosphatase, calcium, lactric acid dehydrogenase, bilirubin, serum glutamic-oxaloacetic transaminase, cholesterol, uric acid, phosphorous, albumin, total protein, and glucose) has not been shown to be useful for routine preoperative evaluation (255). Mild abnormalities lead to further extensive testing that require consultation, delays in surgery, and increased cost without net benefit. A possible exception is selected use of biochemical testing when the history or physical examination reveals abnormalities. Patients with known liver disease should undergo albumin and bilirubin testing using the Child's risk classification (Table 19.15). This system was originally designed to predict mortality following portosystemic shunt surgery. It divides patients into three classes of severity based on five easily assessed clinical parameters. Measurement of prothrombin time may also be helpful in patients with significant histories of liver disease. If a history of hepatitis is ascertained, the patient should be tested for serum aminotransferase, alkaline phosphatase, bilirubin, and albumin levels. Serologic documentation of hepatitis is also important. If a patient has a known malignancy, there may be some benefit from biochemical testing of the liver as a screen for metastatic disease, although this has not been proved conclusively.

Table 19.15. Child's Classification of Liver Dysfunction

Anesthesia

With few exceptions, most anesthetic agents, including those administered by epidural or spinal routes, reduce hepatic blood flow and decrease oxygenation of the liver. Other perioperative factors—hemorrhage, intraoperative hypotension, hypercarbia, congestive heart failure, and intermittent positive pressure ventilation, especially in critically ill patients—lead to decreased hepatic perfusion and hypoxia (256).

Drug Metabolism

Patients with altered liver function should be carefully monitored because of the prolonged action of many medications used during surgery. In addition to impaired metabolism, hypoalbuminemia decreases drug binding, which alters serum levels and biliary clearance rates. The degree of hepatic metabolism varies greatly, depending on the type of medication being considered. For inhalation anesthetics, isoflurane is preferred because it undergoes minimal hepatic metabolism in comparison with halothane or enflurane. Narcotics, induction agents, sedatives, and neuromuscular blocking agents all undergo abnormal metabolism in patients with decompensated liver disease. Diazepam, meperidine, and phenobarbital cause prolonged depression of consciousness and may precipitate hepatic encephalopathy because of impaired hepatic detoxification. Streptokinase, heparin, and serotonin are the preferred theophylline, and benzodiazepine metabolism in patients with impaired liver function. Muscle relaxants, such as D-tubocurarine, pancuronium, and vecuronium, cause prolonged neuromuscular blockade in patients with impaired liver function and are not ideal drugs to use in this situation. Atracurium is not metabolized by the liver and, therefore, is the preferred muscle relaxant for patients with abnormal hepatic function. Succinylcholine metabolism is greatly prolonged in patients with hepatic dysfunction and must be used with great caution (257).

Determination of Operative Risk

Although it is well known that acute hepatobiliary damage results in increased morbidity and mortality in the surgical patient, estimating the operative risk in patients with hepatic dysfunction is troublesome, because it is often difficult to determine which patients are at risk based on the history and physical examination. The most accurate method for risk assessment of surgery in patients with hepatic dysfunction is Child's classification (Table 19.15). Using this system, accurate assessment of
morbidty and mortality can be directly related to the degree of liver dysfunction (259). The Child's classification has been shown to be useful for patients undergoing a variety of different types of abdominal surgery. Operative mortalities of 10%, 31%, and 76% have been reported for each of the three Child's classifications, respectively (259). The major cause of perioperative death was sepsis. This classification correlated significantly with postoperative complications such as bleeding, renal failure, wound dehiscence, and sepsis.

Acute Viral Hepatitis

Acute viral hepatitis poses an increased risk of operative complications and perioperative mortality and, therefore, elective surgery is contraindicated (260). Elective surgery should be delayed for approximately 1 month after the results of all biochemical tests have returned to normal (261). In patients with eczematous pregnancy, however, the risk of postpartum secondary prevention secondary must take place before normal pregnancy, whenever normal obstetric therapy. In these situations, the perioperative morbidity (12%) and mortality (9.5%) rates are much higher than when they are performed under ideal situations (257).

Chronic Hepatitis

Chronic hepatitis is a group of disorders characterised by inflammation of the liver for at least 6 months. The disease is divided by morphological and clinical criteria into chronic persistent hepatitis and chronic active hepatitis. A liver biopsy is usually required to establish the extent and type of injury. The surgical risk in these patients correlates most closely with the disease severity. The risk of surgery in patients with asymptomatic or mild disease is minimal, in contrast to a significant risk for those patients who have symptomatic chronic active hepatitis (262). Elective surgery is contraindicated in symptomatic patients, and nonelective surgery is associated with significant morbidity (261). In the nonselective situation, patients taking long-term glucocorticoid therapy should be given appropriate stress coverage with a higher dose of glucocorticoids during the perioperative period. Preoperatively, patients who are not taking steroids should receive prednisolone and azathioprine, which have been shown to reduce the perioperative risk of complications and may result in remission in up to 80% of patients (263). More recently, a controlled randomised trial showed the superiority of the hepatitis B core antigen and hepatitis B viral DNA replication in approximately 30% of patients (264). Interferon-α has also been used in the treatment of hepatitis C. Consideration should be given to using these medications for patients in whom surgery cannot be avoided but is not emergent.

Asymptomatic carriers of the hepatitis B virus (individuals who test positive for the hepatitis B surface antigen) are not at increased risk for postoperative complications in the absence of elevated aminotransferase levels and liver inflammation. There is, however, a significant risk to the health care professional when operating on these individuals. In cases of needle stick in which the patient's hepatitis status is unknown, both the health care worker and the patient should be tested for HCV antibody and HBV serologic markers. If markers for HBV infection are present, hepatitis B immune globulin should be administered to unvaccinated medical personnel. A vaccination series should then be initiated during the early postoperative period. If the health care worker is immune (surface antibody positive), no treatment is necessary (257). All medical personnel, and especially those in the surgical subspecialties, should receive a full course of recombinant hepatitis B vaccine as recommended by the Centers for Disease Control and Prevention (265).

Alcoholic Liver Disease

Alcoholic liver disease encompasses a spectrum of diseases including fatty liver, acute alcoholic hepatitis, and cirrhosis. Elective surgery is not contraindicated in patients with fatty liver because liver function is preserved. If nutritional deficiencies are discovered, they should be corrected prior to elective surgery. Acute alcoholic hepatitis is characterized on biopsy by hepatocyte edema, polymorphonuclear leukocyte infiltration, necrosis, and the presence of Mallory bodies. Elective surgery in these patients is contraindicated (266). Abstinence from alcohol for approximately 6 to 12 weeks along with clinical resolution of the biochemical abnormalities are recommended before surgery is considered. Severe alcoholic hepatitis may persist for several months despite abstinence and, if any question of continued activity exists, a liver biopsy should be repeated (267). In cases of urgent or emergent surgery on patients with alcohol dependence, a benzodiazapine taper is appropriate as prophylaxis against alcohol withdrawal.

Cirrhosis

Cirrhosis is an irreversible liver lesion characterized histologically by parenchymal necrosis, nodular degeneration, fibrosis, and a disorganization of hepatic lobular architecture. The most serious complication of cirrhosis is portal venous hypertension that ultimately leads to bleeding from esophageal varices, ascites, and hepatic encephalopathy. Conventional liver biochemical test results correlate poorly with the degree of liver impairment in patients with cirrhosis. Hepatic dysfunction, however, may be somewhat quantified by low albumin levels and prolonged prothrombin times.

Surgical risk is clearly increased in patients with cirrhosis, although it is substantially greater in emergency surgery than in elective surgery. Perioperative mortality correlates with the severity of cirrhosis and can be estimated through the use of the Child’s classification (Table 15.1). Surgery in patients with Child’s class A cirrhosis is not contraindicated, whereas cirrhosis with Child’s class B or C poses a major risk and requires careful preoperative consideration. Meticulous preoperative preparation may improve the surgical outcome (268).

References

The genital and urinary tracts are intimately associated anatomically and embryologically from the earliest stages of their development. The bladder is located directly above the anterior vaginal wall, and the urethra is fused to it. Both of these structures, as well as other structures of the pelvic floor, are placed at risk during pregnancy and childbirth. Each organ system in the pelvic floor—urinary, genital, intestinal—traverses the pelvis and exits through its own orifice. Thus, these systems are intricately related in function and anatomic support (1). Disorders of each of these components should be evaluated in light of their impact on the function of the surrounding structures and the functional anatomy of the pelvic floor. The term urogynecology has been coined to describe the area of gynecology that deals with disorders of the female lower urinary tract; however, it has become apparent that urinary tract disorders are only one facet of a wide range of pelvic floor disorders that afflict women. As part of this growing recognition, the American Board of Obstetrics and Gynecology and the American Board of Urology have recently agreed to begin the process of jointly accrediting fellowship programs in Female Pelvic Medicine and Reconstructive Surgery. This effort to train both urologists and gynecologists in the treatment of all aspects of pelvic floor dysfunction is a positive step toward improving the care of patients afflicted with these common conditions.

Pelvic Floor Anatomy

The striated muscles of the pelvic floor, in combination with their fascial attachments, work together across the entire pelvis to prevent pelvic organ displacement, to maintain continence, and to control expulsive activities. An appreciation of the fact that these organ systems have complex interrelationships should help clinicians realize that patients’ problems are not necessarily limited to a single organ; rather, each disturbance of pelvic support or continence exists within a complex pelvic “ecosystem” and, as a result, may be linked to problems in other organ systems.

Pelvic Support

The bony pelvis surrounds and protects its contents but, by itself, actually provides them with little support. The pelvic organs are supported primarily by the muscular activity of the pelvic floor, aided by ligamentous attachments. Rather than functioning as a rigid structure, the pelvic floor muscles provide dynamic support through constant activity, functioning more like a self-regulating trampoline that continually adjusts its tension in response to changing circumstances (2, 3).

The functional anatomy of the muscles of the pelvic floor (the levator ani) has been studied for many years but remains poorly understood (4). The pelvic floor muscles contract to maintain urinary and fecal incontinence and relax to permit bowel and bladder emptying. The pelvic floor plays a role in normal female sexual responsiveness (5). It must distend tremendously to allow the delivery of a term infant but must contract again during the postpartum period to allow its varied functions to continue. Because the urethra, bladder, rectum, and supporting structures of the pelvis are all part of the pelvic floor, the functions of these organs cannot really be understood without an understanding of the pelvic musculature (see Chapter 5) (6, 7).

Levator Ani Muscle

The nomenclature of the pelvic muscles has long been subject to debate. The levator ani muscle (the broad general term for most of the muscles of the pelvic floor) has been described as consisting of a diaphragmatic portion (ilioococygeus) and the more important pubovisceral portion (8). The ilioococygeus portion of the levator ani consists of a thin muscular sheet that arises from the pelvic sidewall on either side of the arcus tendineus and ischial spine and inserts into a midline raphe behind the rectum. The pubovisceral (pubococcygeus) portion of the levator ani muscle consists of a thick U-shaped band of muscle arising from the pubic bone and attaching to the lateral walls of the vagina and rectum (Fig. 20.1). Therefore, the rectum is supported by a muscular sling that pulls it toward the pubic bones when these muscles contract. This muscular band is often called the puborectalis or the pubococcygeus muscle, but a more accurate term is the pubovisceral muscle because these muscles arise from the pubic bone and insert directly onto pelvic viscera or provide a supporting sling for them.
When the pubovisceral muscle contracts, it pulls the rectum, vagina, and urethra anteriorly toward the pubic bone and constricts the lumens of these pelvic organs (Fig. 20.2). It is this contractile property that is so important in maintaining urinary and fecal continence and in providing support for the genital organs (vagina, cervix, uterus) that lie upon and are supported by the levator plate. The medial portions of the pubovisceral muscle (levator ani) pass laterally to the arcus tendineus fasciae of the pelvis and attach to the endopelvic fascia surrounding the vaginal wall at a point opposite the upper half of the urethra (9, 10 and 11) (Fig. 20.3). The pubovisceral muscle attaches to a web of endopelvic fascia rather than directly to the urethra in this area. This portion of the muscle (pubococcygeus) contains large quantities of type I ("slow-twitch") muscle fibers that are tonically contracted. This baseline level of muscular activity provides constant resilient support for the urethra. At the same time, type II ("fast-twitch") fibers allow the pubovisceral muscle to respond quickly to rapid changes in intraabdominal pressure (coughing, sneezing) and to maintain urethral closure under such conditions (12). Reflex contraction of both types of muscle fibers helps support all of the contents of the pelvis.

As with the external anal sphincter, the levator ani muscles exhibit constant baseline tone in addition to their ability to contract and offset increases in intraabdominal pressure that would force pelvic contents downward. The phenomenon of constant baseline tone is separate from the ability of these muscles to contract forcefully. This aspect of pelvic muscle function is poorly understood, but it is critical for proper pelvic support because closure of the pelvic floor allows the pelvic viscera to rest on a muscular shelf. The constant adjustments in muscle activity maintain pelvic floor closure in response to changing circumstances and keep the pelvic ligaments from stretching.

Pelvic Ligaments

It is often erroneously believed that the various pelvic ligaments are the most important factors in pelvic support. Ligaments are poorly suited to maintaining support over time because fibrous tissues elongate when subjected to constant tension. The pelvic ligaments serve mainly to keep structures in positions where they can be supported by muscular activity rather than acting as weight-bearing structures themselves. The loss of normal muscular support leads to sagging and widening of the urogenital hiatus and predisposes patients to the development of pelvic organ prolapse (13) (Fig. 20.4).
Although fascia and ligaments are believed to be essential for support of the pelvic organs, this belief comes more from the amount of attention given to these structures in the performance of gynecologic surgery than from any empiric evidence regarding their role in pelvic support. However, the pelvic ligaments (i.e., the round, infundibulopelvic, and cardinal) are loose condensations of areolar tissue, blood vessels, and muscle fibers. By themselves, they have little supportive strength; rather, they function as “moorings” to hold the uterus and vagina in place. The pelvic ligaments and the endopelvic fascia attach the uterus and vagina to the pelvic sidewalls so that these structures can be supported by the muscles of the pelvic floor. The entire complex then rests on the levator plate, where it can be closed by increases in intraabdominal pressure by a flap-valve effect.

### Connective Tissue

Connective tissue is the “glue” of the body. It is composed primarily of elastin and collagen fibers in a polysaccharide ground substance. The composition of connective tissue is not constant but varies in different sites throughout the body. Connective tissue forms capsules to help maintain the structural integrity of organs. It forms the fascia that covers muscles and the tendons and allows them to attach to other structures in the body. If connective tissue fails, muscular support is weak because the attachments that permit muscles to exercise their functions are unreliable. Connective tissue is not static; instead, it is a dynamic tissue that undergoes constant turnover and remodeling in response to stress. Connective tissue turnover and repair are especially important in relation to wound healing and recovery from surgery. Hormonal changes appear to have significant effects on collagen, and these effects are probably of great importance during pregnancy and parturition, as well as in aging. Exercise appears to increase collagen turnover, as measured by increased proline hydroxylase activity in 65-year-old women who exercised for 8 weeks. Nutrition has an important role in the maintenance of connective tissue integrity. Vitamin C deficiency (scurvy) produces defects in collagen synthesis and repair that can result in the breakdown of seemingly normal connective tissue, even including the reopening of old, previously healed wounds.

Studies suggest that connective tissue abnormalities are a significant factor contributing to prolapse and related conditions. For example, joint hypermobility is a common clinical marker for abnormal collagen levels. Several studies have now shown an association between joint hypermobility and pelvic floor prolapse. Studies evaluating patients with a history of Ehlers-Danlos syndrome, a disorder of collagen synthesis, have revealed an increased incidence of urinary incontinence associated with this disorder. Fibroblasts grown in tissue culture from the fascia of women with recurrent genital prolapse have an imbalance of collagen types, with excessive synthesis of weaker type III collagen. Both collagen content and collagen strength appear to be decreased in the fascia of women with stress incontinence. However, pelvic support defects are affected by many different factors, and the ultimate clinical presentation (and perhaps the surgical solution) may be different for each patient.

### Lower Urinary Tract Function

The bladder is a complex organ that has a relatively simple function: to store urine effortlessly, painlessly, and without leakage and to discharge urine voluntarily, effortlessly, completely, and painlessly. To meet these demands, the bladder must have normal anatomic support as well as normal neurophysiologic function.

#### Normal Urethral Closure

Normal urethral closure is maintained by a combination of intrinsic and extrinsic factors. The extrinsic factors include the levator ani muscles, the endopelvic fascia, and their attachments to the pelvic sidewalls and the urethra. This forms a hammock beneath the urethra that responds to increases in intraabdominal pressure by remaining tense, allowing the urethra to be closed against the posterior supporting shelf. When this supportive mechanism becomes faulty for some reason—the endopelvic fascia has detached from its normal points of fixation, muscular support has weakened, or a combination of these two processes—normal support is lost, and anatomic hypermobility of the urethra and bladder neck develops. For many women, this loss of support is severe enough to cause loss of closure during periods of increased intraabdominal pressure, and stress incontinence results. However, many women remain continent in spite of loss of urethral support.

#### Innervation

The lower urinary tract receives its innervation from three sources: (a) the sympathetic and (b) parasympathetic divisions of the autonomic nervous system.
and (c) the neurons of the somatic nervous system (external urethral sphincter). The autonomic nervous system consists of all effenter pathways with ganglionic synapses that lie outside the central nervous system. Although knowledge of the norpinephrine of the autonomic nervous system is incomplete, it appears that the sympathetic system primarily controls bladder storage and that the parasympathetic nervous system controls bladder emptying. The somatic nervous system plays only a peripheral role in neurologic control of the lower urinary tract through its innervation of the pelvic floor and external urethral sphincter.

The sympathetic nervous system originates in the thoracolumbar spinal cord, principally T11 through L2 or L3. The ganglia of the sympathetic nervous system are located close to the spinal cord and use norepinephrine as the preganglionic neurotransmitter. The postganglionic sympathetic system is a parasympathetic nervous system with the sympathetic nervous system innervation of all effenter pathways with ganglionic synapses that lie outside the central nervous system. Although knowledge of the norpinephrine of the autonomic nervous system is incomplete, it appears that the sympathetic system primarily controls bladder storage and that the parasympathetic nervous system controls bladder emptying. The somatic nervous system plays only a peripheral role in neurologic control of the lower urinary tract through its innervation of the pelvic floor and external urethral sphincter.

The sympathetic nervous system originates in the thoracolumbar spinal cord, principally T11 through L2 or L3. The ganglia of the sympathetic nervous system are located close to the spinal cord and use norepinephrine as the preganglionic neurotransmitter. The postganglionic sympathetics nervous system is a parasympathetic nervous system with the sympathetic nervous system innervation of all effenter pathways with ganglionic synapses that lie outside the central nervous system. Although knowledge of the norpinephrine of the autonomic nervous system is incomplete, it appears that the sympathetic system primarily controls bladder storage and that the parasympathetic nervous system controls bladder emptying. The somatic nervous system plays only a peripheral role in neurologic control of the lower urinary tract through its innervation of the pelvic floor and external urethral sphincter.

Bladder storage and bladder emptying involve the interplay of the sympathetic and parasympathetic nervous systems. The modulation of these activities appears to be influenced by a variety of nonadrenergic, noncholinergic neurotransmitters and neuropeptides, which fine-tune the system at various facilitative and inhibitory levels in the spinal cord and higher areas of the central nervous system (30,31 and 32). Thus, neuropathy at almost any level of the neurourologic axis can have an adverse effect on lower urinary tract function.

Micturition

Micturition is triggered by the peripheral nervous system controlled by the central nervous system. It is useful to consider this event as occurring at a micturition threshold, a bladder volume at which reflex detrusor contractions occur. The threshold volume is not fixed but instead is variable, and it can be altered depending on the contributions made by sensory afferents from the perineum, bladder, colon, and rectum as well as input from the higher centers of the nervous system. The micturition threshold is, therefore, a floating threshold that can be altered or reset by various influences.

The spinal cord and higher centers of the nervous system have complex patterns of inhibition and facilitation. The most important facilitative center above the spinal cord is the pontine-mesencephalic gray matter of the brain stem, often called the pontine micturition center, which serves as the final common pathway for all bladder motor neurons. Transection of the tracts below this level leads to detrusor blading emptying, whereas destruction of tracts above this level leads to detrusor hyperreflexia. The cerebellum serves as a major center for coordinating pelvic floor relaxation and the rate, force, and range of detrusor contractions, and there are multiple interconnections between the cerebellum and the brain-stem reflex centers. Above this level, the cerebral cortex and related structures exert inhibitory influences on the micturition reflex. Thus, the upper cortex exerts facilitative influences that release inhibition, permitting the anterior pontine micturition center to send efferent impulses down the complex pathways of the spinal cord, where a reflex contraction in the sacral micturition center generates a detrusor contraction that causes bladder emptying.

Colorectal Function

The sigmoid (S-shaped) colon begins at the pelvic brim and straightens as it enters the pelvis to become the rectum. Below the cut-off site, it expands into the rectal ampulla, filling the posterior pelvis from the left side. An anorectal angle of 90 degrees is formed at this point by the action of the puborectalis portion of the levator ani muscle complex, separating the anal canal below from the rectum above. The anorectal angle is believed to be one factor among several that are important in the maintenance of normal anal continence. The puborectalis muscle maintains this angle through its normal tone, and during normal defecation, it relaxes to depress the pelvic floor and then contracts to elevate the pelvic floor during and after bowel emptying.

The anorectal continence mechanism consists of an internal sphincter composed of smooth muscle and an external sphincter composed of striated muscle. The internal sphincter is a visceral muscle under autonomic control and normally has a high resting tone. The external sphincter is a striated muscle under voluntary control. In addition, there are sensory nerves in the rectum and pelvic floor. Continence is maintained at the level of the internal anal sphincter by gradual increases in the level of tonic contraction of the internal anal sphincter. This seal works only if the anal lining is sufficiently bulky to permit closure, and it is maintained by a combination of vascularity and infolding of the anal lining. The contractile efficiency of the internal sphincter is aided by contraction of the external anal sphincter. Relaxation of the puborectalis muscle creates a reflex relaxation of the internal anal sphincter. Under these circumstances, contraction of the internal anal sphincter. The efficiency of this process is closely linked to rectal sensation. Afferent sensation from the rectum appears to travel with the parasympathetic nerves to sacral segments S2 to S4. Sensation from the anal canal also travels to these sacral segments through the inferior hemorrhoidal branches of the pudendal nerve. The somatic apparatus of the rectum allows patients to distinguish between solid feces, liquid stool, and flatus. Impairment of this ability can have serious social consequences.

Innervation

The innervation of the gut is similarly complex. There are two ganglionic complexes in the bowel wall: (a) a myenteric plexus between the longitudinal and circular muscle coats, and (b) a submucosal plexus. The innervation of the smooth muscle of the bowel involves excitatory and inhibitory nonadrenergic, noncholinergic neurotransmitters and cotransmitters, primarily acetylcholine, substance P, and vasoactive intestinal polypeptide. The sphincters appear to be under separate neuronal control from nonspheincteric smooth muscle of the bowel. Sym pathetic stimulation (norepinephrine) appears to cause contraction of the internal anal sphincter, whereas parasympathetic stimulation causes relaxation of the internal anal sphincter. The internal anal sphincter receives sympathetic innervation by the hypogastric nerves from L5, and the parasympathetic innervation comes from sacral segments S1 to S3. The external anal sphincter is innervated by branches of the pudendal nerve, originating in the sacral segments S2 to S4, with some branches from the coccygeal nerve plexus (S4 to S5).

Like the bladder, the colon and rectum undergo a filling and emptying cycle; unlike the bladder, the lower end of the gastrointestinal tract is not a closed viscus but rather a one-way conduit through which waste matter passes (33). Like the bladder, colorectal function can be categorized into storage (continence) and emptying (defecation) components.

Anal Continence

Anal continence is maintained by a combination of colonic compliance and mechanisms for retention in the rectosigmoid that keep the distal rectum collapsed and empty. The forces of retention are both mechanical and physiologic. The mechanical forces promoting retention of stool involve the S-shaped anteroposterior angulations of the sigmoid colon and the spiral folds in the lumen formed by the valves of Houston. Also, the puborectalis muscle creates a sharp angulation of the anorectum, which is accentuated by contraction of this muscle. Increases in intraabdominal pressure accentuate these angulations. These pressure increases have consequences.

The most important factors in maintaining fecal continence are sphincteric factors. The anus has both internal and external sphincters. Both of these sphincters are tonically contracted in the resting state, with the internal sphincter more so than the external sphincter. The external sphincter contains both slow-twitch and fast-twitch fibers. It remains tonically contracted even during sleep. In addition to its tonic baseline contractility, the external anal sphincter can respond with a quick, forceful contraction during periods of stress to maintain anal control, and its degree of contraction varies with posture and activity. The internal sphincter is at or near its state of maximal contraction all of the time. It relaxes only to allow the passage of stool when the rectum reaches a threshold of distention. When this occurs, relaxation of

...
the internal sphincter allows the passage of matter into the distal anal canal. This stimulates multiple nerve endings to give warning of an impending movement of matter, which is detected as solid, liquid, or gaseous in nature. Continence is maintained by a reflex contraction of the external anal sphincter, which occurs concurrently with internal sphincter relaxation. Voluntary contraction of the anal sphincter, in conjunction with rectal movement, allows the individual to withhold a bowel movement until it is appropriate to release it.

**Defecation**

Defecation is the emptying phase of the colonic cycle. This may occur involuntarily in certain pathologic states or as a response to prolonged overdistention of the rectum, but defecation usually is a voluntary process. Voluntary defecation begins with closure of the glottis, which helps increase intraabdominal pressure, and by closure of the muscles of the pelvic floor. The diaphragm descends, and the muscles of the abdominal wall are contracted, raising intraabdominal pressure. The anal sphincter also contracts, further increasing intraabdominal pressure. Segmental contractions in the colon are inhibited. When the bolus of feces reaches the upper rectum, the muscles of the pelvic floor relax, the pelvic floor descends, and the acute rectal angle that existed at rest is straightened. Constriction of the distal muscles allows pressure to build up in the rectum, and when the internal sphincter relaxes, the bolus of stool is expelled. As the bolus passes, there is complete inhibition of electrical activity in the external sphincter, which contracts again only after the stool has been passed. The act of defecation represents the only known condition in which the external sphincter responds to increased intraabdominal pressure by relaxation rather than by contraction. At the end of defecation, the pelvic floor is elevated to its normal position, and the sphincters return to their tonically contracted resting state (“the closing reflex”).

The complex intricate mechanisms involved in maintenance of continence and defecation are poorly understood, grossly undervalued, and generally taken for granted until impairment occurs (34). The same is undoubtedly true for all aspects of pelvic floor function.

**Lower Urinary Tract Dysfunction**

Symptoms arising in the lower urinary tract account for a significant number of patient visits to gynecologists. Disturbances in bladder function produce a wide variety of urinary tract symptoms. To help the clinician organize an initial patient evaluation, these symptoms can be classified according to whether they are disturbances of storage, emptying, sensation, or bladder contents (Table 20.1).

### Table 20.1. Classification and Definition of Lower Urinary Symptoms in Women

#### Urinary Incontinence

Urinary incontinence is defined as involuntary loss of urine that is a social or hygienic problem and that is objectively demonstrable (37). Urinary incontinence is a symptom, not a diagnosis. It is not a normal part of aging, although the prevalence of the problem increases with age, and it is not a trivial complaint. Urinary incontinence affects 13 million Americans, with an estimated 1 million new cases diagnosed each year. The total annual cost to care for patients with incontinence in the United States is estimated at $11.2 billion in the community and $5.2 billion in nursing homes (38). The differential diagnosis of urinary incontinence is extensive (Table 20.2); however, urinary incontinence is almost always treatable. It can almost always be improved and frequently can be cured, often using relatively simple, nonsurgical interventions.

### Table 20.2. Differential Diagnosis of Urinary Incontinence

#### Principles of Investigation

The initial evaluation of most patients with incontinence is not difficult, but it requires a systematic approach to consider all possible causes. The following items should be part of the basic evaluation:

1. History
2. Physical examination
3. Urinalysis, with urine culture and cytology as appropriate
4. Measurement of postvoid residual urine
5. Frequency/volume bladder chart

When these steps have been completed, some patients benefit from urodynamic studies to create a more comprehensive bladder biophysical profile before treatment.

#### History

Every incontinent patient should undergo a thorough history, including a review of symptoms, general medical history, review of past surgery, and current medications. It is helpful to write down the patient’s chief complaint in her own words and expand the history from this point. The patient’s most troubling symptoms must be ascertained—how often she leaks urine, how much urine she leaks, what provokes urine loss, what helps the problem or makes it worse, and what treatment (if any) she has had in the past.

The general medical history often reveals systemic illnesses that have a direct bearing on urinary incontinence, such as diabetes mellitus (which produces osmotic...
diuresis if glucose control is poor), vascular insufficiency (which can lead to incontinence at night when peripheral edema is mobilized into the vascular system, resulting in increased diuresis), chronic pulmonary disease (which can lead to stress incontinence from chronic coughing), or a wide variety of neurologic conditions that can affect the neurourologic axis at any point from the cerebral cortex to the peripheral nervous system.

Many medications affect the lower urinary tract (39,40).

1. Sedatives such as the benzodiazepines may accumulate in the patient's system and cause confusion and secondary incontinence, particularly for elderly patients.
2. Alcohol may have similar effects to benzodiazepines and also impairs mobility as well as produces diuresis.
3. Anticholinergic drugs may impair detrusor contractility and may lead to voiding difficulty and overflow incontinence. Drugs with anticholinergic properties are widespread and include antihistamines, antidepressants, antipsychotics, opiates, antispasmodics, and drugs used to treat Parkinson's disease.
4. a-Adrenergic agents may have a profound effect on the lower urinary tract. a-Agonists, which are often found in over-the-counter cold remedies, increase outlet resistance and may lead to voiding difficulty.
5. a-Blockers, which are often used in the treatment of hypertension (e.g., prazosin, terazosin), may decrease urethral closure and lead to stress incontinence (41).
6. Calcium-channel blockers may reduce bladder smooth muscle contractility and lead to voiding problems or incontinence; they may also cause peripheral edema, which may lead to nocturia or nighttime urine loss.
7. Angiotensin-converting enzyme inhibitors may result in a chronic and bothersome cough that can result in increasing stress urinary incontinence in an otherwise asymptomatic patient (42).

Physical Examination

The physical examination of the patient with incontinence should include detection of general medical conditions that may affect the lower urinary tract. Such conditions include cardiovascular insufficiency, pulmonary disease, occult neurologic processes (e.g., multiple sclerosis, stroke, Parkinson's disease, and anomalies of the spine and lower back), as well as abnormalities of genitourinary development. The pelvic examination, including an evaluation of urethral support, is of crucial importance.

1. Patients with urinary incontinence should be examined with a full bladder, particularly if stress incontinence is a complaint.
2. The patient should stand with her feet separated to shoulder width and cough several times to see if the physical sign of stress incontinence can be demonstrated. If urine loss occurs, confirm with the patient that this is the problem that has been bothering her. Many multiparous women may lose a small amount of urine during such an examination but not be bothered by it.
3. Many women with urge incontinence caused by detrusor overactivity may demonstrate urine loss during a cough stress test, but this finding may not be relevant to their real complaint. The physical findings must be set within the context of the patient's history to be relevant.
4. The patient's complaint should be reproduced by the physician and confirmed with the patient, particularly if surgery is contemplated.

Urinalysis

Examination of the urine by dipstick testing and microscopy is necessary to exclude infection, metabolic abnormalities, and kidney disease.

1. Urine culture will help rule out infection, which can be associated with incontinence.
2. Urine cytology is useful as a screening test for urinary tract malignancy, but the utility of the test depends greatly on the accuracy of the laboratory performing the cytology. Routine urinary cytology is not helpful, but testing should be performed in women older than 50 years of age with irritative urinary tract symptoms, particularly if those symptoms are of sudden onset.
3. Hematuria should be evaluated with cytology, intravenous urography, and cystoscopy. Bladder biopsy should be performed by the surgeon who will treat the patient in the event that a malignancy is discovered.

Measurement of Postvoid Residual Urine

Incomplete bladder emptying is a frequent cause of incontinence. Patients with a large postvoid residual urine have a diminished functional bladder capacity because of the dead space occupied in the bladder by retained urine. This stagnant pool of urine is also a frequent source of urinary tract infections, because the major defense of the bladder against infection is frequent, complete emptying.

A large postvoid residual can contribute to urinary incontinence in two ways. If the bladder is overstretched, increases in intraabdominal pressure can force urine past the urethral sphincter, causing stress incontinence. In some cases, bladder overdistention may provoke an uninhibited contraction of the detrusor muscle, leading to incontinence. Both conditions may exist together, further complicating the problem.

Patients with an elevated postvoid residual urine should begin a regimen of clean, intermittent self-catheterization to improve bladder emptying. In many cases, this technique may be the only therapy needed to correct the incontinence and eliminate recurrent urinary tract infections. The recent development of sacral nerve root neuromodulation for nonobstructive voiding dysfunction now offers an additional treatment option for some of these women (43).

Frequency/Volume Bladder Chart

A frequency/volume bladder chart is an invaluable aid in the evaluation of patients with urinary incontinence, but use of this tool often is neglected (44,45). A frequency/volume chart is a voiding record kept by the patient for several days. Use of a plastic measuring "hat" that fits over the patient's toilet bowl is very helpful in keeping accurate records. Patients should be instructed to write down the time of every void on the chart and measure the amount of urine voided. The time of any incontinent episodes should be recorded, and it is also helpful to maintain an annotated record of symptoms or activities associated with urine loss. If desired, the patient can also be instructed to keep a record of fluid intake, although in most cases intake can be estimated with some accuracy from the amount of urine produced.

A frequency/volume bladder chart gives an accurate record of 24-hour urinary output, the total number of daily voids, the average voided volume, and the functional bladder capacity (largest volume voided in normal daily life). This information allows the clinician to confirm complaints of urinary frequency with objective data and to determine whether part of the patient's problem is an abnormally high (or low) urinary output. For example, incontinence is a common complaint of many patients with diabetes, and the first step in the management of such patients is to control their blood glucose levels and decrease their urinary output rather than using medications or surgery, which often is ineffective. Conversely, many patients with incontinence decrease their fluid intake dramatically in an attempt to control their urine loss, not realizing that the resulting highly concentrated urine is often much more irritating to their bladders than a higher volume of a more diluted urine. As a rule, daily urine output should be 1,500 to 2,500 mL, with an average voided volume of about 250 mL, a functional bladder capacity (largest voided volume) of 400 to 600 mL, and seven or eight voids per day. The frequency/volume chart is the foundation for conservative management of urinary incontinence based on fluid manipulation and behavioral management of voiding habits.

Urodynamic Studies

At its most basic level, a urodynamic study is anything that provides objective evidence about lower urinary tract function (46). In this sense, measurement of a patient's voided urine volume and catheterization to determine her postvoid residual urine are urodynamic studies. A frequency/volume chart is also a valuable urodynamic study. Obtaining clinically useful information does not always require the use of expensive, complex technology.

Bladder Filling Test

If a patient with a complaint of urinary incontinence comes for her examination without a full bladder, a great deal of information can be obtained by a simple bladder filling test (47). The patient should urinate and measure the volume she voids. The residual urine can be measured by draining it through a 10- or 12-Fr. red rubber catheter placed into the bladder. Once the residual urine has been drained out, a bag of sterile water or saline attached to the catheter can be used to fill the patient's bladder at a rate of 60 to 75 mL/min until her functional bladder capacity is reached.

If the patient experiences urgency with accompanying urine loss during bladder filling, it is highly likely that she has motor urge incontinence caused by detrusor overactivity. If the patient leaks an isolated spurt of urine each time she coughs, and this leakage is demonstrated repetitively and confirmed as the problem for which she is seeking help, she has stress incontinence. Further evaluation is required for patients who exhibit mixed incontinence (the presence of both stress and urge
incontinence), who exhibit prolonged leakage with coughing (suggestive of a cough-induced detrusor contraction), who have marked incontinence with a nearly empty bladder or with minimal effort, who develop incontinence after their prolapse is treated, or who report incontinence that cannot be verified by simple testing.

**Multichannel Urodynamic Studies** Multichannel urodynamic studies produce a biophysical profile of a patient’s bladder and urethral function, but such studies are helpful only if they are interpreted with reference to the patient’s history and the results of her physical examination. Clinicians who recommend that patients undergo urodynamic studies without first taking a careful history and performing a thorough physical examination are likely to obtain useless or irrelevant information from these expensive investigations. A detailed history and a thorough physical examination often can predict reliably the type of incontinence when these findings are combined with those derived from some simple urodynamic tests (44,49 and 50).

A wide variety of sophisticated studies of bladder and urethral function have been developed to measure various aspects of bladder storage and bladder emptying. These studies include uroflowmetry, filling cystometry, pressure-flow voiding studies (with and without simultaneous electromyography of the pelvic floor), urethral pressure profilometry, and determination of leak-point pressure.

The bladder is affected by neural impulses running along afferent and efferent sensory pathways and generates a pressure–volume relationship in the cycle of micturition (Fig. 20.6). As bladder volume increases, tension-stretch receptors in the bladder wall are activated, and the afferent sensory impulses gradually lead to a desire to void. Normally, this occurs between 150 and 250 mL. Normally, a patient is able to suppress a micturition reflex until an appropriate time. She should then be able to relax the pelvic floor and generate a sustained contraction of the bladder detrusor muscle until emptying is complete, after which the detrusor relaxes and the cycle begins again.

![Figure 20.6 Pressure-volume relationship of the micturition cycle.](image)

**Cystometry** Cystometry is the technique by which the pressure–volume relationship of the bladder is measured. It can be divided into two phases: (a) filling cystometry and (b) voiding cystometry (also called a pressure-flow study). Simple cystometry is carried out when bladder pressure only is measured during filling. Because the bladder is an intraabdominal organ, however, the pressure recorded in the bladder is a combination of several other pressures, most notably the pressure created by the activity of the detrusor muscle itself and the pressure exerted on the bladder by the weight of the surrounding intraabdominal contents (e.g., uterus, intestines, straining, or exertion). For this reason, the technique of subtracted cystometry is used.

Subtracted cystometry is an attempt to measure the pressure exerted in the bladder by the activity of the detrusor muscle. Subtracted cystometry is carried out by measuring total intravesical pressure \( P_{\text{tot}} \) with a bladder pressure catheter, approximating intraabdominal pressure \( P_{\text{abd}} \) by measuring either rectal or vaginal pressure, and using an electronic instrument to subtract the latter from the former to give the true detrusor pressure \( P_{\text{det}} \) or the subtracted pressure:

\[
P_{\text{det}} = P_{\text{tot}} - P_{\text{abd}}
\]

Measurements can be made using either expensive electronic microtip transducer pressure catheters or inexpensive fluid-filled pressure lines. The technique for such a study is shown in Figure 20.7.

![Figure 20.7 Subtracted filling cystometry.](image)

1. Fluid (usually sterile water or saline, sometimes radiographic contrast dye) is infused at a rate of 50 to 100 mL/min. The volume infused and the pressure measurements are recorded continuously. The patient's bladder may be filled with her lying supine, in a modified lithotomy position, sitting, or standing. When possible, standing cystometry is usually preferable because most patients with incontinence complain of this problem when they are erect.
2. The point at which any leakage occurs should be noted carefully.
3. During filling, the point at which the first desire to void is experienced should be noted, along with the point at which the patient experiences a strong desire to void, urgency, and her cystometric capacity.
4. Provocative maneuvers are performed, such as coughing, heel-bouncing, and listening to the sound of running water in an attempt to produce urinary incontinence and to provoke any uninhibited detrusor contractions, which may be the cause of the patient's symptoms.

Normal cystometric values for women are shown in Table 20.3.
Table 20.3. Approximate Normal Values of Female Bladder Function

At cystometric capacity (ideally, the same as the patient's functional bladder capacity), the filling catheter should be removed, leaving only the pressure measurement lines in place (Fig. 20.8). If the pressures are allowed to equilibrate for 1 minute, bladder compliance can be calculated by dividing the bladder volume in milliliters by the pressure of water in centimeters. The patient should then void. The urine flow rate can be measured and correlated with the detrusor pressure. This technique allows a better assessment of voiding function than measurement of urine flow rate alone.

Figure 20.8 Pressure–flow voiding study. The filling catheter has been removed. Volume voided, urine flow rate, total bladder pressure, rectal (abdominal) pressure, and subtracted detrusor pressure are recorded. (From Wall LL, Addison WA. Basic cystometry in gynecologic practice. Postgrad Obstet Gynecol 1988;26[2]:3, with permission).

Urethral Pressure Profile

In addition to an assessment of filling and emptying, specific urodynamic tests allow some quantitative assessment of sphincteric integrity. The urethral pressure profile is a test designed to measure urethral closure. Because continence requires the pressure in the urethra to be higher than the pressure in the bladder, it was believed that measuring the pressure differential between the two would provide useful clinical information. The urethral pressure profile is generated by slowly pulling a pressure-sensitive catheter through the urethra from the bladder, which is usually filled with a standardized volume of fluid (Fig. 20.9). The urethral closure pressure ($P_{\text{close}}$) is the difference between the urethral pressure ($P_{\text{ure}}$) and the bladder pressure ($P_{\text{ves}}$):

$$P_{\text{close}} = P_{\text{ure}} - P_{\text{ves}}$$

Figure 20.9 Parameters normally measured during urethral pressure profile studies (International Continence Society).

Although this pressure can be used to differentiate groups of normal women from groups of those with stress incontinence (women with stress incontinence tend to have higher urethral pressure levels than those who do not), there is considerable overlap between the two groups. It has also been suggested that women with stress incontinence have lower urethral closure pressure (<20 cm H$_2$O) than those who do not have this condition; however, there is considerable debate about this (51, 52 and 53). Because stress incontinence, by definition, occurs during increases in intraabdominal pressure that are generated by some kind of physical activity, it is not obvious why measurement of resting urethral pressure should be relevant to stress-related leakage, which is a dynamic event. In general, the urethral pressure profile has been a disappointing test with questionable clinical utility.

Leak-Point Pressure Test

A more promising test appears to be the leak-point pressure test (54). The idea behind this test is quite simple: the amount of force that it takes to produce stress incontinence should be related to the severity of the stress incontinence and to the strength of the sphincteric unit. The leak-point pressure is the intravesical (or sometimes intraabdominal) pressure measured at the moment that stress incontinence occurs. It is usually determined at a bladder volume of 200 mL, but the technique has not been completely standardized. When the appropriate bladder volume has been reached, patients are asked to cough with gradually increasing force (cough leak-point pressure), and finally to strain slowly (Valsalva) to increase intravesical pressure gradually. The lowest pressure at which leakage occurs is recorded as the cough or the Valsalva leak-point pressure. If leakage is not demonstrated, the highest pressure that has been obtained can be recorded with the notation "no leakage" to the specified pressure as measured in cm H$_2$O. This figure appears to give a reasonable estimation of sphincteric strength. Standardization and interpretation of these tests are in early stages, and further research is required.

Extraurethral Causes of Incontinence

Involuntary urine loss can occur through two basic routes. Most urinary incontinence represents unwanted urine loss through the urethra (transurethral incontinence); however, urine loss can also occur through abnormal openings. These openings can be created by congenital causes or some form of trauma. The congenital causes of urinary incontinence are not common and usually are easy to diagnose. The most extreme cases are caused by bladder extrophy, in which there is a congenital absence of the lower anterior abdominal wall and anterior portion of the bladder, resulting in the entire bladder opening directly to the outside.
Sexual Health and Reproduction

**Ectopic Ureter**

The most common and most subtle congenital anomaly causing extravasational urine loss is an ectopic ureter (55). Generally, ectopic ureters are detected early in life, but occasionally one may escape detection until adolescence or early adulthood. In infancy, an ectopic ureter should be suspected when a mother seeks care for her baby whom she says is never dry. Normally, infants have periods of dryness interspersed with periods of wetness. If a parent notes that every time the baby is checked her diaper is wet, this is the first clue that an ectopic ureter may exist because this ureter will most likely drain outside the bladder, causing continuous urinary leakage. Most commonly, the ectopic ureter drains into the vagina, but occasionally, it may drain into the urethra distal to the point of continence. Ectopic ureter has been reported as an uncommon cause of suburethral mass (57). This condition can be diagnosed easily by excretory urography.

**Urinary Fistula**

A traumatic opening between the urinary tract and the outside is called a fistula. Worldwide, the most common cause of fistulas is obstructed labor. This was also true in the Western world 150 years ago, but advances in the provision of basic obstetric services and advanced obstetric intervention have virtually eliminated this problem in developed countries. The rest of the world is not so fortunate.

Obstructed labor often occurs in rural areas where girls are married young (sometimes as early as 9 or 10 years of age) and where transportation is poor and access to medical services is limited. In such circumstances, pregnancy often occurs shortly after menstruation begins and before maternal skeletal growth is complete. When labor begins, cephalopelvic disproportion is common, and little can be done to correct fetal malpresentations. Women may be in labor as long as 5 to 6 days without intervention, and if they survive, they usually give birth to a stillborn infant. In such cases, the soft tissues of the pelvis have been crushed by constant pressure from the fetal head, leading to an ischemic vascular injury and subsequent tissue necrosis. When this tissue sloughs, a genitourinary or rectovaginal fistula develops. Many of these patients have complex or multiple fistulas, involving total destruction of the urethra and sloughing of the entire bladder base. Obstetric fistulas are frequently as large as 5 to 6 cm in diameter.

After such fistulas develop, the lives of these young women (most of whom are younger than 20 years of age) are ruined unless they can gain access to curative surgical services. The constant, uncontrolled dribble of urine makes them offensive to their husbands and family members. They can no longer live with their families. Most of them eventually become destitute social outcasts—and yet these are otherwise healthy functional young women. The social and economic costs of this problem are enormous, but the problem has largely been neglected by the world medical community. The morbidity associated with obstetric fistulas remains, along with the related problem of maternal mortality, one of the single most neglected issues in international women's health care (58).

In the industrialized world, the most common causes of genitourinary fistulas are surgery, malignancy, and radiation therapy or the interrelation of all three factors. Most often, a vesicovaginal fistula develops after an otherwise uncomplicated vaginal or abdominal hysterectomy in which a small portion of the bladder was inadvertently trapped in a surgical clamp or was transfixed by a suture. These fistulas most often occur at the vaginal apex and are no larger than 1 to 2 mm. The amount of urine that can leak through a fistula of any size, however, is enormous.

A wide variety of techniques are available for fistula repair (59,60). Traditionally, fistula repair has been performed after a waiting period to allow the resolution of inflammation and formation of scar tissue. This is particularly important in the case of obstetric fistulas, in which the extent of the vascular injury to the soft tissues of the pelvis may not be apparent for many weeks. However, there has been a recent trend toward early closure of small gynecologic fistulas (61). The keys to closure of a vesicovaginal fistula include wide mobilization of tissue planes so that the fistula edges can be approximated without any tension, close approximation of tissue edges, closure of the fistula in several layers, and meticulous attention to postoperative bladder drainage for 10 to 14 days. The closure of large fistulas will be enhanced by the use of tissue grafts (e.g., Martius labial fat-pad grafts, gracilis muscle flaps) that bring an additional blood supply to nourish an area that has sustained vascular injury.

**Stress Urinary Incontinence**

Stress incontinence occurs during periods of increased intraabdominal pressure (e.g., sneezing, coughing, or exercise) when the intravesical pressure rises higher than the pressure that the urethral closure mechanism can withstand, and urine loss results. Stress urinary incontinence is the most common form of transurethral urinary incontinence in women. A community survey of 1,060 randomly selected women older than 18 years of age in South Wales, for example, revealed that 22% of women had this complaint (62). In a survey of 144 collegiate female varsity athletes, 27% complained of stress incontinence while participating in their sport (63). The activities most likely to produce urinary loss were jumping, high-impact landings, and running. Even in otherwise fit and vigorous women, the continence mechanism is particularly susceptible to stress incontinence.

The term stress incontinence refers to three distinct entities: a symptom, a sign, and a condition (37). Confusion can occur if the differences between these three entities are not appreciated.

**Symptoms and Signs**

The symptom of stress incontinence refers to the patient's complaint that she leaks urine when intraabdominal pressure is increased. Such urine leakage may result from a variety of conditions: genuine stress incontinence, a detrusor contraction provoked by coughing or change of position, incomplete bladder emptying, or a urethral diverticulum. The patient's complaint of stress incontinence makes it likely, but not certain, that she has this problem, but the complaint must be confirmed by some objective means. A patient should never undergo surgery for stress incontinence on the basis of symptoms alone.

The sign of stress incontinence refers to the physical demonstration of urine loss during conditions of increased intraabdominal pressure (e.g., coughing) while the patient is being examined. Mere demonstration of stress urinary leakage during a physical examination does not mean that the patient has a clinical problem with stress incontinence. According to the International Continence Society's definition, incontinence exists when urine loss becomes a social or hygienic problem (37). Many women experience occasional stress urinary leakage that is merely annoying or inconvenient. These women do not consider themselves incontinent, nor do they need surgery; however, studies have also shown that there is little relationship between the volume of urine lost and the distress that it causes a patient with incontinence (64).

**Genuine Stress Incontinence**

A specific technical term, genuine stress incontinence, is used to refer to the urodynamic diagnosis of stress incontinence (37). Genuine stress incontinence is said to exist when a patient has demonstrable urinary leakage when intraabdominal pressure exceeds the maximum urethral closure pressure in the absence of a detrusor contraction. This term can only be used for a patient who has undergone urodynamic testing and who has met these test criteria, which prove that her urine loss is caused by ineffective urethral closure during periods of increased intraabdominal pressure (65,66). This urodynamic diagnosis must be analyzed with reference to the patient's complaint; one may have genuine stress incontinence that is nonetheless not a clinical problem or is a less severe problem than urge incontinence caused by detrusor muscle overactivity.
Effective urethral closure is maintained by the interaction of extrinsic urethral support and intrinsic urethral function, which can be affected by intrinsic sphincteric weakness or deficiency that caused by anatomic hypermobility of the urethra, which produces faulty urethral closure under stress conditions such as sneezing, and straining. These muscle groups can be rehabilitated through exercise and physical therapy, which allows them to maintain tone over a long period and to increase tone suddenly to compensate for the increased abdominal pressure that occurs with coughing, sneezing, and straining.

Clinical appreciation of the importance of extrinsic support and intrinsic urethral function have led surgeons to separate stress incontinence into two broad types: the presence of genuine stress incontinence owing to ineffective urethral closure rather than detrusor overactivity.

Clinical treatment of stress incontinence has been based on an understanding of the factors that contribute to the condition. These factors include extrinsic factors such as obesity, smoking, or excessive fluid intake, as well as intrinsic factors such as the inherent biologic strength of the urinary sphincter, the level of physical stress placed on the sphincter, and the psychosocial milieu in which the patient lives. Other women may be profoundly relieved to find out that the small amount of leakage they experience from time to time is not abnormal. In any case, the interaction of these three biopsychosocial factors opens up a variety of strategies for the management of stress incontinence. Surgical intervention is only one strategy, and it addresses only the biologic competence of the sphincteric mechanism rather than either of the other factors that interact to produce the clinical problem.

Clinical appreciation of the importance of extrinsic support and intrinsic urethral function have led surgeons to separate stress incontinence into two broad types:

1. That caused by anatomic hypermobility of the urethra, which produces faulty urethral closure under stress
2. That caused by intrinsic sphincteric weakness or deficiency

The latter type is more prevalent, probably accounting for somewhere between 80% and 90% of stress urinary incontinence.

Nonsurgical Treatment

Many extrinsic, as well as intrinsic, factors influence urethral closure, and surgery is not the only option, nor is it always the best choice, for this condition. Nonsurgical approaches to stress incontinence are based on manipulation of the factors that contribute to the condition. These approaches may involve reducing factors that worsen the problem (e.g., obesity, smoking, or excessive fluid intake) or by intervening actively to enhance the ability of the patient's pelvic floor to compensate for increased intraabdominal pressure (e.g., making adaptive changes in posture, rehabilitating pelvic muscles, improving estrogen status, using α-adrenergic stimulants, or wearing a device to improve urethral support).

Muscle Strengthening By its connection with the endopelvic fascia, the musculature of the levator ani complex provides substantial support for the urethra, vagina, and rectum as they descend through the pelvic floor (66). The perirethral levator ani muscles contain both type I (slow-twitch) and type II (fast-twitch) muscle fibers, which allows them to maintain tone over a long period and to increase tone suddenly to compensate for the increased abdominal pressure that occurs with coughing, sneezing, and straining. These muscle groups can be rehabilitated through exercise and physical therapy (67). There are two possible ways in which this therapy
improves stress urinary incontinence. First, strengthening the striated urogenital sphincter could enhance its ability to constrict the urethral lumen, yielding a stronger closure force in the urethra at rest or increasing the forces of urethral closure generated during a cough or other stressful situations. Second, because the levator ani muscles play an important role in pelvic and urethral support, exercise could improve the support of the proximal urethra, generating improved continence during a cough, when the muscles are active, without producing a noticeable rise in resting urethral pressure measurements.

Kegel was the first person to investigate pelvic floor muscle strengthening. He developed the patient's awareness of the pubococcygeus muscle and instructed her in exercises to strengthen this muscle with a crude pneumatic biofeedback device called a perineometer. He stressed the importance of supervised instruction and encouragement in the performance of these exercises and reported good success rates in relieving symptomatic stress incontinence by his program. Although nearly all gynecologists are familiar with these exercises, they rarely are taught and used as Kegel did originally, and this form of therapy has often degenerated into a few brief words of oral instruction in which the patient is told to stop and start her urine stream a few times each day while voiding. Programs based on this approach are not only disappointing in their results but also can train women to become dysfunctional voiders.

For muscular rehabilitation of the pelvic floor to be effective, exercises must be supervised, performed regularly, and aided by some form of feedback so that the patient can judge her progress. Careful supervision makes a dramatic difference in the degree of success that can be obtained (67,68). Using an intensive program of physical therapy over 3 months with pretherapy and posttherapy urodynamic and radiographic evaluations, Benvenuti and colleagues cured 32% of their patients of genuine stress incontinence and brought about marked improvement in symptoms in the remaining 68%. Both tonic and phasic contractility of the pubococcygeus muscle were improved, and there was clear-cut improvement of bladder neck support, as seen on radiographic evaluation in 13 of 15 patients who underwent repeat studies. After 12 to 36 months of follow-up, 77% reported that they had maintained the functional level they had attained at the end of treatment (69).

Similarly, Peatle and co-workers trained 30 premenopausal women with genuine stress incontinence in pelvic muscle rehabilitation with an ingenious form of resistive therapy using a set of weighted vaginal cones (70). These cones are of the same size but of increasing weight (from 20 to 100 g). After inserting a cone into the vagina, it can only be retained in place by contracting the pelvic floor. As one cone is successfully retained for 15 minutes, the next heaviest cone is used, thus progressively increasing the retained weight. The feeling that the cone is slipping out of the vagina results in a form of sensory biofeedback that causes an increased contraction in the pelvic floor in an attempt to retain it. At the end of 1 month of therapy, 19 patients (70%) reported cure or significant improvement of symptoms, and only 11 (37%) opted for subsequent surgical intervention.

Physical therapy will not cure or improve all cases of stress incontinence; however, properly supervised and rigorously performed techniques for pelvic muscular rehabilitation can play a significant role in the treatment of genuine stress incontinence (69). Patients can expect improvement in their symptoms by tensing the muscles of the pelvic floor on holding these positions at each, 15 to 20 times per session, three sessions per day. This will strengthen slow-twitch muscle fibers. Patients should also practice a similar number of rapid contractions to strengthen the fast-twitch muscle fibers. Pelvic muscle exercises should be taught to patients one-on-one during a pelvic examination because many patients contract the wrong muscles; teaching Kegel exercises to large groups in classrooms is not worthwhile. Because pelvic muscle rehabilitation is virtually without side effects, involves the patient in her own care, and may prevent the deterioration of subsequent pelvic organ prolapse if used regularly, physicians should be encouraged to incorporate pelvic muscle exercises into routine health maintenance programs for women.

Drug Therapy

The urethra and bladder neck is maintained in large part by a -adrenergic activity from the sympathetic nervous system. For this reason, many pharmacologic agents have been used with varying degrees of success to treat stress incontinence. These drugs include imipramine (which has a concomitant relaxing effect on the detrusor), ephedrine, pseudoephedrine, phenylpropanolamine, and norepinephrine. Unfortunately, many of these compounds also increase vascular tone and may, therefore, lead to problems with hypertension, a condition that afflicts many postmenopausal women with stress incontinence. These effects may preclude the use of -agonists in such patients. A recent U.S. Food and Drug Administration (FDA) statement urged caution in the use of phenylpropanolamine, a -agonist, in women because of an apparent increased epidemiologic risk for hemorrhagic cerebral vascular accidents. Although the risk remains very low, it is not possible to predict who is at risk for this complication (71). The use of these agents in the treatment of stress urinary incontinence appears to be more limited than originally thought. Of equal importance, however, is the role of -blockers such as prazosin in causing stress incontinence. These drugs are commonly used in treating hypertension because of their relaxing effects on vascular smooth muscle; however, they may also relax the bladder neck and urethra to the point at which incontinence develops. For patients who have symptoms of stress incontinence while taking this or a related drug, their antihypertensive medication should be changed before surgery is considered because their incontinence may resolve spontaneously with a change of medication (72).

Postmenopausal women with urogenital atrophy resulting from estrogen deprivation and concurrent urinary incontinence should receive hormone replacement therapy as part of their therapeutic regimen unless such therapy is contraindicated. Not only will many complaints of urgency, frequency, and irritation often disappear, but evidence suggests that estrogen replacement enhances the effectiveness of -adrenergic receptors in the urethra (72,73).

Electrical Stimulation

In addition to physical therapy and selected pharmacologic agents, electrical stimulation therapy has been used to treat stress incontinence. This treatment may offer advantages to women with moderate to severe weakness of the pelvic floor muscles who have difficulty performing pelvic muscle exercises themselves. Electrical stimulation, particularly when used in conjunction with individual instruction by a pelvic floor physical therapist, also is useful in teaching the patient how to tense the muscles correctly. Passage of direct electrical current to the muscles of the pelvic floor causes them to contract and simultaneously causes a reflex inhibition of detrusor activity. The stimulus can be applied trans vaginally or transrectally in either continuous or intermittent fashion. When compared with sham devices and pelvic floor exercises, electrostimulation has produced mixed results in the treatment of stress urinary incontinence (74,75). Although many authors have reported the use of -agonists in such patients. A recent U.S. Food and Drug Administration (FDA) statement urged caution in the use of phenylpropanolamine, a -agonist, in women because of an apparent increased epidemiologic risk for hemorrhagic cerebral vascular accidents. Although the risk remains very low, it is not possible to predict who is at risk for this complication (71). The use of these agents in the treatment of stress urinary incontinence appears to be more limited than originally thought. Of equal importance, however, is the role of -blockers such as prazosin in causing stress incontinence. These drugs are commonly used in treating hypertension because of their relaxing effects on vascular smooth muscle; however, they may also relax the bladder neck and urethra to the point at which incontinence develops. For patients who have symptoms of stress incontinence while taking this or a related drug, their antihypertensive medication should be changed before surgery is considered because their incontinence may resolve spontaneously with a change of medication (72).

Postmenopausal women with urogenital atrophy resulting from estrogen deprivation and concurrent urinary incontinence should receive hormone replacement therapy as part of their therapeutic regimen unless such therapy is contraindicated. Not only will many complaints of urgency, frequency, and irritation often disappear, but evidence suggests that estrogen replacement enhances the effectiveness of -adrenergic receptors in the urethra (72,73).

Anterior Colporrhaphy

Anterior vaginal repair is the oldest operation for stress incontinence in gynecology. It was described by Howard Kelly in 1914 (81). He believed that stress incontinence was caused by an open vesical neck rather than from loss of urethral support, and he designed an operation to cure this condition by pulling the bladder neck closed using periurethral Kelly plication sutures. This operation remained the standard first approach to stress incontinence until the middle of the twentieth century and still is popular among many practitioners.

Many different operations have been lumped together under the term anterior colporrhaphy, including simple plication of the bladder neck, elevation of the bladder neck by plicating the fascia under the urethra, and elevation and fixation of the bladder neck by passing sutures lateral to the urethra and driving the needles anteriorly, well behind the back of the public symphysis for fear about the pubic symphysis (82).

The mechanism of this operation, when it works, is preventing excessive displacement of endopelvic fascia beneath the urethra so that the urethra can be closed during coughing or sneezing. The main advantage of this operation is that it avoids an abdominal incision, which may not be well tolerated by older women. It also allows the operation to be performed in conjunction with other vaginal surgery, such as vaginal hysterectomy for uterine prolapse.

The problem with most techniques of anterior colporrhaphy is that they do not hold up well over time (82,83,84). In essence, this operation attempts to take
weak support from below and to push it back up from below, with hope that these structures will maintain their strength and position over time. Although there have been excellent long-term results shown with anterior colporraphy, most of these results use specific techniques requiring skillful dissection of the endopelvic fascia, deep bold bites of suture, and fixation of permanent sutures to the pubic bone from below: in essence, a transvaginal retropubic bladder neck suspension (85,86).

Most surgical series that have evaluated techniques of anterior colporraphy for stress incontinence show long-term success rates of only 35% to 65%, a figure that most would regard as unacceptably low. Anterior colporraphy should be reserved primarily for patients requiring cystocele repair who do not have significant stress incontinence.

**Surgery to Correct Urethral Hypermobility**

**Retropubic Urethropexy** The modern era of retropubic surgery for stress incontinence began in 1949, when Marshall, Marchetti, and Krantz described their technique for urethral suspension in a male with postprostatectomy incontinence (87). Since that time, a variety of modifications of this operation have been described, all of which share at least two characteristics: they are performed through an open low abdominal incision or with laparoscopically assisted exposure of the space of Retzius, and they all involve attachment of the periurethral or perivesical endopelvic fascia to some other supporting structure in the anterior pelvis (Fig. 20.13). In the Marshall-Marchetti-Krantz operation, the periurethral fascia is attached to the back of the pubis. Another approach, the Burch colposuspension, involves the attachment of the fascia at the level of the bladder neck to the ilipectineal ligament (Cooper’s ligament) (85,89). With the paravaginal repair, the lateral endopelvic fascia along the urethra and bladder is reattached to the arcus tendinous fascia pelvis (90,91). In the Turner-Warwick vaginaobturator shelf procedure, the endopelvic fascia, vagina, or both are attached to the fascia of the obturator internus muscle (92,93). All of these operations cure stress incontinence by correcting anatomic hypermobility of the urethra and bladder neck. The long-term success rate for patients undergoing these operations as primary procedures for stress incontinence is in the range of 70% to 90% (94,95,96,97 and 98).

Retropubic urethropexy has had high success rates; however, the traditional route, which requires an abdominal incision, results in increased morbidity when compared with transvaginal corrective procedures. Presumably, laparoscopically assisted retropubic urethropexy would have a decreased recovery time when compared with the traditional open approach; however, the learning curve is prolonged with this technique, and the published results of the success rate of this operation to date are mixed (99,100) and 101. Many surgeons have made substantial modifications to the operation in an attempt to perform it laparoscopically, and these modifications may be a factor explaining these differences in outcome.

No operation is perfect, however (102,103). Depending on how high and tight the suspending sutures are tied, these operations may introduce an element of urethral kinking or obstruction, with subsequent voiding difficulty (104,105 and 106). This can be a significant long-term complication for patients undergoing this type of surgery. Operations that put sutures directly into the pubic symphysis may cause debilitating osteitis pubis, which can disable an otherwise healthy woman for several months. The normal vaginal axis is almost horizontal, with the vagina resting on top of the levator plate (Fig. 20.14). Because the vagina is a tubular structure, pulling up on the anterior vagina also elevates the posterior vagina. This can pull the posterior vagina out of its normal position, opening the rectouterine pouch of Douglas and thereby predisposing patients to enterocele formation, uterine prolapse, and vaginal vault erosion. For this reason, culdoplasty can be performed at the time of bladder neck suspension to reduce the incidence of future prolapse (107).

**Transvaginal Urethropexy** Needle suspension procedures are so named because they suspend the urethra and bladder neck through a technique that involves passage of sutures between the vagina and anterior abdominal wall using a specially designed long needle carrier. To perform these operations, a vaginal incision is typically made at the level of the bladder neck, the endopelvic fascia is perforated, the space of Retzius is entered from below, and a permanent suture is passed down through a low abdominal incision to the retropubic space, where it is fixed to the endopelvic fascia at the level of the bladder neck. The long needle is then passed back up through the retropubic space to the abdominal incision, where it is tied in place (Fig. 20.15). The first needle suspensions were performed by a gynecologist, Dr. Armand Pereyra, in the 1950s, but many urologic surgeons have since made modifications to the technique (108,109,110,111,112 and 113).

Figure 20.14 Normal location of structures over the pelvic floor. Note that the normal vagina is almost horizontal, lying over the levator plate. Any operation that pulls the vagina forward, away from its normal location, increases the risk of enterocele formation and the development of rapidly progressive prolapse.

Figure 20.15 Guidance of the long needle through the space of Retzius using the surgeon’s index finger. (From Wall LL. Stress urinary incontinence. In Rock
These operations are designed to correct stress incontinence resulting primarily from anatomic hypermobility of the bladder neck and urethra. If the suspending sutures are pulled too tight, an element of obstruction can be created. They are relatively simple and take less time to perform than open procedures, but this advantage is often offset by the fact that they are not as effective in curing stress incontinence. Initial cure rates are between 70% and 90%, but these rates appear to decrease significantly over time in many series, with 5-year success rates of 50% or less (95,114,115,116,117 and 119). In addition to a lower success rate, other complications include perforation of the bladder or urethra by the long needles, infections, formation of granulation tissue around sutures and the synthetic bolsters often used in fixing the sutures to the fascia at the bladder neck or abdominal wall, development of prolapse as a result of changes created in the vaginal axis, chronic pulling pelvic pain created by the suspension sutures, and nerve entrapment syndromes (118,120,121 and 122). Because the long-term success rate of needle urethropexy is poor, this operation is falling out of favor. Surgeons performing needle urethropexy should know their long-term continence rates to make sure that they are offering their patients an appropriate treatment option.

Tension-free Vaginal Tape

The poor success rates of needle urethropexy operations have led many surgeons to search for a similarly attractive, low-morbidity alternative with better long-term success. Ulmson described a new technique for correcting stress urinary incontinence in 1996 (123). This technique involves the use of polypropylene mesh placed under the midurethra with minimal tension. To perform this operation, a small midurethral incision is made in the vaginal epithelium mucosa. A 40 x 1-cm mesh tape covered by a plastic sheath and attached to two 5-mm curved trocars is passed lateral to the urethra and through the endopelvic fascia into the retropubic space. The trocar is then passed along the back of the pubic bone, through the rectus fascia, into two small suprapubic skin incisions. The tension on the tape is adjusted, the sheath is removed, and the emaining tape is cut off at the level of the skin. This technique has the advantage of being performed quickly using limited anesthesia (less than 30 minutes and experienced hands). The procedure requires the use of a catheter guide to deviate the urethra and cystoscopy to ensure that bladder or urethral perforations are recognized immediately because the trocar is passed blindly.

The short-term results reported to date by various authors are encouraging, but long-term data must be evaluated before the role of this operation in the treatment of stress incontinence can be determined (124,125). The complications reported appear to be similar to those occurring with needle urethropexies. Concern about the use of synthetic materials placed through a vaginal incision remain; reports of transl vaginal sling operations performed using other types of synthetic materials have documented complications with this approach in the past (126,127 and 128).

Sling Procedures and Periurethral Injections

Sling Operations After reviewing reports that included patient follow-up for more than 48 months, the American Urological Association and the Female Stress Urinary Incontinence Guideline Panel concluded that the two most effective surgical treatments for stress incontinence are retropubic bladder neck suspensions and sling procedures (130). This panel confirmed that the use of sling operations in women with complex or recurrent stress urinary incontinence is a safe and effective treatment. Given the high success rates with complex incontinence, many surgeons are now performing sling procedures as a primary procedure, rather than reserving such operations for patients who have failed previous operations. Traditionally, sling operations have been used principally for patients with complicated stress incontinence, usually resulting from intrinsic sphincteric damage or weakness. Probably no more than 15% to 20% of women with stress incontinence need a sling procedure to be cured. Patients requiring a sling typically have demonstrable stress incontinence with normal urethral support or stress incontinence with a low leak-point pressure. Other candidates might be women with stress incontinence who engage in very heavy occupational lifting, who have severe chronic obstructive lung disease, and who have posthysterectomy vaginal vault erosion. Such patients appear to have an increased risk for surgical failure if their stress incontinence is treated with transvaginal procedures. This approach has been tried for years with minor success (131,132,133,134,135,136,137,138,139 and 140). The sling can be made of organic or inorganic materials. Organic materials can be autologous tissues harvested from the patient (e.g., fascia lata, rectus fascia, tendon, round ligament, rectus muscle, vagina), processed allografts from human donors (e.g., fascia lata, dermis), or heterologous tissues processed for surgical use (e.g., peritoneum, dermis). Synthetic materials (e.g., Silastic, Gore-Tex, Marlex) are popular because of their consistent strength and easy availability, but these substances are often plagued by problems with erosion and infection when they are used around the urethra (127,128 and 129).

Sling Operations have traditionally been performed using a combined vaginal and abdominal approach. The anterior vagina is opened, the space of Retzius is dissected on each side of the bladder neck, and a sling is passed around the bladder neck and urethra and is then attached to the anterior rectus fascia or some other structure to cradle the urethra in a supporting hammock. This both supports the urethra and allows it to be compressed during periods of increased intraabdominal pressure (130,131,132,133,134,135,136,137,138,139 and 140). The sling can be made of organic or inorganic materials. Organic materials can be autologous tissues harvested from the patient (e.g., fascia lata, rectus fascia, tendon, round ligament, rectus muscle, vagina), processed allografts from human donors (e.g., fascia lata, dermis), or heterologous tissues harvested from another species and processed for surgical use (e.g., ov dura mater, porcine dermis). Synthetic materials (e.g., Silastic, Gore-Tex, Marlex) are popular because of their consistent strength and easy availability, but these substances are often plagued by problems with erosion and infection when they are used around the urethra (127,128 and 129).

Numerous advances have made it possible to perform sling procedures completely through the vaginal approach using bone anchors, bone screws, and sutures capturing devices. These devices decrease the morbidity resulting from an abdominal incision and may allow for earlier discharge and resumption of normal activity. The safety and efficacy of these modifications to the traditional sling procedure must be confirmed with comparative long-term outcome studies. The most common problem encountered by patients for whom a sling procedure has been performed is obstructed voiding after surgery. The sling does not have to be pulled tight to work, but the common temptation of less experienced surgeons is to make the sling too tight in hopes of ensuring that the patient is cured. Not infrequently, patients with a sling require long-term bladder drainage using either a suprapubic catheter or clean intermittent self-catheterization. The symptoms of outlet obstruction (less than 30 minutes in experienced hands). The procedure requires the use of a catheter guide to deviate the urethra and cystoscopy to ensure that bladder or urethral perforations are recognized immediately because the trocar is passed blindly.

Tension-free Vaginal Tape

The poor success rates of needle urethropexy operations have led many surgeons to search for a similarly attractive, low-morbidity alternative with better long-term success. Ulmson described a new technique for correcting stress urinary incontinence in 1996 (123). This technique involves the use of polypropylene mesh placed under the midurethra with minimal tension. To perform this operation, a small midurethral incision is made in the vaginal epithelium mucosa. A 40 x 1-cm mesh tape covered by a plastic sheath and attached to two 5-mm curved trocars is passed lateral to the urethra and through the endopelvic fascia into the retropubic space. The trocar is then passed along the back of the pubic bone, through the rectus fascia, into two small suprapubic skin incisions. The tension on the tape is adjusted, the sheath is removed, and the emaining tape is cut off at the level of the skin. This technique has the advantage of being performed quickly using limited anesthesia (less than 30 minutes in experienced hands). The procedure requires the use of a catheter guide to deviate the urethra and cystoscopy to ensure that bladder or urethral perforations are recognized immediately because the trocar is passed blindly.

The short-term results reported to date by various authors are encouraging, but long-term data must be evaluated before the role of this operation in the treatment of stress incontinence can be determined (124,125). The complications reported appear to be similar to those occurring with needle urethropexies. Concern about the use of synthetic materials placed through a vaginal incision remain; reports of transl vaginal sling operations performed using other types of synthetic materials have documented complications with this approach in the past (126,127 and 128).

Figure 20.16 Mechanism of action of sling procedures for stress incontinence. A: Normal urethra. B: Incompetent urethra with intrinsic sphincteric deficiency. The lumen is gaping, scarred, and has lost its normal coaptation and pliability. C: Correction of intrinsic sphincteric deficiency using a sling operation. The urethra is supported and the urethral lumen is partially compressed by the sling. (From Wall LL. Stress urinary incontinence. In Rock JA, Thompson JD, eds. TeLinde’s operative gynecology. 8th ed. Philadelphia: JB Lippincott, 1997, with permission.)
with limited success, but advances in chemistry have allowed the development of materials better suited to the injection procedure, namely polytetrafluoroethylene paste (Polytef), glutaraldehyde cross-linked bovine collagen (Contigen), and pyrolytic carbon-coated zirconium beads (Durasphere). A small-gauge needle is inserted into the periurethral tissues, and the material is injected along the urethra at the level of the bladder neck. This seems to work by bulking up the bladder neck, allowing enhanced urethral closure under stress, rather than by changing the resting urethral pressure. Teflon is harder to work with and requires the use of a psoas vector. It also has been shown to migrate to other areas of the body under some circumstances. Contigen can be passed easily through small-bore needles under local anesthesia but requires preoperative skin testing to check for possible allergic reactions (3%). Durasphere is nonantigenic (thus no skin testing is required) and does not migrate. Durasphere appears to have similar reduction in leakage episodes as compared with collagen and is more likely to require only a single injection (147). This bulking agent does require a larger-gauge needle for injection and is somewhat more difficult to inject than collagen. These techniques may require several injections to achieve continence, and the long-term success of these operations remains poorly studied. The development of a bulking agent that is easy to inject, is nonantigenic, has a minimal inflammatory response, and does not degrade or migrate should result in increased efficacy in properly selected patients.

Salvage Operations

The best opportunity to cure stress incontinence occurs at the time of the initial operation. Subsequent surgeries have a lower success rate, and the chances of success seem to diminish with each subsequent operation (65). In some cases, the surgeon is faced with each scarred, fibrotic nonfunctional urethra in a hopelessly incontinent patient. This type of patient requires what can best be called "salvage" operations—a last ditch effort for cure. Such patients may benefit from periurethral collagen injections. Others may benefit from the placement of a deliberately obstructive sling, with the plan that the patient will drain her bladder by self-catheterization for the rest of her life. Still others may benefit from the implantation of an artificial urinary sphincter, a high-technology approach to incontinence that appears to work better for males than females (148,149). Finally, others may require urinary diversion. Only a small percentage of women with stress incontinence require such measures.

Urinary Incontinence Caused by Detrusor Overactivity

Although stress incontinence is the most common type of urinary continence in women, urge incontinence caused by detrusor overactivity is the most common form of incontinence in older women and the second most common form of urinary incontinence overall (150). In this condition, urine loss is caused not by failure of urethral support or closure but rather by uninhibited contractions of the detrusor muscle. Patients with this condition typically experience sudden, unexpected loss of large volumes of urine or leakage associated with a sudden urge to urinate that cannot be controlled. In both cases, urine loss occurs from an unsuppressed contraction of the bladder muscle, a failure to inhibit the micturition reflex. When this occurs as the result of a known neuropathologic process relevant to bladder disorders (e.g., stroke, Parkinson’s disease, multiple sclerosis), it is referred to as detrusor hyperreflexia. In cases in which there is no evidence of neuropathology (most cases), the condition is referred to as detrusor instability. Both conditions can be called detrusor overactivity (65). Detrusor overactivity should be suspected in all cases in which the patient has symptoms of urgency, frequency, and urge incontinence. For patients who have frequency and urgency without incontinence, detrusor overactivity rarely is the cause of their problem. For most such cases, the cause of the symptoms is a disorder of bladder motility, and occasionally, blurred vision caused by blockade of the sphincter of the iris and the ciliary muscle of the lens of the eye. Other drugs, such as imipramine, may produce orthostatic hypotension and cardiac arrhythmias. Patients should be encouraged to titrate their medication to their symptoms and to vary the dosage (within acceptable limits) according to their needs.

Diagnosis

The diagnosis of incontinence caused by detrusor overactivity can be confirmed by cystometry. A rule for all incontinence evaluations is to demonstrate incontinence and confirm with the patient that what has been demonstrated reproduces her complaint. Subtracted filling cystometrography for patients with an overactive detrusor should show phasic pressure waves that produce urgency and urge incontinence (Fig. 20.17). False-negative and false-positive results can occur. False-positive results occur for patients with asymptomatic detrusor activity, detrusor activity that is irrelevant to the complaint, or detrusor activity that is situational (e.g., caused by test anxiety). The false-negative results occur because 20-minute cystometrography is not always an accurate measure of daily bladder activity. Looking for detrusor instability with such a test is like looking for an episodic cardiac arrhythmia using 12-lead electrocardiography, as opposed to looking for the arrhythmia using a 24-hour Holter monitor. The sensitivity of the latter test is far greater than that of the former. The same principles apply to stationary subtracted cystometry when compared with long-term ambulatory urodynamic studies (153,154 and 155). In most patients with a strong history of urge incontinence, a detrusor problem is the cause of leakage.

Treatment

Detrusor overactivity can be treated using drugs or behavioral modification (159). The best initial choice is probably a combination of the two therapies. If possible, long-term management of this condition should be based on behavioral therapy for two main reasons. The first is that the drugs used in treating detrusor instability have unpleasant anticholinergic side effects. Most patients tire of these problems over time and discontinue medications. Second, the cure rates with behavioral treatment are comparable to those with drug therapy, and any drug therapy for this condition will be enhanced by modifying the behavior that contributes to detrusor overactivity.

Drug Therapy

The drugs used in treating detrusor muscle overactivity can be grouped into different categories according to their pharmacologic characteristics; however, for all practical purposes, these drugs are anticholinergic agents that exert their effects on the bladder by blocking the activity of acetylcholine at muscarinic receptor sites. Most of these drugs have a short half-life, which means that they must be taken frequently. All of these drugs have side effects, the most common of which are dry mouth resulting from decreased saliva production, increased heart rate because of vagal blockade, feelings of constipation resulting from decreased gastrointestinal motility, and occasionally, blurred vision caused by blockade of the sphincter of the iris and the ciliary muscle of the lens of the eye. Other drugs, such as imipramine, may produce orthostatic hypotension and cardiac arrhythmias. Patients should be encouraged to titrate their medication to their symptoms and to vary the dosage (within acceptable limits) according to their needs.

The introduction of two new medications for the treatment of detrusor overactivity has resulted in significant attention being given to urinary incontinence in the media—tolterodine and long-acting oxybutynin. Tolerodine (Detril) is a muscarinic receptor antagonist with a long half-life, which means it can be taken once or twice daily and demonstrated similar results to immediate-release oxybutynin in the reduction of urinary frequency and episodes of urge-related urinary leakage. Significant reduction in the common complaint of a bothersome dry mouth was found in the tolerodine group compared with the group taking immediate-release oxybutynin and the placebo group (156,157). Long-acting oxybutynin (Ditropan XL) relies on a slow-release mechanism known as oral osmotic (GROS) technology to deliver a constant dose of oxybutynin throughout the day. By reducing fluctuations in serum levels through this constant-release mechanism, the new delivery system attempts to reduce the side-effect profile associated with traditional formulations. Long-acting oxybutynin appears to have better patient
The patient is instructed to void on a timed schedule, starting with a relatively frequent interval of every hour while she is awake. When she can maintain this schedule for 1 week, the voiding interval is increased by 15 minutes. It is increased gradually by 15 minutes every week until a balance is achieved between her desire to void and her need to void. She is informed that this is not due to thirst. Some patients increase their fluid intake to combat this problem, with a subsequent worsening of their incontinence. If dry mouth is a problem, patients should relieve it by chewing gum, sucking on a piece of hard candy, or eating a piece of moist fruit.

Behavioral Therapy

Behavioral therapy for detrusor instability is based on the assumption that the underlying pathophysiology is the escape of the detrusor from the cortical control over micturition that had previously been established during childhood toilet-training. The object of bladder retraining (or bladder drill, as it is sometimes called) is to reestablish the authority of the cerebral cortex over bladder function. This is performed through a regimen of timed voiding, gradually increasing the intervals between voids until the cycle of urgency, frequency, and urge incontinence is broken.

Behavioral therapy is carried out as follows:

1. The patient is instructed to void on a timed schedule, starting with a relatively frequent interval of every hour while she is awake.
2. When she wakes up in the morning, she voids at 6:00 AM, 7:00 AM, 8:00 AM, and so forth throughout the day. If it is 7:00 AM, and she does not feel the need to void, she must do so anyway. The object is to make her bladder do what it wants to do, instead of responding to the whims of her bladder. If it is 7:55 AM and she is desperate to urinate, she cannot do so. She must wait until 8:00 AM, even if this means that she leaks some urine onto a pad. When the appropriate time arrives, she should empty her bladder.
3. At night, the patient is allowed to void only when she is awakened from sleep by the need to do so.
4. When she can maintain this schedule for 1 week, the voiding interval is increased by 15 minutes. It is increased gradually by 15 minutes every week until a normal voiding interval of 2.5 to 3 hours has been established.

This program works very well for patients with detrusor instability. The secret of success is gradual increases in the interval between voids. The best predictor of success is patient compliance; those who follow this program get excellent results. Unfortunately, patients who have suffered a neurologic insult that has resulted in detrusor hyperreflexia do not respond as well to bladder retraining because the problem is actually one of the neural pathway destruction rather than the need to reestablish cortical control mechanisms. Frequently, these patients have a bigger volume of urine that sets off a contraction that they cannot control voluntarily. Such patients may benefit from a timed voiding schedule in which they void at regular intervals (such as every 2 hours) to keep their bladder volume below the trigger point. Attempting to lengthen the interval between voids often does not work well.

Functional Electrical Stimulation

Functional electrical stimulation similar to that used with stress urinary incontinence has also been used in treating overactive bladders that have not responded to other medical and behavioral therapy. Several prospective, double-blind studies have demonstrated cure or improvement in 50% of patients with overactive bladders (160,161) using this technology. Economic and reimbursement issues, as well as issues related to access, patient compliance, and acceptability of the therapy, have limited the use of electrical stimulation for the treatment of detrusor overactivity in the past, but many of these questions are being answered, opening up a whole new range of exciting treatment possibilities in the future.

Sacral Nerve Root Neuromodulation

Even with the development of newer anticholinergic medications with fewer side effects, there continues to be a select group of patients with overactive bladders who remain refractory to standard medical and behavioral treatment. Surgical treatment of this condition has traditionally involved substantial morbidity and major urinary denervation, reconstruction, or both in order to achieve therapeutic benefits. For example, augmentation cystoplasty for refractory urge incontinence has significant short-term operative morbidity and often results in long-term voiding dysfunction that requires clean intermittent catheterization to achieve bladder emptying. The development of implantable sacral nerve root stimulators has led to FDA approval of sacral root neuromodulation in patients with refractory urinary urgency and frequency, urge incontinence, and voiding dysfunction. This therapy offers patients with severe symptoms an alternative to urinary augmentation or diversion. Sacral nerve stimulation therapy is performed in two phases. In the first phase, a percutaneous nerve evaluation test (PNE) is performed to determine which patients respond to this type of therapy. This phase is followed by surgical implantation of a permanent electrode lead adjacent to the third sacral nerve root connected to a pulse generator in those patients who are identified as appropriate candidates after a successful test stimulation (this technique results in more than 50% improvement in symptoms).

A multicenter prospective study demonstrated that 63% of test patients responded to the initial procedure. After implantation, 47% of patients became completely dry, and 77% were successful in eliminating “heavy” leakage episodes. Despite substantial success in nearly 80% of patients who received implants, 30% of patients required further surgical revision because of pain or other complications at the generator or implant site. There were no permanent injuries or nerve damage in the initial trials (162,163). This therapy offers an alternative to radical surgery for many patients in whom other treatment options have been unsuccessful.

Mixed Incontinence

Patients are said to have mixed incontinence when they have motor urge incontinence as a result of detrusor overactivity along with stress incontinence. Because most patients have mixed symptoms, every effort should be made to confirm the diagnosis and to demonstrate stress and urge incontinence objectively before establishing such a diagnosis. Patients with mixed incontinence often pose complicated management problems, and controversy exists regarding the best method of treating them. In the confirmed presence of both types of urinary incontinence, one reasonable approach is to try to determine which symptom is more bothersome to the patient—stress incontinence or urge incontinence—and to proceed from that point (164). Others advocate using conservative therapy to treat urge incontinence first, proceeding with surgery only if stress incontinence persists. Because patients with mixed incontinence have a lower voiding threshold than patients with genuine stress incontinence alone, this approach is reasonable. However, some patients experience de novo onset of detrusor overactivity after stress incontinence surgery, and detrusor instability resolves in some patients with mixed incontinence after surgery for stress incontinence. Bladder neck suspension surgery is contraindicated for patients with detrusor instability alone as the cause of their incontinence. Patients with mixed incontinence, a small functional bladder capacity, and high-pressure detrusor contractions on filling cystometry should undergo operations for stress incontinence only after careful consideration of their individual circumstances and a comprehensive clinical and urodynamic evaluation.
Voiding difficulty and stress incontinence pose special surgical problems, and many women with these conditions do not void normally after surgery, particularly if an attempt is made to void using a self-catheterization. Voiding symptoms in 70% of patients (155,156) for some patients with refractory urge incontinence. If test stimulation results in successful voiding, the implanted pulse generator results in clinical improvement in 80% of patients (157,158). Neuromodulation of the sacral nerve roots (S3 or S4) has proved to be an effective treatment option for some patients with nonobstructive urinary retention as well as for those with refractory urge incontinence (159). Even though self-catheterization can be used to treat women who have all types of voiding dysfunction, some women find this difficult or cumbersome to perform. Self-catheterization is quite acceptable, however, for patients who have neurogenic bladder dysfunction (160). The implementation of self-catheterization is an acute confusional state that may result from disorientation. It is often associated with overactive bladder and the presence of a potentially enlarged and obstructing prostate gland. Nonetheless, women do suffer from voiding difficulties, which may be defined as emptying dysfunction resulting from a failure of pelvic floor relaxation or failure of the detrusor muscle to contract appropriately. True outflow obstruction (defined as a detrusor pressure of more than 50 cm H2O in association with a urine flow rate of less than 15 mL/sec) is rare in women and, when seen, is usually found in patients who have undergone obstructive bladder neck surgery for stress incontinence (162,163). For normal voiding to occur, the pelvic floor and urethral sphincter must relax, which should occur in conjunction with a coordinated contraction of the detrusor muscle that leads to complete bladder emptying. Of course, the bladder may be emptied by other mechanisms, such as by abdominal straining in the absence of a detrusor contraction, or simply by relaxation of the pelvic floor if the closure mechanism is exceptionally weak; however, complete bladder emptying is not the same as normal voiding. Some women may empty their bladders completely, but only by expending great effort over several minutes. In such cases, voiding is clearly abnormal, even though the bladder is empty when voiding ceases. In the worst cases, voiding is both difficult and incomplete. An example of voiding difficulty is the detrusor-sphincter dyssynergia that occurs in some patients with multiple sclerosis and other neuropathic conditions (166,167). With this condition, there is a lack of coordination between detrusor contraction and urethral relaxation, and the urethral sphincter contracts at the same time as the detrusor. This means that outlet resistance to voiding increases at the same time that intravesical pressure is increasing; hence, voiding becomes difficult if not impossible. Great effort is required to overcome urethral resistance; the patient voids with an interrupted stop-and-start stream and usually leaves a significant amount of residual urine.

### Treatment

Voiding difficulty can be managed in several different ways, depending on the cause of the condition. Patients with pelvic floor spasticity (in the absence of a neurologic insult) can often be trained to relax the pelvic floor through biofeedback therapy and to void normally. Mild sedatives are sometimes helpful in this process, as are α-blockers (e.g., prazosin, phenoxybenzamine), which reduce urethral tone. For patients who are unable to generate a detrusor contraction, attempts have been made to enhance detrusor contractility using a cholinergic agonist such as bethanechol chloride. Although cholinergic medications are successful in making strips of bladder muscle contract in a laboratory, there is little evidence that such drugs are helpful clinically (170). Self-catheterization allows the patient to accomplish this task using a small (14 Fr.) plastic catheter that she inserts through the urethra into the bladder, draining its contents. The catheter is then removed, washed with soap and water, dried, and stored in a clean, dry place. Elaborate sterile procedures are not necessary. Although bacteria are introduced into the bladder in this process, frequent emptying through self-catheterization greatly reduces the risk for urinary tract infection for these patients. The urine of women after self-catheterization regimens will always be colonized with bacteria; however, this condition should not be treated unless symptomatic infection occurs.

### Sacral Nerve Root Neuromodulation

Even though self-catheterization can be used to treat women who have all types of voiding dysfunction, some women find this difficult or cumbersome to perform. Neuromodulation of the sacral nerve roots (S3 or S4) has proved to be an effective treatment option for some patients with nonobstructive urinary retention as well as for some patients with refractory urge incontinence. If test stimulation results in successful voiding, the implanted pulse generator results in clinical improvement in voiding symptoms in 70% of patients (163). Although this technology requires a major surgical procedure, many women favor this therapy over lifelong self-catheterization.

### Suppressive Antibiotics

Voiding difficulty and stress incontinence pose special surgical problems, and many women with these conditions do not void normally after surgery, particularly if an attempt is made to void using a self-catheterization. Voiding symptoms in 70% of patients (155,156) for some patients with refractory urge incontinence. If test stimulation results in successful voiding, the implanted pulse generator results in clinical improvement in 80% of patients (157,158). Neuromodulation of the sacral nerve roots (S3 or S4) has proved to be an effective treatment option for some patients with nonobstructive urinary retention as well as for some patients with refractory urge incontinence. If test stimulation results in successful voiding, the implanted pulse generator results in clinical improvement in voiding symptoms in 70% of patients (163). Although this technology requires a major surgical procedure, many women favor this therapy over lifelong self-catheterization.
obstructive operation is performed. After surgery, voiding difficulty can be managed with self-catheterization and reassurance. If outflow obstruction is diagnosed on a pressure-flow voiding study (low flow in the presence of high pressure), however, it may be necessary to take down the obstructive operative procedure and resuspend the bladder neck at a lower, less obstructed, level (106).

Chronic suppressive antibiotic therapy should not be used; instead, acute infections should be treated with an appropriate antibiotic for 3 days. This treatment prevents the selection of potentially dangerous drug-resistant bacteria, which pose a risk for these patients.

Acute Urinary Retention

Acute urinary retention exists when there is a sudden inability to void (172). The condition is painful, and, upon catheterization, a large volume of urine is released. Sometimes, the explanation is found readily, as in the case of a woman who develops urinary retention after the administration of an epidural anesthetic. A careful search should always be performed to determine the cause of the retention, particularly if any neurologic signs are present. The patient should be catheterized to decompress her bladder and prevent overdistention. Most patients should be taught self-catheterization. This procedure not only gives patients a better method of long-term bladder emptying than an indwelling catheter but also provides them with a “safety valve” in the event that the problem recurs unexpectedly in the future.

Disorders of Bladder Sensation

Most patients with disorders of bladder sensation experience pain rather than lack of bladder sensation. The cause of most painful bladder conditions is unknown, and the therapies currently in use are only partially successful, similar to the treatment of most chronic pain syndromes. As a result, disorders of bladder sensation are among the most frustrating urogynecologic conditions.

Diagnosis

A careful history should be obtained, along with a sterile urine specimen for analysis and culture. Many women treated repetitively for chronic cystitis have taken multiple courses of antibiotics on the basis of symptoms without ever having had a culture-proven infection. Detrusor instability may be the cause of frequency, urgency, and urge incontinence but is not usually a factor in dysuria or painful urination. Women older than 50 years of age (particularly smokers and workers exposed to chemicals) are at risk for bladder cancer, and this possibility must be considered, especially if hematuria is present. Urinary cytology is sometimes helpful in detecting early tumors of the urinary tract, and cystoscopy and intravenous urography are mandatory in the evaluation of patients with hematuria.

Interstitial cystitis is a syndrome that presents as frequency, urgency, and bladder pain in the presence of a small bladder capacity, with bladder pain experienced on filling and relieved by voiding. Many different pathophysiological processes factor into this condition, which complicates treatment (173). A number of possible causes must be considered in the differential diagnosis of painful voiding, including urethral diverticulum; vulvar disease; endometriosis; chemical irritation from soaps, bubble bath, or feminine hygiene products; urinary stones; urogenital atrophy from estrogen deprivation; and sexually transmitted diseases (174).

The diagnosis of interstitial cystitis is largely one of exclusion; strict diagnostic guidelines have been developed for research protocols, but the criteria used to diagnose this condition in clinical practice are vague, shifting, and confusing. Hydrodistention of the bladder is believed to be of diagnostic value if Hunner’s ulcers are seen; but this finding occurs infrequently in patients with irritative bladder symptoms. The cystoscopic findings of terminal hematuria and diffuse pelechial hemorrhage or glomerulations are often seen on reinspection after filling to capacity. Bladder biopsies rarely assist in the diagnosis but may rule out other causes of the patient’s symptoms. The use of a potassium chloride infusion test has been described in the evaluation of patients with painful bladder symptoms and is believed to be suggestive of interstitial cystitis in those patients with a positive response (175). The ideal diagnostic test for interstitial cystitis has not been determined.

Treatment

Typically, the clinician has no definitive diagnosis at the end of the evaluation and must rely on symptomatic treatment.

1. Frequency-urgency syndromes should be managed with a careful voiding regimen (similar to that used in the treatment of detrusor instability) and local care. The use of urinary tract analgesics such as Urised is often helpful in reducing urethral irritation. Urised is a polypharmaceutical agent containing a mixture of methenamine, methylene blue, phenyl salicylate, benzoic acid, atropine sulfate, and hyoscyamine, which has a soothing effect on many irritative urethral symptoms.
2. Restricting the patient’s intake of alcohol, caffeine, fruit juice, spices, artificial sweeteners, and food colorings often is helpful.
3. Instruction in the basics of vulvar and perineal hygiene is important (thorough drying; avoidance of most body powders, perfumes, or colored irritating soaps; avoidance of tight-fitting undergarments).
4. Hydrodistention of the bladder has been recommended as a treatment option and can result in clinical improvement in some patients.
6. Pentosan polysulfate (Elmitron) is an oral agent with heparin-like activity. This medication is designed to attempt to replacement of the glycoaminoglycan sulfate layer that is believed deficient in these patients.
7. Some patients benefit from the instillation of 50 mL of a 50% solution of dimethylsulfoxide (DMSO) for 20 to 30 minutes every other week for four or five sessions.
8. Because it has been theorized that bladder pain may result from increased histamine release, some patients benefit from medications that block these inflammatory mediators, such as diphenhydramine hydrochloride, 25 to 50 mg orally three times per day, in combination with 300 mg of cimetidine three times per day.

Pelvic Organ Prolapse

Pelvic support problems account for thousands of gynecologic surgical procedures each year, and yet our understanding of these conditions has advanced remarkably slowly over the past century. An increased appreciation of the various contributions of muscle, nerve, and connective tissue to pelvic organ support will probably change this situation within the next decade. Many basic questions have not yet been asked, and many basic clinical issues remain unresolved.

Definition and Classification

A prolapse is a downward or forward displacement of one of the pelvic organs from its normal location. Traditionally, prolapse has referred to displacement of the bladder, the uterus, or the rectum. These displacements have usually been graded on a scale of 0 to 3 (or 0 to 4); the grade increases with increasing severity of the prolapse, with 0 referring to no prolapse and 3 (or 4) referring to total prolapse (“procidentia”) (176, 177, 178 and 179). All forms of female genital prolapse are described with reference to the vagina. True rectal prolapse (as contrasted to a rectocele) is discussed separately.

A variety of terms are used to describe female genital prolapse. Although these terms are generally unsatisfactory and somewhat inaccurate, they are so fixed in the literature that it is impossible to avoid discussing these terms.

- A cystocele is a downward displacement of the bladder.
- A cystourethrocele is a cystocele that includes the urethra as part of the prolapsing organ complex.
- A uterine prolapse is a descent of the uterus and cervix down the vaginal canal toward the vaginal introitus.
- A rectocele is a protrusion of the rectum into the posterior vaginal lumen.
- An enterocele is a herniation of the small bowel into the vaginal lumen.

Unfortunately, these descriptive terms are inaccurate and misleading. They prejudge the true nature of any prolapse by focusing attention on the bladder, rectum, or uterus rather than on the specific defects that are responsible for alterations in vaginal support. Furthermore, these terms are used in combination with an imprecise (and usually unspecified) system of grading, and they do not convey useful comparative information. The lack of an accurate system of classification of pelvic support...
What is observed during a pelvic examination of patients with these conditions is an alteration in vaginal anatomy: anterior vaginal wall descent, posterior vaginal wall descent, a lateral vaginal support defect, cervical descent, or descent of the vaginal apex (in patients who have had a hysterectomy). To name these areas of vaginal descent after the organs that are presumed to be responsible for them prejudices many clinical issues and can lead the surgeon into problems for which he or she may not be prepared; for example, when an “occult” enterocele is discovered during a rectocele repair or when vaginal eversion occurs after surgery because its apex was not believed to be involved in the support defect. Similarly, lumping defects of vaginal support into organ compartments or broad categories such as “cystocele” or “rectocele” draws attention from the precise nature and location of the defects of pelvic support that are present.

As a result of the deficiencies in the traditional classification, the International Continence Society standardized terminology of female pelvic organ prolapse was developed and published in 1996 (180). The International Continence Society, the American Urogynecologic Society, and the Society of Gynecologic Surgeons have all adopted this standard system for the classification of female pelvic organ prolapse. In this system, anatomic descriptions of specific sites in the vagina replace the traditional terms (i.e., cystocele, rectocele, enterocele). This descriptive system contains a series of nine site-specific measurements. The classification uses six points along the vagina (two points on the anterior, middle, and posterior compartments) measured in relation to the hymen. The anatomic position of the six defined points should be measured in centimeters proximal to the hymen (negative number) or distal to the hymen (positive number), with the plane of the hymen representing zero. Three other measurements in the pelvic organ prolapse quantitative examination (POPQ) include the genital hiatus, perineal body, and the total vaginal length.

The genital hiatus is measured from the middle of the external urethral meatus to the posterior midline hymen. The perineal body is measured from the posterior margin of the genital hiatus to the midanal opening. The total vaginal length is the greatest depth of the vagina in centimeters when the vaginal apex is reduced to its full normal position (Fig. 20.18). All measurements except the total vaginal length are measured at maximal straining.

Figure 20.18 Standardization of terminology for female pelvic organ prolapse (POP-Q classification). This diagram demonstrates the anatomic position of the POP-Q sites including six sites involving the anterior (Aa, Ba), middle (C, D), and posterior (Ap, Bp) compartments with the genital hiatus (gh), perineal body (pb), and total vaginal length (tvl). (From Bump RC, Mattiasson A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. Am J Obstet Gynecol 1996;175:12, with permission.)

The anterior vaginal wall measurements are termed Aa and Ba, with the Ba point moving depending on the amount of anterior compartment prolapse. Point Aa represents a point on the anterior vagina 3 cm proximal to the external urethral meatus, which corresponds to the bladder neck. By definition, the range of position of this point is –3 to +3. Point Ba represents the most distal or dependent point of any portion of the anterior vaginal wall from point Aa to just anterior to the vaginal cuff or anterior lip of the cervix. This point can vary depending on the nature of the patient’s support defect. For example, point Ba is ~3 in the absence of any prolapse (it is never less than –3) to a positive value equal to the total vaginal length in a patient with total eversion of the vagina.

The middle compartment consists of points C and D. Point C represents the most dependent point of the posterior fornix; point D represents the level of the uterosacral ligament attachment to the posterior cervix. It is meant to differentiate suspensory failure from cervical elongation.

Point D is the location of the posterior fornix; it is omitted if the cervix is absent. This point represents the level of the uterosacral ligament attachment to the posterior cervix. It is meant to differentiate suspensory failure from cervical elongation.

The posterior compartment is measured similarly to the anterior compartment; the corresponding terms are Ap and Bp. The nine measurements can be recorded as a simple line of numbers (i.e., –3, –3, –8, –10, –3, –3, 11, 4, 3 for points Aa, Ba, C, D, Ap, Bp, total vaginal length, genital hiatus, and perineal body). The six vaginal sites have possible ranges, which are dependent on the total vaginal length (Table 20.6). After collection of the site-specific measurements, stages are assigned according to the most dependent portion of the prolapse (Table 20.7). The POPQ examination often appears confusing on initial review; however, a measuring device (i.e., a marked ring forceps or marked cotton-tip applicator) can assist in instructing those unfamiliar with this staging system. The POPQ examination provides a standardized measurement system to allow for more accurate postoperative outcome assessments and to ensure uniform, reliable, and site-specific descriptions of pelvic organ prolapse. An inexpensive demonstration videotape describing the system and showing its use in several patients is available from the American Urogynecologic Society.

Table 20.6. Possible Ranges of the Six Site-specific Pelvic Organ Prolapse Quantitative Examination Measurements

Table 20.7. Stages of Pelvic Organ Prolapse
Symptoms of Prolapse

Asymptomatic pelvic prolapse generally does not require treatment, but the patient should be informed that she is losing some aspects of pelvic support, which may require treatment in the future. Symptomatic prolapse may manifest in several different ways. The most common symptom is a feeling of pressure or that something is protruding from the vagina. Patients often say they feel like they are sitting on an egg or they may complain of a dragging discomfort, which is described as a low backache or feeling of heaviness. Generally, this feeling is relieved by lying down, is less noticeable in the morning, and worsens as the day progresses, particularly if patients are on their feet for long periods. Specific types of prolapse may be associated with specific symptoms. Loss of anterior vaginal support often leads to urethral hypermobility, which in turn often (but not necessarily) results in stress urinary incontinence. A large anterior vaginal prolapse (or vaginal vault erosion) can produce symptoms of voiding difficulty. In such cases, the large prolapse comes out below the urethra, either compressing it from below or kinking it so that bladder emptying is incomplete or intermittent. An anterior protrusion of the rectum into the vaginal canal (rectocele) can cause symptoms of inefficient rectal emptying, often described by the patient as constipation. In severe cases, the patient may have to splint the posterior vagina with a finger during defecation, thereby reducing the pocket that is trapping stool back into its normal position. In most cases, however, constipation in women has causes other than a rectocele. The symptoms that result from a massive prolapse in which the entire uterus or vagina protrudes below the pelvic floor are self-explanatory.

Examination

In examining a patient with pelvic organ prolapse, all aspects of vaginal support should be carefully surveyed. Each area of vaginal anatomy should be described separately, and because prolapse is almost invariably worse when the patient is upright, the clinician should become accustomed to examining patients in the standing position as well as in the standard dorsal lithotomy position. The patient should stand on the floor with one foot elevated on a well-supported footstool. The examining gown can be lifted slightly to expose the genital region (Fig. 20.19). A standing pelvic examination allows the prolapse to be assessed when it is at its worst. A rectovaginal examination performed in this position is the best way of detecting an occult enterocele because the small bowel can be palpated easily in the cul-de-sac between the thumb and forefinger. A standing pelvic examination can be conducted quickly and efficiently.

![Figure 20.19](image)

Figure 20.19 Standing examination of the patient to detect the extent of pelvic organ prolapse. An enterocele is detected during a standing rectovaginal examination by palpating the small bowel between the thumb and index finger.

For a patient with prolapse, the traditional speculum examination of the vagina should be supplemented with a site-specific examination of the vagina using either a single-bladed speculum (such as a Sims speculum) or by taking a traditional Graves speculum apart and using the posterior blade as a single-sided retractor. This technique allows the clinician to perform the POPQ measurements by obtaining an adequate view of the anterior, posterior, and lateral vagina, looking for specific defects of vaginal support (Fig. 20.20A, Fig. 20.20B, and Fig. 20.20C). This is important because a large prolapse of one side of the vagina may hold a smaller prolapse from the other side in place. This can result in misdiagnosis, such as when a large cystocele obscures the presence of a large rectocele, or when erosion of the vaginal apex is mistaken for a large cystocele.

![Figure 20.20](image)

Figure 20.20 Examination of a prolapse whose nature is unclear. A: Without more careful examination, the components of this prolapse are uncertain. When a speculum is place posteriorly (B) and anteriorly (C) to inspect each vaginal wall separately, the prolapse goes away. This indicates that the patient has a prolapse of the vaginal apex, which has been elevated by the speculum in each instance. (From Wall LL, Norton PA, DeLancey JOL. Practical urogynecology. Baltimore: Williams & Wilkins, 1993:307, with permission.)

As a general rule, any prolapse that lies within the vaginal lumen above the plane of the hymenal ring is of limited significance, particularly if the patient does not have symptoms.

Treatment

Asymptomatic prolapse does not need treatment. An exception is a woman with stress incontinence and prolapse who is about to undergo surgical bladder neck suspension. Most operations for stress incontinence elevate the anterior vagina and, in doing so, pull the posterior vagina forward. This opens the cul-de-sac, pulling it off the levator plate and thereby creating an opening for enterocele formation, the development of uterine prolapse, vaginal vault erosion, or worsening of an asymptomatic rectocele (198). Under these conditions, additional surgery in the form of a culdoplasty, rectocele or enterocele repair, or in some cases, hysterectomy, may be advisable.

Symptomatic prolapse can be treated conservatively or surgically, depending on the individual. Although pelvic muscle exercises may be of benefit to women with stress incontinence by strengthening urethral support, they have not proved beneficial for patients with significant prolapse. The pelvic muscles provide most of the support for the pelvic organs; after this support has become inefficient, increasing stress is placed on the connective tissue involved in pelvic support. When fascial attachments have been disrupted in the presence of poor muscular tone and clinically significant prolapse has developed, attempts to correct the problem by restoring muscular tone are not efficient. Pelvic muscle exercises are virtually never harmful, but under these circumstances, they are not likely to correct the problem.
Conservative management of prolapse usually involves fitting the patient with a pessary. A wide variety of shapes and sizes of pessaries are available. The use of pessaries is an important part of gynecologic practice that has been neglected in contemporary gynecologic residency training programs (181). Each patient should be fitted individually with her pessary, much as each individual is fitted for a contraceptive diaphragm. The patient who is using a pessary should have a wet-swab-normal vagina. Postmenopausal women should be given hormone replacement therapy, or alternatively, they should use intravaginal estrogen cream on a regular basis. For women who are past menopause, it is preferable to use intravaginal estrogen cream 4 to 6 weeks before the pessary is inserted because this makes the pessary more comfortable to wear, dramatically increases compliance, and promotes long-term use.

Complications of pessary use include chronic irritation and erosion of a pessary into the bladder, creating a vesicovaginal fistula (182,183). All such cases are caused by neglect rather than the pessary itself. Patients who are using pessaries, particularly older women, should be examined on a regular basis. Some pessaries, such as the small doughnut pessary, can be left in place for months at a time without removal or inspection. Other pessaries, such as the cube pessary, which provides vaginal support through a gentle suction effect, ideally should be removed by the patient at bedtime each night and replaced in the morning to avoid erosions. The exact schedule of care should be based on individual circumstances. At the initial fitting, the patient should be encouraged to insert and remove the pessary herself. If the pessary fits and the patient is comfortable, it is helpful to reexamine her within 1 week and at least every 4 to 6 months thereafter.

Surgery

Traditionally, prolapse has been treated by surgery, the nature of which depends on the type of prolapse. The goal of surgery should be to relieve the patient of her symptoms by repairing each aspect of abnormal pelvic support in a durable and long-lasting manner. A detailed description of the various operations for managing pelvic support defects is beyond the scope of this chapter and can be obtained elsewhere (184,185), however, a few general remarks are in order.

Most patients with prolapse have defects in more than one location; thus, attention should be paid to correcting all defects during the same operation. Operations for prolapse are generally, but not always, carried out through the vaginal route rather than through the abdominal surgical route. Some conditions, such as stress urinary incontinence, are more reliably handled by an abdominal operation.

Operations for Vaginal Prolapse

Vaginal Hysterectomy Uterine prolapse is generally treated with vaginal hysterectomy, which may be accomplished by several different techniques. The advantage of vaginal hysterectomy is that it allows other vaginal surgery (e.g., anterior and posterior colporrhaphy or enterocèle repair) to be performed at the same time, without the need for a separate incision or for repositioning the patient. At the time of hysterectomy for prolapse, special attention should be paid to closing the cul-de-sac using a McCall culdoplasty and to reattaching the endopelvic fascia and the uterosacral ligaments to the vaginal cuff to provide additional support (186). The vaginal endopelvic fascia is plicated to the bladder neck and to the uterosacral ligaments to prevent descent of the uterus and to provide additional support for the vagina. The peritoneum of the cul-de-sac can be used both as a prophylactic procedure to prevent future posthysterectomy vaginal vault prolapse and as treatment for uterine prolapse. A modification to the standard plication, the high lateral fixation of the vaginal apex bilaterally without midline plication of the uterosacral ligaments, recreates normal anatomy with durable results (188,189). With any reconstructive procedure that requires plication or suspension to the uterosacral complex, care must be taken to avoid the ureters and ensure their postoperative patency (190).

Manchester/Fothergill Operation An alternative to hysterectomy for patients with uterine prolapse is the Manchester operation, originally described in 1888 by Donald and subsequently modified by Fothergill. In this operation, the bladder is dissected off the cervix, which is then amputated. The cardinal ligaments are sewn to the anterior vaginal wall at its outlet.

The vaginal hysterectomy is accomplished with a uterosacral colpopexy, suturing mesh or fascia to the uterosacral ligaments and then to the anterior longitudinal ligament of the sacrum. There is little information available regarding long-term follow-up of such patients.

Obstetric Colporrhaphy Repair of posterior vaginal prolapse for rectocele and enterocèle is also performed vaginally using posterior colporrhaphy. In a rectocele repair, the posterior vaginal wall is reconstructed with a pedicle of fascia from the posterior vaginal wall and the levator ani muscles. The posterior vaginal epithelium is closed by suturing the vaginal defect. The rectocele is identified by pushing the rectum into the posterior vaginal wall. The posterior vaginal wall is opened in the traditional fashion, the posterior vaginal epithelium is closed, and the peritoneum is closed with two or three sutures of permanent material; the sac should be excised, and the vagina should be closed once more over the defect. If the peritoneal body is not adequate, the patient is insufflated with air, and the defects are repaired with a posterior colporrhaphy. The perineal body is closed with running sutures of permanent material, and the rectocele is closed with running sutures of permanent material. The surgeon should consider both the patient's future anatomic and functional considerations to ensure that a satisfactory repair is achieved.

Operative Repair of Complete Eversion of the Vagina Among the most challenging cases are those involving complete eversion of the vagina in patients who have had a previous hysterectomy. This condition virtually always requires surgical correction because of the large size of the prolapse, its propensity to enlarge over time because of increases in intraabdominal pressure, and the rare danger of vaginal eversion if it is not treated.

Colpectomy and Colpocleisis For some patients, particularly elderly women who are not sexually active and who lead a sedentary lifestyle, the condition can be managed by surgically removing the vagina and closing off the space (colpectomy and colpocleisis). The correction of a significant and bothersome pelvic prolapse in the rare danger of vaginal evisceration if it is not treated.

Colpopexy A different procedure is required for younger women and for women who wish to retain sexual function. For these women, the condition can be managed transvaginally or transabdominally. With the transvaginal approach, vaginal eversion is corrected by suturing one or both sides of the vaginal apex (usually the right side) to the sacrospinous ligament with one or two sutures—a transvaginal sacrospinous colpopexy. Other transvaginal reconstructive procedures for the management of advanced posthysterectomy vaginal vault prolapse (stage 3 to 4) include enterocèle ligation and uterosacral ligament suspension or vaginal vault suspension using the iliococcygeal fascia on the pelvic sidewall. These procedures are performed transvaginally and have demonstrated effectiveness in restoring normal vaginal anatomy (157,158). In the transabdominal approach, the vaginal apex is suspended from the anterior longitudinal ligament along the sacrum using a graft of fascia or artificial mesh that is sutured to the vagina and to the sacrum in a retroperitoneal position—a transabdominal sacral colpopexy. The vaginal suspension should always be combined with a meticulous culdocoplasty to repair the endocervix that coexists with vaginal eversion. All these operations are highly successful in reestablishing the vaginal apex (196,197,198) and (199). Because the lines of force produced by increases in intraabdominal pressure are directed across the vagina differently after the two operations, patients who have recurrent prolapse postoperatively tend to have different problems. As a rule, recurrent anterior
vaginal prolapse is more common in patients with vaginal erosion if they have had a sacropspinous ligament fixation, whereas recurrent posterior vaginal prolapse is more common if they have undergone an abdominal sacral colpopexy. Some authors have suggested that recurrent posterior relaxation can be prevented by a colpoproctopectomy in which mesh is attached all the way down to the perineal body during the suspension operation (200). It is unclear which is the best route for correcting posthysterectomy vaginal vault prolapse, and there are few clinical data comparing the vaginal or abdominal approaches (201,202). The most appropriate procedure must be individualized to each patient's clinical findings and the operating surgeon's expertise in reconstructive pelvic surgery.

Colorectal Dysfunction

Pelvic floor disorders span all three anatomic compartments of the pelvis: urinary, genital, and colorectal. Any approach to pelvic floor dysfunction that ignores colonic and rectal problems will not meet the needs of these women. Disorders of colonic and rectal function are disproportionately prevalent among women and represent a major area of continuing clinical neglect in women's health care [3]. Although gynecologists and urologists have made great strides in jointly evaluating and treating urinary incontinence, to date neither specialty has done a creditable job of incorporating the treatment of posterior compartment problems into patient care. Because they are often the first physicians that women see for pelvic floor disorders, gynecologists have an obligation to become knowledgeable about common colorectal complaints. Not only can many of these problems be evaluated and treated initially by gynecologists, but a familiarity with colorectal conditions and a good working relationship with a colon and rectal surgeon or an interested gastroenterologist will also help educate practitioners of these specialties about the genital urinary complaints that frequently accompany disorders of the posterior pelvis. Among the more common conditions with which gynecologists should be familiar are anal incontinence, rectal prolapse, constipation, fecal impaction, and irritable bowel syndrome (see Chapter 14).

Anal Incontinence

Anal incontinence refers to involuntary passage of flatus or feces (either liquid or formed stool) through the anal canal. The term anal incontinence is therefore a more comprehensive term than fecal incontinence, which refers only to the involuntary passage of stool (203,204). Many women have disabling loss of gas, even though they are able to control feces. Although it is becoming more acceptable socially to talk about urinary incontinence, discussion of fecal loss still remains a taboo subject. Even patients with severe anal incontinence often will refuse to bring this problem to the attention of their doctor because of the extreme embarrassment involved. Physicians must ask patients directly (but sensitively) about loss of bowel control in order to elicit this complaint. The problem is more prevalent than most people realize: in one large household survey, 7.1% of the general population reported some degree of anal incontinence (205).

Diagnosis

Normal anal continence depends on the harmonious integration of many factors, including anal sphincter function, anorectal sensation and reflexes, colonic transit, rectal distensibility (compliance), stool consistency, stool volume, and the patient's level of mental functioning. As in the case of urinary incontinence, there are multiple potential causes of anal incontinence (203,204,205,206,207,208) and (209) (Table 20.8).

History

A thorough history regarding bowel function should delineate the nature and frequency of anal loss. Loss of flatus alone is usually (but not necessarily) less troublesome than frequent loss of formed stool. The presence of liquid stool or diarrhea often represents a challenge that a decompensated sphincter cannot withstand, and this condition may respond favorably to bulking agents. If the history is uncertain, administration of a normal saline enema often is helpful in determining the diagnosis. The patient who can retain 1,000 to 1,500 mL of normal saline without leakage is unlikely to have a significant problem with anal incontinence (207). Important pieces of information include changes in stool frequency or consistency, history of blood in the stool, associated medical conditions (especially diabetes and related neurologic problems), medication use, obstetric history, and any history of pelvic or perianal surgery. It is also important to determine whether the patient ever notices anything protruding from the anus because rectal prolapse often is associated with anal incontinence.

Examination

The perineum should be carefully inspected to determine the state of hygiene, the presence of fissures, and the status of the anal sphincter. Pelvic muscle reflexes should be checked in all patients with anal incontinence, and a vaginal and bimanual examination should be performed. The possibility of a disrupted sphincter or a rectovaginal fistula must be considered. The patient should be examined while straining to check for the presence of rectal prolapse. All patients should undergo a digital rectal examination with testing of the stool for occult blood: at least 50% of rectal carcinomas lie within reach of the examiner's finger. Many patients with fecal incontinence have a fecal impaction, which should be removed (210,211). The puborectalis muscle should be palpated through the posterior rectum. When the patient contracts this muscle, the examiner's finger should move anteriorly. Poor sphincter tone is indicated by gaping of the rectum when the puborectalis muscle is depressed. Direct inspection of the large intestine through the use of flexible sigmoidoscopy or colonoscopy should be considered in all patients.

Tests

The American Gastroenterological Association has recently reviewed the major tests currently available for the evaluation of anorectal function (212). Anorectal manometry, endoanal ultrasound, and evacuation proctography (defecography) are the most useful diagnostic tests; there are others, but they are less useful in clinical decision making.

Anorectal Manometry

Anorectal manometry is a test performed to evaluate anorectal sensation, resting and squeeze pressures, compliance (distensibility), and reflexes. The test may be performed with solid-state transducers or water-perfusion techniques. In anorectal manometry, the pressure-measuring device is slowly withdrawn through the rectum and anal canal at rest and during intermittent squeeze maneuvers. Pressure gradients are calculated, and the response of the anorectal junction to distention with an air-filled balloon is evaluated. Specific resting and squeeze values cannot distinguish continent from incontinent patients, but patients with low squeeze pressures are more likely, as a group, to be incontinent than those who have higher values. Patients with low anal compliance (often due to radiation fibrosis or proctitis) tend to have urgency symptoms; when these patients undergo anorectal surgery, they tend to have less successful operative outcomes. Measurement of sensory thresholds is important in patients with anal incontinence because one of the most effective interventions is biofeedback training to improve anorectal sensation (213).

Endoanal Ultrasound

Endoanal ultrasonography is performed after vaginal childbirth has revealed a very high rate of occult sphincter injury in women who did not have a known perineal laceration at delivery (214). Although many of these women do not have symptoms in the immediate postpartum period, the long-term consequences of...
Rectal Prolapse

Rectal prolapse is relatively uncommon but nonetheless is a significant clinical problem for those unfortunate enough to experience it. About 90% of patients with rectal prolapse are women. Normally, the rectum is attached firmly to the levator ani muscle complex through an extensive interweaving of longitudinal muscle fibers. This attachment is important because the rectum undergoes multiple changes in position and location during the normal act of defecation. Without this attachment, the rectum would slip down through the levator muscle hiatus during defecation. In rectal prolapse, this actually occurs. An intussusception of the rectum develops (for reasons not totally clear). Gradually, over time, the intussusception pulls the rectum away from its sacral attachments, ultimately allowing it to appear at or beyond the anal verge. Predisposing factors associated with rectal prolapse are summarized in Table 20.9.

Evacuation Proctography: Evacuation proctography is a radiographic test in which stoollike contrast material (usually a barium paste) is instilled into the rectum. The utility of the test can be enhanced by putting additional contrast in the bladder and vagina and by having the patient ingest contrast material before the study to opacify the small bowel. Cinefluoroscopic images are then taken with the patient sitting on a radiolucent commode so that the mechanism of rectal evacuation can be studied. The test is useful for evaluating puborectalis muscle function, detecting the presence of occult enterocoeles, and evaluating patients for the presence of rectal prolapse and intussusception. These studies are most useful if done collaboratively by a pelvic floor physician and radiologist with special interest in this area.

Because the external anal sphincter is innervated by the pudendal nerve, assessment of pudendal nerve function would appear to have a role in the evaluation of patients with anal incontinence. Unfortunately, the pudendal nerve is hidden in the pelvis and traverses a tortuous pathway from the sacral spinal cord to the perineum, which varies significantly among different individuals. To date, it has not been possible to measure the length of the pudendal nerve accurately in individual patients; therefore, precise measurement of pudendal nerve conduction velocity (time of impulse transmission/length of pudendal nerve) is not possible. Numerous attempts have been made to correlate the time (latency) between a stimulus applied to the pudendal nerve at the ischial spine and its appearance at the anal sphincter, but the studies that correlate these results with clinical findings and surgical outcome are conflicting and their utility is questionable.

Surgical repair should be considered in patients who have a demonstrable sphincter defect. The best results appear to be obtained using an overlapping sphincteroplasty rather than an end-to-end reaproximation of the torn sphincter. Although restoration of complete continence in most patients with an old sphincter injury is unlikely, the chance of a successful operation is improved if the sphincter muscles are intact and if the patient is an otherwise suitable candidate, irrespective of age. Patients with a rectovaginal fistula will obviously benefit from fistula closure. For some patients, construction of an anal neosphincter using transplanted gracilis muscle driven by an implanted pacemaker may be of benefit. Patients who have severe persistent incontinence after biofeedback therapy, medical management, and surgical treatment may be candidates for colostomy. An algorithm for the evaluation and treatment of fecal incontinence is given in Figure 20.21.
rectal prolapse is well established (215,220-221).

### Treatment

Partial or incomplete rectal mucosal prolapse generally can be treated with anal surgery, often involving only excision of the affected area. Complete rectal prolapse is a more complicated problem, with more than 200 operations having been described for this condition. The proposed operations include or combine several modes of therapy, such as narrowing the anal orifice, obliteration of the cul-de-sac, restoration of the pelvic floor, resection of bowel, and suspension or fixation of the rectum. In general, some form of rectopyexy appears to have the highest success rate, the lowest recurrence rate, and an acceptable level of complications. Several concise but comprehensive reviews of this subject have recently been prepared (222-223 and 224).

### Constipation

Constipation is a common patient concern, yet there is no generally accepted definition of the term (225). Commonly used definitions include frequent straining at stool (more than 25% of the time) or fewer than three bowel movements per week. Nearly 95% of normal individuals have between three bowel movements per day and three bowel movements per week. In surveys of patients not seeking medical care for gastrointestinal disorders, between 10% to 20% appear to have symptoms of constipation; most of these individuals are female (226-227). Constipation is less frequent among the young and increases to its highest prevalence in old age. Because there is no generally accepted definition of constipation, the physician must generally take the patient's reports of this problem at face value and then attempt to understand what she means by this term. Constipation is a symptom, rather than a disease, produced by many different factors (228) (Table 20.10). Most patients who describe themselves as constipated can be treated with laxatives, increased fiber intake, and the development of regular dietary habits. Only a small percentage of patients have “intractable” constipation, but these patients should undergo an appropriate evaluation.

### Diagnosis

Because of its high prevalence among women, physicians should be well versed in the treatment of constipation. The goal of treatment for patients with chronic constipation is restoration of normal frequency and consistency of stools without the need to strain during defecation (229). Restoration should be accomplished with as little artificial intervention as possible, and it should result in the diminution of any associated symptoms such as crampy abdominal pain or bloating. Because stool of normal consistency is about 70% water, the mainstays in the treatment of constipation are water and fiber. The fiber serves as a bulking agent that can trap water and promote an increased mass of stool. The normal dietary fiber intake should be 14 g/d. Unprocessed bran is the most readily available fiber supplement. If it is not available, psyllium can also be used. The type of fiber is not nearly as important as adequate fiber intake. One inexpensive and highly useful dietary recipe for use by constipated patients involves mixing about 1 cup of Miller's bran, ½ cup of applesauce, and ¼ cup of prune juice to desired consistency, storing it under refrigeration, and taking 1 to 2 tablespoons per day. This can be taken straight, or mixed with fruit or cereal, and titrated to the desired results.

### Treatment

Laxatives are an important adjunct to fiber and water in the treatment of constipation. Literally hundreds of laxative preparations are available. They can be divided into two main groups: stimulant laxatives and mechanical laxatives. Stimulant laxatives (e.g., cascara, senna, castor oil, bisacodyl, and diphenylmethane) cause increased peristaltic activity in the colon. Stimulant laxatives may be used occasionally, but chronic use should be avoided because the bowel may become dependent on them. Side effects of stimulant laxatives can include cramps and, in some cases, explosive defecation. The mechanical laxatives include salts such as sodium phosphate or magnesium sulfate, mineral oil, and surfactants such as docusate sodium. These agents increase peristalsis by changing stool consistency or increasing stool bulk. Agents such as lactulose produce an osmotic catharsis. Oral agents such as mineral oil work by decreasing water absorption from the stool, thereby keeping it soft. If taken orally, mineral oil should be used with caution because inhalation can lead to serious aspiration pneumonia, particularly in elderly or debilitated patients.

Enemas and suppositories are also useful. An enema is particularly helpful in removing an acute fecal impaction. The best enemas are usually the simplest: warm tap water or equal parts of water, glycerin, and mineral oil. The use of these agents is preferable to soap enemas or hypertonic phosphate enemas, which are particularly irritating. Injudicious use of enemas can cause electrolyte imbalances or colonic perforation. Suppositories are helpful in the periodic evacuation of the lower bowel. Insertion of a simple glycerin suppository will usually initiate defecation within 1 hour without chemical stimulation of the colon.

Attention should always be paid to other factors influencing the normal action of the gut. Patients should be taught not to suppress defecation but to make use of the normal gastrocolic reflex that promotes a call to stool about 30 minutes after a meal (usually breakfast). Regular meals help promote regular bowel movements.

Regular exercise, even exercise as simple as a brisk walk, has an important influence on regular defecation, as well as on general fitness and well-being.

Attention to good bowel habits, adequate fiber intake, and occasional laxative use should help prevent fecal impaction. Although this condition can occur at any age, elderly and institutionalized patients are at particular risk for impaction (210). Continued passage of stool does not rule out impaction. Many impacted patients develop diarrhea and anal incontinence, as well as nausea, anorexia, vomiting, and abdominal pain, as loose bowel contents bypass the point of impaction. The diagnosis of fecal impaction can usually be established by rectal examination, although a fecal impaction is sometimes located high in the colon. The impacted stool may be hard or soft and may be a single mass or multiple pellets. If the patient's presentation suggests an impaction but one cannot be detected on rectal examination, it may be useful to obtain an x-ray of the abdomen. Fecal masses or unusual air-fluid levels may be detected with this technique. Once diagnosed, the impaction should be removed by fragments the fecal mass manually and removing it piecemeal. This can be accomplished using local anesthesia (lidocaine jelly) and liberal amounts of lubricant, combined with pressure on the posterior vagina. After the mass has been broken up, tap water enemas and bisacodyl suppositories will help finish expelled. The patient should then be placed on a bowel regimen thereafter to prevent the recurrence of future impactions.

Conservative measures, including adequate fluid intake, a high-fiber diet, and occasional laxative use, should allow most women with constipation to regain normal bowel habits of at least three movements per week. If a trial of 3 to 6 months of conservative therapy in a compliant patient is unsuccessful, the proposed operations include or combine several modes of therapy, such as narrowing the anal orifice, obliteration of the cul-de-sac, restoration of the pelvic floor, resection of bowel, and suspension or fixation of the rectum. In general, some form of rectopyexy appears to have the highest success rate, the lowest recurrence rate, and an acceptable level of complications. Several concise but comprehensive reviews of this subject have recently been prepared (222-223 and 224).

Gynecologists in particular should be on guard against the common assumption that all women with constipation and a rectocle have a condition that is correctable by surgery. A common complaint is that the patient usually constipated prior to the development of the rectocle. The further examination of patients with constipation should include endoscopic examination of the colon and rectum and referral to a colorectal physiology laboratory for more sophisticated studies, including segmental colonic transit studies, anal rectal manometry, pelvic floor electromyography, and defecography (225). If blood is present in the stool, if the constipation is painful, if constipation is the result of a sudden change in bowel habits, or if the clinician is otherwise suspicious of a more serious disease process, these studies should be performed earlier in the course of treatment. When the usual sets of studies reveal no cause, constipation is considered functional or nonorganic (228). Most patients with severe functional constipation are young women.
These women appear to have disorders of conduction of the pelvic floor. The symptoms of the incontinence can result from factors such as pregnancy, childbirth, age, and other factors that put stress on the pelvic floor muscles. The pelvic floor muscles are responsible for controlling the flow of urine and stool. The effects of these disorders on the pelvic floor muscles are explored in this chapter.
Laparoscopy is a procedure that uses a narrow telescope to view the interior of a viscus space. Although the first medical endoscopic procedures were performed more than 100 years ago, the potential of this method has only recently been realized. Endoscopes are currently used to perform a variety of operations. In gynecology, endoscopes are used most often to diagnose conditions by direct visualization of the peritoneal cavity (laparoscopy) or the inside of the uterus (hysteroscopy).

When used appropriately, endoscopic surgery offers the benefits of reduced pain, improved cosmesis, lower cost, and faster recovery. The indications for endoscopic surgery are outlined here and detailed in the appropriate chapters. The technology, potential uses, and complications of laparoscopy and hysteroscopy are summarized here.

Laparoscopy

The past three decades have witnessed rapid progress and technologic advances in laparoscopy ([1], [2], [3], [4], [5], [6], [7], [8], [9], [10], and [11]). Operative laparoscopy was developed in the 1970s; and in the early 1980s, laparoscopy was first used to direct the application of electrical or laser energy for the treatment of advanced stages of endometriosis ([6] and [7]). The use of high-resolution, lightweight video cameras in operative laparoscopy has made it easier to view the pelvis during the performance of complex procedures ([8], [9], and [10]). Subsequently, many other procedures that were previously performed using traditional techniques, such as hysterectomy, became feasible with the laparoscope ([11]). However, the endoscopic approach may have drawbacks in some patients. Although some laparoscopic procedures appear to reduce the cost and morbidity associated with surgery, others have not been shown to be effective replacements for more traditional operations. The techniques and indications for operative endoscopy are evolving.

Diagnosis

The objective lens of a laparoscope can be positioned to allow wide-angle or magnified views of the peritoneal cavity. Laparoscopy is the standard method for the diagnosis of endometriosis and adhesions because no other imaging technique provides the same degree of sensitivity and specificity.

There are limitations to laparoscopy, however. The view is restricted, and if tissue or fluid becomes attached to the lens, vision may be obscured. Also, soft tissues or the inside of a hollow viscus cannot be palpated. For assessment of soft tissue, an imaging modality, such as ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) scans, is superior. Because of its ability to view soft tissue, ultrasonography is more accurate than laparoscopy for the evaluation of the inside of adnexal masses. The intraluminal contour of the uterus can be demonstrated only by hysteroscopy or contrast imaging. Ultrasonography, in combination with serum assays of b-human chorionic gonadotropin (b-hCG) and progesterone, can be used to diagnose ectopic pregnancy, usually allowing medical therapy to be given without laparoscopic confirmation ([12]). As a result of the advances in blood tests and imaging technology, laparoscopy is more often used to confirm a clinical impression than for initial diagnosis.

Laparoscopy may disclose abnormalities that are not necessarily related to the patient's problem. Although endometriosis, adhesions, leiomyomas, and small cysts in the ovaries are common, they are frequently asymptomatic. Thus, diagnostic laparoscopy must be performed prudently, interpreting findings in the context of the clinical problem and other diagnoses.

Therapy

The role of laparoscopy in the operative management of gynecologic conditions is still being defined. Many procedures previously in the domain of traditional abdominal and vaginal operations are feasible with laparoscopy. In addition to the benefits of endoscopic procedures in general, laparoscopic surgery is less likely than laparotomy to form adhesions. Because sponges are not used, the amount of direct peritoneal trauma is reduced substantially, and contamination of the peritoneal cavity is minimized. The lack of exposure to air allows the peritoneal surface to remain more moist and, therefore, less susceptible to injury and adhesion formation.

Despite these advantages, there are potential limitations: exposure of the operative field can be reduced, manipulation of the pelvic viscera is limited, and the caliber of the suture required may be larger than otherwise desired. In many cases, the cost of hospitalization increases, despite a shortened stay, because of prolonged operating room time and the use of more expensive surgical equipment and supplies. Efficacy may be reduced because surgeons may not adequately replicate the abdominal operation. In some patients, there is an increased risk for complications, which can be attributed to the innate limitations of laparoscopy, the level of surgical expertise, or both. With an adequate combination of ability, training, and experience, however, operative time and complications are comparable to those of traditional abdominal surgery.

Tubal Surgery

Sterilization Laparoscopic sterilization has been extensively used since the late 1960s and can be performed under local or general anesthesia. The tubes may be occluded by suture, clips, or Silastic rings, but electrosurgical desiccation with bipolar energy is the technique used most often (see Chapter 10). If an operative laparoscope is used, only one incision is required. Otherwise, a second port is needed for the introduction of the occluding instrument. Patients remain in the hospital...
for several hours, even when general anesthesia is used. Postoperative pain is usually minor and related to the effects of the anesthesia, gas that remains in the peritoneal cavity (shoulder pain, dyspnea), and in the case of occlusive devices, pain at the surgical site. These effects normally disappear within a few days. The failure rate is about 5.4 per 1,000 woman-years (13,14).

**Ectopic Gestation**

Ectopic gestation can be managed using laparoscopy to perform the same procedures done with laparotomy, including salpingostomy, salpingectomy, and segmental resection of a portion of the oviduct (see Chapter 17) (15). Salpingostomy is performed with scissors, a laser, or an electrosurgical electrode after carefully injecting the mesosalpinx with a dilute vasopressin-containing solution (20 units per 100 mL of normal saline). For salpingectomy, the vascular pedicles are usually secured with electrosurgical desiccation, ligatures, clips, or a combination thereof. Tissue is removed from the peritoneal cavity through one of the laparoscopic ports.

When salpingostomy is performed by any route, there is about a 5% chance that trophoblastic tissue remains. In such instances, medical treatment with methotrexate is considered appropriate (see Chapter 17). Consequently, b-hCG levels should be measured weekly until there is confidence that complete excision has occurred (16,17).

**Ovarian Surgery**

**Ovarian Masses**

Laparoscopic removal of selected ovarian masses is a well-established procedure (18,19). However, controversy exists regarding the selection of cases that can be removed by laparoscopy, because of concerns about an adverse effect on prognosis with malignant tumors (20). Preoperative ultrasonography is mandatory. Sonoluent lesions with thin walls and no solid components are at very low risk for malignancy and, therefore, are suitable for laparoscopic removal. For postmenopausal women, the measurement of CA125 may be useful in identifying candidates for laparoscopic management (21,22). Lesions with ultrasonographic findings suggestive of mature teratoma (dermoid) may also be suitable for endoscopic management (23). The ovarian tumors should be assessed by frozen histologic section, and any malignancy should be managed expeditiously by laparotomy (22,24).

Oophorectomy and cystectomy are performed similar to those for laparotomy (18). For cystectomy, scissors are used to separate the cyst from the ovary; if oophorectomy is performed, the vascular pedicles are ligated with sutures, clips, linear cutting staplers, electrosurgical desiccation, or a combination thereof. Most cysts are drained before extraction, through either a laparoscopic cannula or a posterior colpotomy. If there is concern about the impact of spilled cyst contents, the specimen can be removed in a retrieval bag inserted into the peritoneal cavity.

Although in the past the ovary has routinely been closed after cystectomy, this practice may be unnecessary and could contribute to the formation of adhesions (25). However, complete disruption of the ovarian cortex may make closure necessary. If so, the edges of the ovarian incision can be sutured.

**Other Ovarian Surgery**

Many cases of ovarian torsion previously treated by laparotomy and oophorectomy can be managed laparoscopically (26,27). If there is no apparent necrosis, the adnexa should be untwisted. Otherwise, adnexectomy is indicated.

Polycystic ovarian syndrome can be treated laparoscopically using electrosurgery and laser vaporization (28,29) and (30). Although such procedures have been shown to be successful, the occurrence of postoperative adhesions in 15% to 20% of patients underscores the need first to exhaust medical treatment (31,32).

**Uterine Surgery**

**Myomectomy**

Laparoscopic myomectomy, although feasible, is rarely performed, in part because its efficacy is yet to be established, especially as it relates to the treatment of infertility and menorrhagia (33,34). Also, laparoscopic myomectomy requires more technical skills than many other endoscopic procedures.

Unless the myoma involves the endometrial cavity, it is unlikely to contribute to heavy menstrual bleeding. Leiomyomas that cause pressure are often large and located in or near vital vascular structures. Myomectomy should be performed only when indicated (as opposed to expectant or medical management), and laparotomy should be used if there are technical limitations (35). The only leiomyomas that are clearly appropriate candidates for laparoscopic excision are those pedunculated or subserosal lesions that cause pain in association with torsion (16,36).

**Hysterectomy**

In many patients, hysterectomy can be performed under laparoscopic direction. Laparoscopic hysterectomy encompasses a variety of procedures, including the facilitation of vaginal hysterectomy with variable extents of endoscopic dissection, supracervical hysterectomy by dissection, amputation and mechanical removal of the fundus, and the removal of the entire uterus with the assistance of the laparoscope (37). The procedure is performed with scissors, sutures, electricity, clips, and, in some instances, linear cutting and stapling devices to dissect or ligate pedicles. Laparoscopic hysterectomy offers no advantage for women in whom vaginal hysterectomy is possible because the endoscopic approach is more expensive and has a higher risk for postoperative morbidity (38,39).

**Infertility Operations**

Laparoscopic treatment of infertility includes operations used to reconstruct the normal anatomic relationships altered by an inflammatory process: fimbrioplasty, adhesiolysis, and salpingostomy for distal obstruction (40). Fimbrioplasty is distinguished from salpingostomy because it is performed in the absence of preexisting complete distal obstruction. Endometriosis associated with adnexal distension can be treated by laparoscopic adhesiolysis. There is no known additional benefit of laparoscopic (or medical) treatment to coexistent active endometriosis. Laparoscopy has been superseded by ultrasound for the retrieval of oocytes for in vitro fertilization but is still used for procedures in which gametes (gamete intrafallopian transfer) or zygotes (zygote intrafallopian transfer) are placed into the fallopian tube.

Adhesiolysis may be accomplished by blunt or sharp dissection with scissors, laser, or an electrosurgical electrode. These instruments are usually passed through an ancillary port; those who use laser energy frequently use the channel of the operating laparoscope. Although there has been controversy regarding the most appropriate modality, both methods are probably equally effective in appropriately trained hands.

Laparoscopic operations for the treatment of mechanical infertility are probably equally effective to similar procedures performed by laparotomy. In patients with extensive adhesions, however, the effectiveness of all procedures is limited. Assisted reproductive technologies such as in vitro fertilization and embryo transfer are necessary in these situations (16,41).

**Endometriosis**

The laparoscopic management of endometriomas parallels that of adnexal masses, although the ultrasonographic complexity of endometriomas may make it difficult to distinguish them preoperatively from a neoplasm. The relationship of the endometrioma to the ovarian cortex and stroma makes it difficult to find surgical dissection planes. There is a tendency either to compromise the function of the remaining ovary by attempting complete removal or to leave part of the endometrioma in place. Therefore, for women who want to retain their fertility, electrosurgical or laser ablative techniques may be used to treat endometriotic tissue that is adherent to the remaining ovary.

Multifocal endometriosis may be treated by mechanical excision or ablation, the latter using coagulation or vaporization with either electrical or laser energy. With proper use, each energy source creates about the same amount of thermal injury (42,43). Endometriosis is frequently deeper than appreciated, making excisional techniques valuable in many instances (18,44).
Laparoscopy can be used to guide procedures to treat pelvic floor prolapse, including enterocele repair, vaginal vault suspension, paravaginal repair, and retropubic cystourethroplasty for urinary stress incontinence. Although these conditions can be treated vaginally, the abdominal approach may offer benefits, particularly with retropubic urethropexy. There is some evidence that this procedure is effective when compared with the traditional approaches (44,45). The laparoscopic treatment of enterocele and vault prolapse may be useful in patients who require abdominal approaches after failure of a previous vaginal procedure.

Gynecologic Malignancies

The role of laparoscopy in the management of gynecologic malignancy has not been clearly established (24,46,47). However, a number of ongoing research protocols relating to cervical, endometrial, and ovarian cancer should help document this role. Lymph node biopsies performed by laparoscopy can be coupled with vaginal hysterectomy for the management of early-stage endometrial cancer. The potential for laparoscopic lymphadenectomy has fostered a resurgence of interest in vaginal radical hysterectomy for stage I carcinoma of the cervix. Laparoscopy is also being investigated for the staging of early ovarian malignancy and for second-look surgery.

Patient Preparation and Communication

The prospective patient must understand the rationale, alternatives, risks, and potential benefits of the selected approach. She should know what would probably happen if the procedure were not done and expectant management were used.

The expectations and risks of diagnostic laparoscopy, as well as those of any other procedures that may be needed, must be explained. The risks of laparoscopy include those associated with anesthesia, infection, bleeding, and injury to the abdominal and pelvic viscera. Infection is uncommon with laparoscopic surgery. For procedures involving extensive dissection, there is a higher risk for visceral injury. The potential for these risks should be clearly presented. The patient should be given realistic expectations regarding postoperative disability.

Because pain and visceral dysfunction normally continue to improve after uncomplicated laparoscopy, the patient should be instructed to communicate immediately any regression in her recovery. After diagnostic or brief operative procedures, patients can be discharged on the day of surgery and usually require 24 to 72 hours away from work or school. If extensive dissection is performed or the surgery lasts longer than 2 hours, hospital admission may be necessary, and the period of disability may be longer.

If the colon may be involved, mechanical bowel preparation should be performed to help improve visualization and minimize the need for a colostomy if the colon is entered. The patient should arrange for a friend or family member to discuss the results of the procedure and to drive her home if she is discharged the same day. Midline analgesia is often necessary.

Technique

Laser and electrical sources of energy manifest their effect by conversion to thermal energy. Highly focused energy produces vaporization or cutting, whereas less focused energy causes desiccation and tissue coagulation. Animal studies fail to demonstrate differences in injury characteristics (41,42 and 43). Randomized controlled studies have shown no differences in fertility outcomes in women undergoing CO₂ laser surgery and electrosurgery (48). Therefore, differences in results are more likely to be caused by other factors, such as patient selection, extent of disease, and degree of surgical expertise. With proper education, modern equipment, and adherence to safety protocols, these techniques can be used safely. To facilitate the discussion of laparoscopic equipment, supplies, and techniques, it is useful to divide procedures into “core competencies,” which are as follows:

1. Patient positioning
2. Operating room organization
3. Peritoneal access
4. Visualization
5. Manipulation of tissue and fluid
6. Cutting, hemostasis, and tissue fastening
7. Tissue extraction
8. Incision management

Patient Positioning

Proper positioning of the patient is essential for safety, comfort of the operator, and optimal visualization of the pelvic organs. Laparoscopy is performed on an operating table that can be rotated around the patient's long axis and tipped to create a steep, head-down (Trendelenburg) position. The footrest can be dropped to 72 hours away from work or school. If extensive dissection is performed or the surgery lasts longer than 2 hours, hospital admission may be necessary, and the period of disability may be longer.

If the colon may be involved, mechanical bowel preparation should be performed to help improve visualization and minimize the need for a colostomy if the colon is entered. The patient should arrange for a friend or family member to discuss the results of the procedure and to drive her home if she is discharged the same day. Midline analgesia is often necessary.

Laparoscopy can be used to guide procedures to treat pelvic floor prolapse, including enterocele repair, vaginal vault suspension, paravaginal repair, and retropubic cystourethroplasty for urinary stress incontinence. Although these conditions can be treated vaginally, the abdominal approach may offer benefits, particularly with retropubic urethropexy. There is some evidence that this procedure is effective when compared with the traditional approaches (44,45). The laparoscopic treatment of enterocele and vault prolapse may be useful in patients who require abdominal approaches after failure of a previous vaginal procedure.

Gynecologic Malignancies

The role of laparoscopy in the management of gynecologic malignancy has not been clearly established (24,46,47). However, a number of ongoing research protocols relating to cervical, endometrial, and ovarian cancer should help document this role. Lymph node biopsies performed by laparoscopy can be coupled with vaginal hysterectomy for the management of early-stage endometrial cancer. The potential for laparoscopic lymphadenectomy has fostered a resurgence of interest in vaginal radical hysterectomy for stage I carcinoma of the cervix. Laparoscopy is also being investigated for the staging of early ovarian malignancy and for second-look surgery.

Patient Preparation and Communication

The prospective patient must understand the rationale, alternatives, risks, and potential benefits of the selected approach. She should know what would probably happen if the procedure were not done and expectant management were used.

The expectations and risks of diagnostic laparoscopy, as well as those of any other procedures that may be needed, must be explained. The risks of laparoscopy include those associated with anesthesia, infection, bleeding, and injury to the abdominal and pelvic viscera. Infection is uncommon with laparoscopic surgery. For procedures involving extensive dissection, there is a higher risk for visceral injury. The potential for these risks should be clearly presented. The patient should be given realistic expectations regarding postoperative disability.

Because pain and visceral dysfunction normally continue to improve after uncomplicated laparoscopy, the patient should be instructed to communicate immediately any regression in her recovery. After diagnostic or brief operative procedures, patients can be discharged on the day of surgery and usually require 24 to 72 hours away from work or school. If extensive dissection is performed or the surgery lasts longer than 2 hours, hospital admission may be necessary, and the period of disability may be longer.

If the colon may be involved, mechanical bowel preparation should be performed to help improve visualization and minimize the need for a colostomy if the colon is entered. The patient should arrange for a friend or family member to discuss the results of the procedure and to drive her home if she is discharged the same day. Midline analgesia is often necessary.

Technique

Laser and electrical sources of energy manifest their effect by conversion to thermal energy. Highly focused energy produces vaporization or cutting, whereas less focused energy causes desiccation and tissue coagulation. Animal studies fail to demonstrate differences in injury characteristics (41,42 and 43). Randomized controlled studies have shown no differences in fertility outcomes in women undergoing CO₂ laser surgery and electrosurgery (48). Therefore, differences in results are more likely to be caused by other factors, such as patient selection, extent of disease, and degree of surgical expertise. With proper education, modern equipment, and adherence to safety protocols, these techniques can be used safely. To facilitate the discussion of laparoscopic equipment, supplies, and techniques, it is useful to divide procedures into “core competencies,” which are as follows:

1. Patient positioning
2. Operating room organization
3. Peritoneal access
4. Visualization
5. Manipulation of tissue and fluid
6. Cutting, hemostasis, and tissue fastening
7. Tissue extraction
8. Incision management

Patient Positioning

Proper positioning of the patient is essential for safety, comfort of the operator, and optimal visualization of the pelvic organs. Laparoscopy is performed on an operating table that can be rotated around the patient's long axis and tipped to create a steep, head-down (Trendelenburg) position. The footrest can be dropped to 72 hours away from work or school. If extensive dissection is performed or the surgery lasts longer than 2 hours, hospital admission may be necessary, and the period of disability may be longer.
Operating Room Organization

The arrangement of instruments and equipment is important for safety and efficiency. The orientation depends on the operation, the instruments used, and whether the surgeon is right- or left-handed. An orientation for a right-handed operator is shown in Fig. 21.2.

For pelvic surgery, the monitor should be placed at the foot of the table within the angle formed by the patient’s legs. If a second monitor is used, one should be positioned at each foot of the patient. If upper abdominal surgery is also to be performed, the additional monitor should be moved to the head of the operating table.

The surgeon stands by the patient’s left side, at an angle facing the patient’s contralateral foot. The nurse or technician and instrument table are positioned near the foot of the operating table to avoid obscuring the video monitor. The insufflator is placed on the patient’s right side, in front of the surgeon, to allow continuous monitoring of the inflation rate and intraabdominal pressure. The electrosurgical generator is also positioned on the patient’s right side to permit visualization of the power output. When a laser is used through a second puncture site, it is also placed to the patient’s right. When the laser is passed through the channel of an operating laparoscope, however, it is situated on the patient’s left side, beside the surgeon.

Peritoneal Access

Before inserting the laparoscope, a cannula or port must be positioned in the abdominal wall to establish access to the peritoneal cavity. The closed technique is a blind approach in which the cannula is introduced with a sharp trocar used to penetrate the abdominal layers. In open laparoscopy, entry into the peritoneal cavity is achieved by a minilaparotomy, with the cannula fixed into position with sutures or other suitable techniques. Gynecologists have generally favored a closed technique, preinflating the peritoneal cavity with CO\(_2\) through a hollow needle. In either case, additional cannulas are inserted by sharp trocars under direct vision to allow the use of laparoscopic hand instruments such as scissors, probes, and other manipulating devices.

Cannula insertion is aided by an understanding of the normal anatomy, especially the location of vessels (Fig. 21.3). A "safety zone" exists inferior to the sacral promontory in the area bounded cephalad by the bifurcation of the aorta, posteriorly by the sacrum, and laterally by the iliac vessels (49). In women placed in the Trendelenburg position, the great vessels are situated more cephalad and anterior, making them more vulnerable to injury unless appropriate adjustments are made in the angle of insertion (Fig. 21.4). Therefore, positioning of the insufflation needle, the initial trocar, and the cannula is best accomplished with the patient in a horizontal position. This approach also facilitates the evaluation of the upper abdomen, which is limited if the intraperitoneal contents are shifted cephalad by the head-down position.

Insufflation Needles

Virtually all insufflation needles are modifications of the hollow needle designed by Verres (Fig. 21.5). In cases uncomplicated by previous pelvic surgery, the preferred site for insertion is as close as possible to (or within) the umbilicus, where the abdominal wall is the thinnest.
A 3-mm incision adequate for the needle is made with a small scalpel, and the abdominal wall is elevated by gripping it in the midline below the umbilicus. Safe insertion of the insufflation needle mandates that the instrument be maintained in a midline, sagittal plane while the operator directs the tip between the iliac vessels, anterior to the sacrum but inferior to the bifurcation of the aorta and the proximal aspect of the vena cava. Therefore, in women of average weight, the insufflation needle is directed at a 45-degree angle to the patient’s spine. In heavy to obese individuals, this angle may be increased incrementally to nearly 90 degrees, accounting for the increasing thickness of the abdominal wall and the tendency of the umbilicus to gravitate caudad with increasing abdominal girth (49). The needle’s shaft is held by the tips of the fingers and steadily but purposefully guided into position only far enough to allow the tip’s entry into the peritoneal cavity. The tactile and visual feedback created when the needle passes through the facial and peritoneal layers of the abdominal wall may provide guidance and help prevent overaggressive insertion attempts. This proprioceptive feedback is less apparent with disposable needles than with the classic Verres needle. With the former, the surgeon must listen to the “clicks” as the needle obturator retracts when it passes through the rectus fascia and the peritoneum. The needle should never be forced.

2. In instances in which known or suspected intraabdominal adhesions surround the umbilicus, alternative sites for insufflation needle insertion should be used. These include the pouch of Douglas, the fundus of the uterus, and the left upper quadrant, most often at the left costal margin (Fig. 21.6). The left upper quadrant is preferred if there has been no previous surgery in this area. In such patients, the stomach must be decompressed with a nasogastric or orogastric tube before the puncture.

3. Before insufflation, the operator should try to detect whether the insufflation needle has been malpositioned in the omentum, mesentery, blood vessels, or hollow organs such as the stomach or bowel. Using a syringe attached to the insufflation needle, blood or gastrointestinal contents may be aspirated. This examination may be facilitated by injecting a small amount of saline into the syringe. If the needle is appropriately positioned, negative intraabdominal pressure is created by lifting the abdominal wall. This negative pressure may be demonstrated by aspiration of a drop of saline placed over the open, proximal end of the needle or, preferably, by using the digital pressure gauge on the insufflator.

4. Additional signs of proper placement may be sought after starting insufflation. The intraabdominal pressure reading should be low, reflecting only systemic resistance to the flow of CO₂. Consequently, there should be little deviation from a baseline measurement, generally less than 10 mm Hg. The pressure varies with respiration and is slightly higher in obese patients. The earliest reassuring sign is the loss of liver “dullness” over the lateral aspect of the right costal margin. However, this sign may be absent if there are dense adhesions in the area, usually the result of previous surgery. Symmetric distention is unlikely to occur when the needle is positioned extraperitoneally. Proper positioning can also be shown by lightly compressing the xiphoid process, which increases the pressure measured by the insufflator.

5. The amount of gas transmitted into the peritoneal cavity should depend on the measured intraperitoneal pressure, not the volume of gas inflated. Intraperitoneal volume capacity varies significantly between individuals. Many surgeons prefer to insufflate to 20 mm Hg for positioning of the cannulas. This level usually provides enough counterpressure against the peritoneum, facilitating trocar introduction and potentially reducing the chance of bowel or posterior abdominal wall and vessel trauma. After placement of the cannulas, the pressure should be dropped to 10 to 12 mm Hg, which essentially eliminates hypercarbia or decreased venous return of blood to the heart.

Laparoscopic Cannulas

Laparoscopic cannulas are necessary to allow the insertion of laparoscopic instruments into the peritoneal cavity while maintaining the pressure created by the distending gas (Fig. 21.7 and Fig. 21.8). Cannulas are hollow tubes with a valve or sealing mechanism at or near the proximal end. The cannula may be fitted with a Luer-type port that allows attachment to tubing connected with the CO₂ insufflator. Larger-diameter cannulas (8 to 12 mm) may be fitted with adapters or specialized valves that allow the insertion of smaller-diameter instruments without loss of intraperitoneal pressure.

Figure 21.7 Primary laparoscopic cannulas. Left to right: a nondisposable 10-mm cannula with the obturator removed (Olympus America, Inc., Woodbury, NY), a disposable 5- to 12-mm cannula with a “safety” sheath (Autosuture, Inc, Norwalk, CT), and a Hasson cannula used in open laparoscopy (Ethicon Endosurgery, Inc., Cincinnati, OH).
The trocar is a longer instrument of slightly smaller diameter that is passed through the cannula, exposing its tip. Most trocars have sharp tips, allowing penetration of the abdominal wall after a small skin incision. Many disposable trocar-cannula systems are designed with a safety mechanism—usually a pressure-sensitive spring that either retracts the trocar or deploys a protective sheath around its tip after passage through the abdominal wall. None of these protective devices has been shown to make the procedure safer; however, they all increase the cost.

Cannulas can be inserted following minilaparotomy (open laparoscopy), after the successful creation of a pneumoperitoneum (secondary puncture), or without previously instilling intraperitoneal gas (primary puncture). With open laparoscopy, there is less risk for injury to blood vessels and abdominal viscera. However, open laparoscopy cannot prevent all insertion accidents because intestine can be entered inadvertently no matter how small the laparotomy. There is little evidence that secondary puncture is necessary, at least when there are no preexisting abdominal wall adhesions. Therefore, in women with no previous surgery, the primary puncture can be performed with a sharp-tipped trocar-cannula system, which lowers the cost by eliminating the need for the insufflation needle and by reducing operating time. The first, or primary, cannula must be of sufficient caliber to permit passage of the laparoscope and is usually inserted in or at the lower border of the umbilicus. The incision should be extended only enough to allow insertion of the cannula; otherwise, leakage of gas may occur around the sheath. For the primary puncture, an assistant should elevate the abdominal wall. For the secondary puncture, it is unnecessary to lift the abdominal wall during insertion. Both hands can be positioned on the device, using one to provide counterpressure and control to prevent "overshoot" and resultant injury to bowel or vessels. The angle of insertion is the same as for the insufflation needle; adjustments are made according to the patient's weight and body habitus. The laparoscope should be inserted to confirm proper intraperitoneal placement before the insufflation gas is allowed to flow. Laparoscope cannulas can become dislodged and slip out of the incision during a procedure. There are a variety of cannula attachments designed to prevent slippage.

Previous abdominal surgery increases the incidence of adhesions of the bowel to the anterior abdominal wall, frequently near the umbilicus and in the path of the primary trocar. In such patients, another primary insertion site should be selected, even if it is used solely for conveying a narrow "scout" laparoscope, some types of which can be inserted through an insufflation needle (Fig. 21.9). Using such a laparoscope, the presence of adhesions under the incision can be confirmed or excluded, and the umbilical cannula can be inserted under direct vision. Alternate insertion sites for primary cannulas are shown in Fig. 21.6. Of these locations, the left upper quadrant is the most useful because adhesions are rarely present. Nasogastric or orogastric suction must be applied preceding insertion to improve vision and reduce the risk for gastric injury.

Ancillary Cannulas

Ancillary cannulas are necessary to perform most diagnostic and operative laparoscopic procedures. Most of the currently available disposable ancillary cannulas are identical to those designed for insertion of the primary cannula. However, many of the integrated design features of the primary cannula are unnecessary for ancillary cannulas. Consequently, simple cannulas without safety sheaths and insufflation ports are sufficient (Fig. 21.8). Proper positioning of these cannulas depends on a sound knowledge of the abdominal wall vascular anatomy. They should always be inserted under direct vision because injury to bowel or major vessels can occur. Before insertion, the bladder should be drained with a urethral catheter. The insertion sites depend on the procedure, the disease, the patient's body habitus, and the surgeon's preference. The most useful and cosmetically acceptable site for an ancillary cannula is usually in the midline of the lower abdomen, about 2 to 4 cm above the symphysis. The ancillary cannula should not be inserted too close to the symphysis because it limits the mobility of the ancillary instruments and access to the cul-de-sac.

Lower-quadrant cannulas are useful for operative laparoscopy, but the inferior epigastric vessels must be located in order to avoid injury (Fig. 21.3). Transillumination of the abdominal wall from within permits the identification of the superficial inferior epigastric vessels in most thin women. However, the deep inferior epigastric vessels cannot be identified by this mechanism because of their location deep to the rectus sheath. The most consistent landmarks are the medial umbilical ligaments (obliterated umbilical arteries) and the exit point of the round ligament into the inguinal canal. At the pubic crest, the deep inferior epigastric vessels begin their cephalad course between the medially located umbilical ligament and the laterally positioned exit point of the round ligament. The trocar should be inserted medial or lateral to the vessels if they are visualized. If the vessels cannot be seen and it is necessary to position the cannula laterally, the cannula should be placed 3 to 4 cm lateral to the medial umbilical ligament or lateral to the lateral margin of the rectus abdominis muscle. If the insertion is placed too far laterally, it will endanger the deep circumflex epigastric artery. The risk for injury can be minimized by placing a 22-gauge spinal needle through the skin at the desired location, directly observing the entry through the laparoscope. This provides reassurance that a safe location has been identified and allows visualization of the peritoneal needle hole, which provides a precise target for inserting the trocar.

Even after a proper incision, the abdominal wall vessels can be injured if the trocar is directed medially. Large-diameter trocars are more likely to cause injury; therefore, the smallest cannulas necessary to perform the procedure should be used. Ancillary cannulas should not be placed too close together because this results in "knitting" of the hand instruments, which compromises access and maneuverability.

Visualization
During endoscopy, the image must be transferred through an optical system. Although direct optical viewing is feasible and often used for diagnostic purposes, virtually all operative laparoscopy is performed using video guidance.

### Operative versus Diagnostic Equipment

Laparoscopes used for operative purposes have a straight channel, parallel to the optical axis, for the introduction of operating instruments. An advantage of such an endoscope is that it provides an additional port for the insertion of instruments and the tangential application of laser energy. However, operative endoscopes are of relatively larger caliber than diagnostic laparoscopes and have smaller fields of view and increased electrosurgical risks. Diagnostic laparoscopes permit better visualization at a given diameter and are associated with fewer electrosurgical risks.

### Dimeter

Narrow-diameter laparoscopes allow limited transfer of light both into and out of the peritoneal cavity; therefore, they require a more sensitive camera or a more powerful light source for adequate illumination. Ideal illumination is provided by 10-mm diagnostic laparoscopes, but improvements in optics are making more procedures feasible with smaller-caliber devices (Fig. 21.10).

![Figure 21.10 Laparoscopes. Top to bottom: 5-mm diameter (Olympus, Inc., Woodbury, NY), 10-mm diameter (Karl Storz, Agoura Hills, CA), and 2-mm diameter (Imagyn, Inc., Laguna Niguel, CA) laparoscopes. The 2-mm laparoscope can be inserted by a very narrow cannula passed through an insufflation needle.](image-url)

### Lenses

Most laparoscope lenses are made of optical-quality glass. The use of fibers is necessary for very-small-caliber laparoscopes (<3 mm in diameter) because lens integrity is not well protected by the flexible sheath. Relatively large-caliber fibers tend to “pixelate” the image, although the use of densely packed, fine-caliber fibers reduces this tendency, and with an adequate number and quality of fibers, it is eliminated altogether.

### Viewing Angle

The viewing angle depicts the relationship of the visual field to the axis of the endoscope and is usually either zero or 30 degrees to the horizontal. The zero-degree scope is the standard for gynecologic surgery. However, the 30-degree angle provides some advantage in difficult situations such as the performance of retropubic urethropexy.

### Imaging Systems

#### Video Cameras

The video camera captures the image transmitted by the endoscope with one or three light-sensitive, charged-coupled device (CCD) chips located in the camera head and coupled with the endoscope. Generally, the camera is attached to the eyepiece of the laparoscope, but with newer instruments, the chip will be affixed to the end of the device (“chip-on-a-stick”), obviating the need for an optical channel. In either case, the image is transmitted to the body of the camera located outside the operative field, where it is processed and sent to a recording device or monitor.

The key functional features of a camera are its light sensitivity and its horizontal resolution. Light sensitivity is measured in lux (1 lux = 1 lumen/m²); lower minimum lux ratings reflect increased sensitivity of the chips in the camera. The most sensitive cameras are rated at 1 lux, but for adequate imaging, the rating should be no higher than 5 lux when used with a 10-mm laparoscope and a 250- to 300-watt light source. Horizontal resolution is measured in lines; the best single-chip and triple-chip resolutions are about 500 and 700 lines, respectively. The images with the highest resolution are provided by cameras that separate chrominance from luminance (sometimes referred to as Y/C or S-Video) or by those that separate the three components of color (RGB—red, green, blue). These cameras are to be distinguished from the lower-resolution composite signals that are provided with standard coaxial cable television. However, the additional cost of triple-chip technology at this time is justified only for the creation of teaching videos or still images for publication.

### Monitors

The resolution capability of the monitor should be at least equal to that provided by the camera. The best available monitors have the potential to display about 800 horizontal lines of resolution. This degree of resolution is not produced by S-Video or RGB systems; therefore, expensive Y/C- or RGB-capable cameras are unnecessary.

### Light Sources

The more light transmitted through the endoscope, the better the visualization. The best currently available output is achieved from 250 to 300 watts, usually using xenon or metal halide bulbs. Most camera systems are integrated with the light source to vary light output automatically, depending on the amount of exposure required.

### Light Cables

Light guides or cables transmit light from the source to the endoscope. They may be constructed of densely packed fibers (fiberoptic) or can be fluid filled. Fiberoptic cables lose function over time, particularly if they are bent at sharp angles, which breaks the fibers. Fluid-filled guides may initially supply more light but are less convenient than fiberoptic cables because they are heavier and less flexible.

### Camera–Endoscope Couplers

These instruments connect the video camera to the laparoscope. Couplers with a beam splitter allow direct visualization by the surgeon with simultaneous video monitoring for the assistants. By sending the image through two optical channels, however, the brightness of each is reduced. Couplers also vary in focal length, which affects both the amount of screen occupied by the circular image and the depth of field in focus. For example, a coupler with a wide-angled 28-degree lens will fill all of the screen but will have less depth of field in focus than the smaller image of a 32-degree lens.
Some laparoscopes attach directly to the camera, making a coupler unnecessary. This feature further enhances light transmission and reduces problems with fogging of the lens.

**Intraperitoneal Distention**

**Insufflation Machines**

The insufflator delivers CO$_2$ from a gas cylinder to the patient through tubing connected to one of the ports on the laparoscope. Most insufflators can be set to maintain a predetermined intraabdominal pressure. High flow rates (9 to 20 L/min) are especially useful for maintaining exposure when suction of smoke or fluid depletes the volume of intraperitoneal gas.

**Laparoscopic Lifting Systems**

Intraperitoneal retractors attached to a pneumatic or mechanical lifting system can be used to create an intraperitoneal space much like a tent. This “gasless” or “apneumic” technique may have some advantages over pneumoperitoneum, particularly in patients with cardiopulmonary disease. Also, airtight cannulas are not necessary, and instruments do not need to have a uniform, narrow, cylindrical shape. Consequently, some conventional instruments may be used directly through the incisions.

**Manipulation of Fluid and Tissue**

**Fluid Management**

Fluid may be instilled into the peritoneal cavity through wide-caliber arthroscopy or cystoscopy tubing using pressure provided by gravity, an infusion cuff, or a high-pressure mechanical pump. The pumps deliver fluid faster than the other techniques, and the highly pressurized stream of fluid may facilitate blunt dissection (hydro- or aqua-dissection). Removal of small volumes of fluid can be performed with a syringe attached to a cannula, but for large volumes, it is necessary to use suction generated by a machine or a wall source.

The cannulas used for suction and irrigation depend on the irrigation fluid used and the fluid being removed. For ruptured ectopic gestations or other procedures in which there is a large amount of blood and clots, large-diameter cannulas (7 to 10 mm) are preferred. Cannulas with narrow tips are more effective in generating the high pressure needed for hydrodissection.

If large volumes of fluid are required, isotonic fluids should be used to avoid fluid overload and electrolyte imbalance. If electrosurgery is to be performed, however, small volumes of a nonelectrolyte-containing solution such as glycine or sorbitol can be used for hemostasis and irrigation. Heparin (1,000 to 5,000 U/L) can be added to irrigating solution to prevent blood from clotting, thus allowing it to be removed more easily.

**Tissue Manipulation**

**Uterine Manipulators**

A properly designed uterine manipulator should have an intrauterine component, or obturator, and a method for fixation of the device to the uterus. A hollow obturator attached to a port allows intraoperative instillation of liquid dye to demonstrate tubal patency. Articulation of the probe permits acute anteversion or retroversion, both of which are extremely useful maneuvers. If the uterus is large, longer and wider obturators are used so that the manipulations can be performed more effectively. An articulated uterine manipulator is shown in Fig. 21.11.

**Grasping Forceps**

The forceps used during laparoscopy should replicate those used in open surgery. Disposable instruments generally do not have the quality, strength, and precision of nondisposable forceps. Instruments with teeth (toothed forceps) are necessary to grasp the peritoneum or the edge of ovary securely in order to remove an ovarian cyst. Minimally traumatic instruments designed like Babcock clamps are needed to retract the fallopian tube safely. Tenaculum-like instruments are desirable to retract leiomyomas or the uterus. A ratchet is useful to hold tissue in the absence of hand pressure. The instrument should be insulated and capable of transmitting unipolar or bipolar electrical energy for hemostasis.

**Cutting, Hemostasis, and Tissue Fixation**

Cutting can be achieved by mechanical means, electricity, laser energy, and ultrasonic energy (Fig. 21.12). The methods for maintaining or securing hemostasis include sutures, clips, linear staplers, energy sources, and topical or injectable substances (Fig. 21.13). Secure apposition or tissue fixation may be accomplished with sutures, clips, or staples. Because of the visual, tactile, and mechanical limitations of laparoscopy, prevention of bleeding is important.
Laparoscopic procedures can be complicated by infections, trauma, or hemorrhage, as well as by problems associated with anesthetic use. The incidence of infection place under direct laparoscopic vision to prevent the accidental incorporation of bowel into the incisions. A small-caliber laparoscope passed through one of the ancillary ports.

Dehiscence and hernia risk increase when the fascial incision is made by a trocar that is larger than 10 mm in diameter. This technique is useful for control of superficial bleeding.

Laser energy can be focused to vaporize and cut tissue. The most efficient cutting instrument is the CO₂ laser, which has the drawback of requiring linear transmission because light cannot be effectively conducted along bendable fibers. The potassium-titanyl-phosphate (KTP) and neodymium:yttrium-aluminum, garnet (Nd:YAG) lasers are also effective cutting tools. They are capable of propagating energy along bendable quartz fibers but result in slightly greater thermal injury than electrical or CO₂ laser energy. Because of such limitations and the additional expense, these lasers are of limited value.

A laparoscopic instrument has been developed that uses ultrasonic energy for cutting. The device consists of a vibrating pizo electrode located in a handle that causes linear oscillation of a probe tipped with a blade, hook, or clamp. The rapid oscillation (55 kHz) of the probe allows the tip to cut mechanically or create desiccation and hemostasis when cutting tissue that has small blood vessels.

Cutting

The most useful cutting instruments are scissors. Because it is difficult to sharpen laparoscopic scissors, most surgeons prefer disposable instruments that may be used until dull and then discarded. Another mechanical cutting tool is the linear stapler-cutter that can simultaneously cut and hemostatically staple the edges of the incision. The cost and large dimensions of the instruments limit their practical use to only a few highly selected situations, such as separation of the uterus from the ovary and fallopian tube during laparoscopic hysterectomy.

Electrosurgical electrodes that are narrow or pointed are capable of generating the high-power densities necessary to vaporize or cut tissue. Continuous or modulated, usually unipolar, sine-wave outputs are used. For optimal results, they should be used in a noncontact fashion, following (not leading) the energy. Specially designed bipolar cutting probes are available that have one integrated electrode shaped as a needle and the other band-shaped electrode designed to be dispersive. Laparoscopic scissors with unipolar or bipolar electrosurgical attachments are designed to cut mechanically with energy used simultaneously for desiccation and hemostasis when cutting tissue that has small blood vessels.

Electrocautery and Tissue Fixation

Electricity is the least expensive and most versatile method for achieving hemostasis during laparoscopy. The process of electrical desiccation (coagulation) is achieved by contacting the tissue, activating the electrode using continuous "cutting" current of adequate power to heat and coagulate the tissue. For large-caliber vessels, the tissue should be compressed before the electrode is activated, allowing the edges of the vessel to seal or coagulate. Either unipolar or bipolar grasping devices may be used. Fulguration is near-contact spraying of tissue with unipolar, high-voltage energy from the "coagulation" side of the electrosurgical generator. This technique is useful for control of superficial bleeding.

Clips may be placed with specially designed laparoscopic instruments. Nonabsorbable clips made of titanium are useful for relatively narrow vessels, and longer, self-retaining clips are generally preferred for larger vessels. Clips may be of particular value when securing relatively large vessels near an important structure such as the ureter.

Laparoscopic suturing has only recently become accepted as a method of maintaining hemostasis. The cost of materials is far less than that of clips or linear staplers, although operating time may be longer. The two basic methods for securing a ligature around a blood vessel are with intracorporeal and extracorporeal knots, depending on where the suture is tied. Intracorporeal knots are derived from the standard instrument knot and are formed within the peritoneal cavity. Extracorporeal knots are created outside the abdomen under direct vision and then transferred into the peritoneal cavity by knot manipulators.

Topical agents such as microfibrillar collagen are available in 5- and 10-mm diameter laparoscopic applicators. Local injection of diluted vasopressin may be used to maintain hemostasis for myomectomy or removal of ectopic pregnancy.

Removal of Tissue

After excising tissue, it is usually necessary to remove it from the peritoneal cavity. Small samples can be pulled through an appropriate-sized cannula with grasping forceps; however, larger specimens may not fit. If the specimen is cystic, it may be drained by a needle or incised, shrinking it to a size suitable for removal through the cannula or one of the small laparoscopic incisions. Because of the concern for malignancy, an alternative is to place the specimen in an endoscopic retrieval bag after drainage to prevent spillage. More solid tissue may be morcellated with scissors, ultrasonic equipment, or electrosurgery. Electrosurgical morcellation requires special bipolar needles or, if the monopolar technique is used, that the specimen remain attached to the patient to preserve the integrity of the electrical circuit.

Larger specimens may be removed by inserting a larger cannula through an incision in the cul-de-sac (posterior culdotomy) or by extending one of the laparoscopy incisions. With the exception of colotomy, extension of the umbilical incision may be the most cosmetic approach because removal of the tissue can be directed from an endoscope positioned in one of the ancillary ports.

Incision Management

Dehiscence and hernia risk increase when the fascial incision is made by a trocar that is larger than 10 mm in diameter. Closure of the fascia should take place under direct laparoscopic vision to prevent the accidental incorporation of bowel into the incisions. A small-caliber laparoscope passed through one of the narrow cannulas can be used to direct the fascial closure using curved needles or a ligature carrier especially designed for this purpose.

Complications

Laparoscopic procedures can be complicated by infections, trauma, or hemorrhage, as well as by problems associated with anesthetic use. The incidence of infection

At the end of the procedure, it is prudent to obtain a chest x-ray. The patient's condition should be managed expectantly unless a tension pneumothorax results, in

Hypercarbia, and cardiovascular collapse may result. The use of intraperitoneal CO\textsubscript{2} as a distention medium is associated with an increase in P\textsubscript{CO\textsubscript{2}} and a decrease in pH. Elevation of the diaphragm may be associated with basilar atelectasis, resulting in right-to-left shunt and a ventilation–perfusion mismatch (53).

Carbon Dioxide Embolus

Carbon dioxide is the most widely used peritoneal distention medium, largely because of the rapid absorption of CO\textsubscript{2} in blood. However, if large amounts of CO\textsubscript{2} gain access to the central venous circulation, if there is peripheral vasoconstriction, or if the splanchic blood flow is decreased by excessively high intraperitoneal pressure, severe cardiopulmonary compromise may result.

The signs of CO\textsubscript{2} embolus include sudden and otherwise unexplained hypotension, cardiac arrhythmia, cyanosis, and heart murmurs. The end-tidal CO\textsubscript{2} may increase, and findings consistent with pulmonary edema may occur. Accelerating pulmonary hypertension may occur, resulting in right-sided heart failure.

Because gas embolism may result from direct intravascular injection through an insufflation needle, the proper placement of the needle must be ensured. The intraperitoneal pressure should be maintained at less than 20 mm Hg and, except for the initial placement of trocars, at 8 to 12 mm Hg. The risk for CO\textsubscript{2} embolus is also reduced by careful hemostasis because open venous channels are the portal of entry for gas into the systemic circulation. The anesthesiologist should continuously monitor the patient's color, blood pressure, heart sounds, heartbeat, and end-tidal CO\textsubscript{2} to allow early recognition of the signs of CO\textsubscript{2} embolus.

If CO\textsubscript{2} embolus is suspected or diagnosed, the surgeon must evacuate the CO\textsubscript{2} from the peritoneal cavity and place the patient in the left lateral decubitus position, with the head below the level of the right atrium. A large-bore central venous line should be inserted immediately to allow aspiration of gas from the heart. Because the findings are nonspecific, other causes of cardiovascular collapse should be excluded.

Cardiovascular Complications

Cardiac arrhythmias occur relatively frequently during laparoscopic surgery and are related to a number of factors, the most significant of which are hypercarbia and acidemia. Early reports of laparoscopy-associated arrhythmia were associated with spontaneous respiration; therefore, most anesthesiologists have adopted the practice of mechanical ventilation during laparoscopic surgery. The incidence of hypercarbia is reduced by operating with intraperitoneal pressures less than 12 mm Hg (54).

The risk for cardiac arrhythmia also may be reduced by using NO\textsubscript{2} as a distending medium. However, although NO\textsubscript{2} is associated with a decreased incidence of arrhythmia, it is insoluble in blood. External lifting systems avoid the complication of hypercarbia and can also provide protection against cardiac arrhythmia.

Hypotension can occur because of decreased venous return secondary to very high intraperitoneal pressure, and this condition may be potentiated by volume depletion. Vagal discharge may occur in response to increased intraperitoneal pressure, which can cause hypotension secondary to cardiac arrhythmias (55). All of these side effects are more dangerous for patients with preexisting cardiovascular disease.

Gastric Reflux

Gastric regurgitation and aspiration can occur during laparoscopic surgery, especially in patients with obesity, gastroparesis, hiatal hernia, or gastric outlet obstruction. In these patients, the airway must be maintained with a cuffed endotracheal tube, and the stomach must be decompressed (e.g., with a nasogastric tube). The lowest necessary intraperitoneal pressure should be used to minimize the risk for aspiration. Patients should be moved out of the Trendelenburg position before being extubated. Routine preoperative administration of metoclopramide, H\textsubscript{2}-blocking agents, and nonparticulate antacids also reduces the risk.

Extrapertoneal Insufflation

The most common causes of extraperitoneal insufflation are preperitoneal placement of the insufflating needle and leakage of CO\textsubscript{2} around the cannula sites. Although this condition is usually mild and limited to the abdominal wall, subcutaneous emphysema may become extensive, involving the externalities, the neck, and the mediastinum. Another relatively common site for emphysema is the omentum or mesentery, a circumstance that may be mistaken for preperitoneal insufflation.

Subcutaneous emphysema may be identified by the palpation of crepitus, usually in the abdominal wall. Emphysema can extend along contiguous fascial plains to the neck, where it can be visualized directly. Such a finding may reflect mediastinal emphysema, which may indicate impending cardiovascular collapse (55,57 and 58).

The risk for subcutaneous emphysema is reduced by the proper positioning of the insufflation needle and by maintaining a low intraperitoneal pressure after placement of the desired cannulas. Other approaches that reduce the chance of subcutaneous emphysema include open laparoscopy and the use of abdominal wall lifting systems that make gas unnecessary.

If the insufflation has occurred extraperitoneally, the laparoscope can be removed, and the procedure can be repeated. However, difficulty may ensue because of the altered anterior peritoneum. Open laparoscopy or the use of an alternate site, such as the left upper quadrant, should be considered. One approach is to leave the laparoscope in the expanded preperitoneal space while the insufflation needle is reinserted under direct vision through the peritoneal membrane caudad to the tip of the laparoscope (59).

In mild cases of subcutaneous emphysema, the findings quickly resolve after evacuation of the pneumoperitoneum, and no specific intraoperative or postoperative therapy is required. When the extravasation extends to the neck, it is usually preferable to terminate the procedure because pneumomediastinum, pneumothorax, hypercarbia, and cardiovascular collapse may result.

At the end of the procedure, it is prudent to obtain a chest x-ray. The patient's condition should be managed expectantly unless a tension pneumothorax results, in which case immediate evacuation must be performed using a chest tube or a wide-bore needle (14 to 16 gauge) inserted in the second intercostal space in the midclavicular line.

Anesthetic and Cardiopulmonary Complications

One third of the deaths associated with minor laparoscopic procedures such as sterilization are secondary to complications of anesthesia (52). The potential complications of general anesthesia include hypoventilation, esophageal intubation, gastroesophageal reflux, bronchospasm, hypotension, narcotic overdose, cardiac arrhythmias, and cardiac arrest. These risks can be enhanced by some of the inherent features of gynecologic laparoscopy. For example, the Trendelenburg position, in combination with the increased intraperitoneal pressure provided by pneumoperitoneum, places greater pressure on the diaphragm, increasing the risk for hyperventilation, hypercarbia, and metabolic acidosis. This position, combined with anesthetic agents that relax the esophageal sphincter, promotes regurgitation of gastric content, which in turn can lead to aspiration, bronchospasm, pneumonitis, and pneumonia.

Parameters of cardiopulmonary function associated with both CO\textsubscript{2} and N\textsubscript{2}O insufflation include reduced P\textsubscript{O\textsubscript{2}, O\textsubscript{2} saturation, tidal volume, and minute ventilation and increased respiratory rate. The use of intraperitoneal CO\textsubscript{2} as a distention medium is associated with an increase in P\textsubscript{CO\textsubscript{2}} and a decrease in pH. Elevation of the diaphragm may be associated with basilar atelectasis, resulting in right-to-left shunt and a ventilation–perfusion mismatch (53).

Extrapertoneal Insufflation

The most common causes of extraperitoneal insufflation are preperitoneal placement of the insufflating needle and leakage of CO\textsubscript{2} around the cannula sites. Although this condition is usually mild and limited to the abdominal wall, subcutaneous emphysema may become extensive, involving the externalities, the neck, and the mediastinum. Another relatively common site for emphysema is the omentum or mesentery, a circumstance that may be mistaken for preperitoneal insufflation.

Subcutaneous emphysema may be identified by the palpation of crepitus, usually in the abdominal wall. Emphysema can extend along contiguous fascial plains to the neck, where it can be visualized directly. Such a finding may reflect mediastinal emphysema, which may indicate impending cardiovascular collapse (55,57 and 58).

The risk for subcutaneous emphysema is reduced by the proper positioning of the insufflation needle and by maintaining a low intraperitoneal pressure after placement of the desired cannulas. Other approaches that reduce the chance of subcutaneous emphysema include open laparoscopy and the use of abdominal wall lifting systems that make gas unnecessary.

If the insufflation has occurred extraperitoneally, the laparoscope can be removed, and the procedure can be repeated. However, difficulty may ensue because of the altered anterior peritoneum. Open laparoscopy or the use of an alternate site, such as the left upper quadrant, should be considered. One approach is to leave the laparoscope in the expanded preperitoneal space while the insufflation needle is reinserted under direct vision through the peritoneal membrane caudad to the tip of the laparoscope (59).

In mild cases of subcutaneous emphysema, the findings quickly resolve after evacuation of the pneumoperitoneum, and no specific intraoperative or postoperative therapy is required. When the extravasation extends to the neck, it is usually preferable to terminate the procedure because pneumomediastinum, pneumothorax, hypercarbia, and cardiovascular collapse may result.

At the end of the procedure, it is prudent to obtain a chest x-ray. The patient's condition should be managed expectantly unless a tension pneumothorax results, in which case immediate evacuation must be performed using a chest tube or a wide-bore needle (14 to 16 gauge) inserted in the second intercostal space in the midclavicular line.

Electrosurgical Complications
Complications of electrosurgery occur secondary to thermal injury from unintended or inappropriate use of the active electrode, current diversion to an undesirable path, and injury at the site of the dispersive electrode. Active electrode injury can occur with either unipolar or bipolar instruments, whereas trauma secondary to current diversion or dispersive electrode accidents occurs only with unipolar technique. Complications of electrosurgery are reduced by adherence to safety protocols coupled with a sound understanding of the principles of electrosurgery and the circumstances that can lead to injury (16).

Active Electrode Trauma

If the foot pedal is accidentally depressed, tissue adjacent to the electrode will be traumatized. Commonly, the bowel or ureter is involved, or, if the electrode lies on the abdomen, the skin is burned. Direct extension injuries occur when the zone of vaporization or coagulation extends to large blood vessels or vital structures such as the bladder, ureter, or bowel. Bipolar technique may reduce but does not eliminate the risk for thermal injury to adjacent tissue (60). Therefore, blood vessels should be isolated before desiccation, especially when they are near vital structures, and appropriate amounts of energy must be applied to allow an adequate margin of noninjured tissue.

The diagnosis of direct thermal visceral injury may be difficult. If unintended activation of the electrode occurs, nearby intraperitoneal structures should be evaluated carefully. The appearance can be affected by several factors, including the output of the generator, the type of electrode, its proximity to tissue, and the duration of its activation. The diagnosis of visceral thermal injury is often delayed until signs and symptoms of fistula or peritonitis appear. Because these complications may not manifest until 2 to 10 days after surgery, patients should be advised to report any postoperative fever or increasing abdominal pain.

Unintended activation injuries can be prevented if the surgeon is always in direct control of electrode activation and if all electrosurgical hand instruments are removed from the peritoneal cavity when not in use. When removed from the peritoneal cavity, the instruments should be detached from the electrosurgical generator, or they should be stored in an insulated pouch near the operative field. These measures prevent damage to the patient's skin if the electrode is accidentally activated.

Thermal injury to the bowel, bladder, or ureter that is recognized at the time of laparoscopy should be managed immediately with laparotomy, taking into consideration the potential extent of the zone of coagulative necrosis (61). Incisions made with the focused energy from a pointed electrode are associated with a minimal amount of surrounding thermal injury. Prolonged or even transient contact with a relatively large-caliber electrode may produce thermal necrosis that extends several centimeters. In such cases, wide excision or resection will be necessary.

Current Diversion

Current diversion can occur when electrons find a direct path out of the patient's body through grounded sites other than the dispersive electrode. Alternatively, the current can be diverted directly to other tissues before it reaches the tip of the active electrode. In either case, if the power density becomes high enough, unintended and severe thermal injury can result.

Alternate Ground Site Burns

These injuries can occur only with ground-referenced electrosurgical generators (ESUs) because they lack an isolated circuit. In such generators, when the dispersive electrode becomes detached, unplugged, or otherwise ineffective, the current seeks any grounded conductor. If the conductor has a small surface area, the current or power density may become high enough to cause thermal injury (Fig. 21.14). Examples include electrocardiograph patch electrodes or the conductive metal components of the operating table. Modern ESUs are designed with isolated circuits and impedance monitoring systems that shut down the machine if dispersive electrode detachment occurs. Because ground-referenced machines without such safeguards are still in use, it is important to know the type of ESU used in the operating room.

Insulation Defects

If the insulation coating the shaft of an electrosurgical electrode becomes defective, it can allow current diversion to adjacent tissue, often bowel, potentially resulting in significant injury (Fig 21.15A). Therefore, the instruments should be examined before each procedure to detect worn or obviously defective insulation. When applying unipolar electrical energy, the shaft of the instrument should be kept away from vital structures and, if possible, totally visible in the operative field.

Figure 21.14 Risk of ground-referenced generators. Current diversion along alternate pathways is a risk associated with ground referenced electrosurgical generators, particularly if the dispersive electrode is detached. In the example depicted, the relatively high current density at the electrocardiogram electrode site may result in a skin burn.

Figure 21.15 series Direct coupling. Direct coupling is a potential complication of monopolar electrosurgery and may occur secondary to defects in the insulation (A) or, classically, to contract with a conductive instrument that in turn touches other intraperitoneal structures. In the example depicted (B), the active electrode is touching the laparoscope, and current is transferred to bowel through a small enough contact point that thermal injury results. Another common target of such coupling is to noninsulated hand instruments.
Direct Coupling

Direct coupling occurs when an activated electrode touches and energizes another metal conductor such as a laparoscope, cannula, or other instrument, especially one that is not insulated. If the conductor is near or in contact with other tissue, a thermal injury can result (Fig. 21.16). Direct coupling can be prevented by removing the electrode when it is not in use and by visually confirming that there is no contact with other conductive instruments before activation.

Capacitive Coupling

Capacitance is the ability of a conductor to establish an electrical current in an unconnected but nearby circuit. An electrical field is established around the shaft of any activated laparoscopic unipolar electrode, a circumstance that makes the electrode a capacitor. This field is harmless if the circuit is completed through a dispersive, low-power density pathway (Fig. 21.16). For example, if capacitive coupling occurs between the laparoscopic electrode and a metal cannula positioned in the abdominal wall, the current harmlessly "returns" to the abdominal wall, where it traverses to the dispersive electrode (Fig. 21.16A). However, if the metal cannula is anchored to the skin by a nonconductive plastic retaining sleeve or anchor (a hybrid system), the current will not return to the abdominal wall because the sleeve acts as an insulator (Fig. 21.16B). Instead, the capacitor will have to "look" elsewhere to complete the circuit. Therefore, bowel or any other nearby conductor can become the target of a relatively high-power density discharge (Fig. 21.16C). This mechanism can also occur when a unipolar electrode is inserted through an operating laparoscope that, in turn, is passed through a nonconductive plastic laparoscopic cannula. In this configuration, the plastic port acts as the insulator. If the electrode capacitively couples with the metal laparoscope, nearby bowel will be at risk for significant thermal injury (61,62).

Dispersive Electrode Burns

The use of isolated-circuit electrosurgical generators with return electrode monitors has virtually eliminated dispersive electrode–related thermal injury. Return electrode monitoring is actually accomplished by measuring the impedance in the dispersive electrode (patient pad), which should always be low because of the large surface area. Without such devices, partial detachment of the "patient pad" could result in a thermal injury because reducing the surface area of the electrode raises the current density (Fig. 21.17).

Hemorrhagic Complications

Great Vessel Injury

The most dangerous hemorrhagic complications are injuries to the great vessels, including the aorta and the vena cava, the common iliac vessels and their branches, and the internal and external iliac arteries and veins. The injuries most often occur secondary to insertion of an insufflation needle but may be created by the tip of the primary or ancillary trocars. The vessels most frequently damaged are the aorta and the right common iliac artery as it branches from the aorta in the midline. The anatomically more posterior location of the vena cava and the iliac veins provides relative protection, but not immunity, from injury (63). Although most of these injuries are small and amenable to repair with suture, some are larger and require ligation with or without the insertion of a vascular graft. Deaths have been reported.

After vascular injury, patients usually develop profound hypotension with or without hemoperitoneum. In some instances, blood is aspirated through the insufflation needle before the introduction of the distending gas. Frequently, the bleeding may be contained in the retropertitoneal space, which usually delays the diagnosis; consequently, hypovolemic shock may develop. To avoid late recognition, the course of each great vessel must be identified before completing the procedure.

If blood is withdrawn from the insufflation needle, it should be left in place while immediate preparations are made to obtain blood products and perform laparotomy. If hemoperitoneum is diagnosed upon initial visualization of the peritoneal cavity, a grasping instrument may be used, if possible, to occlude the vessel temporarily. Upon entry into the peritoneal cavity, the aorta and vena cava should immediately be compressed just below the level of the renal vessels to gain at least temporary control of blood loss. The most appropriate course of action depends on the site and extent of injury.

Abdominal Wall Vessel Injury

The abdominal wall vessels most commonly injured during laparoscopy are the superficial inferior epigastric vessels as they branch from the femoral artery and vein and course cephalad in each lower quadrant. They are invariably damaged by the initial passage of an ancillary trocar or by the introduction of a wider device later in
the procedure. The problem may be recognized immediately by the observation of blood dripping along the cannula or out through the incision. However, the bleeding may be obstructed by the cannula until it is withdrawn at the end of the operation.

The more serious injuries are those to the deep inferior epigastric vessels, which are branches of the external iliac artery and vein that course cephalad but are deep to the rectus fascia and often deep to the muscles (Fig. 21.3). More laterally located are the deep circumflex iliac vessels, which are not often encountered in laparoscopic surgery. Laceration of these vessels may cause profound blood loss, particularly when the trauma is unrecognized and causes extraperitoneal bleeding.

Signs of injury, in addition to blood dripping down the cannula, include the postoperative appearance of shock and abdominal wall discolorization or hematoma located near the incision. In some instances, the blood may track to a more distant site, presenting as a pararectal or vulvar mass. Delayed diagnosis may be prevented by laparoscopic evaluation of each peritoneal incision after removal of the cannula.

Superficial inferior epigastric vessel trauma usually stops spontaneously; therefore, expectant management is appropriate. A straight ligature can be used to repair lacerated deep inferior epigastric vessels. If a postoperative hematoma develops, local compression should be used initially. Open removal or aspiration of the hematoma should not be undertaken because it may inhibit the tamponade effect and increase the risk for abscess. However, if the mass continues to enlarge or if signs of hypovolemia develop, the wound must be explored.

Intraperitoneal Vessel Injury

Hemorrhage may result from inadvertent entry into a vessel or failure of a specific occlusive technique. In addition to delayed hemorrhage, there may be a further delay in diagnosis at laparoscopy as a result of the restricted visual field and the temporary occlusive pressure exerted by CO₂ in the peritoneal cavity.

Inadvertent division of an artery or vein is usually evident immediately. Transected arteries may go into spasm and bleed minutes to hours later, going unnoticed temporarily because of the limited visual field of the laparoscope. Therefore, at the end of the procedure, all areas of dissection must be carefully examined. CO₂ should be vented, which decreases the intraperitoneal pressure so that blood vessels temporarily occluded by higher pressure can be recognized.

Gastrointestinal Complications

The stomach, the small bowel, and the colon can be injured during laparoscopy. Mechanical entry into the large or small bowel can occur 10 times more often when laparoscopy is performed in patients who have had prior intraperitoneal inflammation or abdominal surgery. Loops of intestine can adhere to the abdominal wall under the insertion site and be injured (64, 65, and 66).

Insufflation Needle Injuries

Needle entry into the gastrointestinal tract may be more common than reported because it often occurs unnoticed and without further complication. Gastric entry may be identified by the increased filling pressure, asymmetric distention of the peritoneal cavity, or aspiration of gastric particulate matter through the lumen of the needle. Initially, the hollow, capacious stomach may allow the insufflation pressure to remain normal. Signs of bowel entry are the same as those for gastric injury, with the addition of feculent odor.

If particulate debris is identified, the needle should be left in place, and an alternate insertion site should be identified, such as the left upper quadrant. Immediately after successful entry into the peritoneal cavity, the site of injury is identified. Defects must be repaired immediately.

Trocars Injuries

Damage caused by a sharp trocar is usually more serious than needle injury. Inadvertent gastric entry usually results from stomach distention because of aerophagia, difficult or improper intubation, or mask induction with inhalation anesthetic. Most often, the injury is created by the primary trocar, although ancillary cannulas may also result in visceral injury.

The risk for gastric perforation can be minimized with the selective use of preoperative nasogastric or oral gastric suction when left upper-quadrant entries are used or when the intubation was difficult. Open laparoscopy can reduce but not eliminate the risk for gastrointestinal complications. For high-risk patients, left upper quadrant needle insertion with a properly decompressed stomach may be preferable (67, 68, and 69).

If the trocar of a primary cannula penetrates the bowel, the condition is usually diagnosed when the mucosal lining of the gastrointestinal tract is visualized. If the large bowel is entered, a feculent odor may be noted. However, the injury may not be immediately recognized because the cannula may not stay within the bowel or may pass through the lumen. Such injuries usually occur when a single loop of bowel is adherent to the anterior abdominal wall. The injury may not be recognized until peritonitis, abscess, enterocutaneous fistula, or death occurs (70, 71). Therefore, at the end of the procedure, the removal of the primary cannula must be viewed either through the cannula or an ancillary port, a process facilitated by routine direct visualization of closure of the incision of the primary port.

Trocars injuries to the stomach and bowel require repair as soon as they are recognized. If the injury is small, a trained operator can repair the defect by laparoscopy using a double layer of running 2-0 or 3-0 absorbable suture. Extensive lesions may require resection and reanastomosis, which in most instances requires laparotomy. The preoperative use of mechanical bowel preparation in selected high-risk cases minimizes the need for laparotomy or colostomy.

Dissection and Thermal Injury

It is often easier to recognize intestinal injury that occurs during dissection than thermal injury to the bowel, particularly if the latter was created with electrical or laser energy. Even if thermal injury is recognized, it is difficult to estimate by visual inspection the extent of the damage because the zone of desiccation may exceed the area of visual damage. In some patients, the diagnosis is delayed until the development of peritonitis and fever, usually a few days later but occasionally not for several weeks (72). When mechanical bowel trauma is recognized during the dissection, treatment is the same as that described for trocar injury. If the diagnosis is delayed until the postoperative recognition of peritonitis, laparotomy must be performed immediately.

Thermal injury may be handled expectantly if the lesion seems superficial and confined. In a study of 33 women with such injuries who were managed expectantly in the hospital, only 2 required laparotomy for perforation (72).

Urologic Injury

Laparoscopy-associated damage to the bladder or ureter may occur secondary to mechanical or thermal trauma. Ideally, such injury should be prevented; otherwise, it is essential that the lesion be identified intraoperatively.

Bladder Injury

Bladder injury can occur from a trocar perforation of the undrained bladder but may also occur while dissecting the bladder from adherent structures or from the anterior uterus (73, 74). The injury may be readily apparent by direct visualization. If an indwelling catheter is in place, hematuria or pneumaturia (CO₂ in the catheter drainage system) may be noticed. A bladder laceration can be confirmed by injecting sterile milk or a diluted methylene blue solution through a transurethral catheter. Thermal injury to the bladder, however, may not be initially apparent and, if missed, can present as peritonitis or a fistula.

Routine preoperative bladder drainage usually prevents trocar-related cystotomies. Separation of the bladder from the uterus or other adherent structures requires good visualization, appropriate retraction, and excellent surgical technique. Sharp mechanical dissection is preferred, particularly when relatively dense adhesions are present.

Very-small-caliber injuries to the bladder (1 to 2 cm) may be treated with bladder catheterization for 5 to 7 days. If repair is undertaken immediately, catheterization is
unnecessary. When a larger injury is identified, it can be repaired laparoscopically (73,74 and 75). However, if the laceration is near the trigone or involves the trigone, an open procedure should be used. The mechanism of injury should be taken into consideration in making this evaluation because electrical injuries often extend beyond the visible limits of the apparent defect.

For small lesions, closure may be performed with layers of absorbable 2-0 to 3-0 sutures. If there is thermal injury, the coagulated portion should be excised. Postoperative catheterization with either a transurethral or suprapubic catheter should be maintained for 2 to 5 days for small fundal lacerations and for 10 to 14 days for injuries to the trigone. Cystography should be performed before removal of the urinary catheter.

**Ureteral Injury**

The most common cause of ureteral injury during laparoscopy is electrosurgical trauma (76,77). However, ureteral injury can occur after mechanical dissection and the use of linear cutting and stapling devices (78,79 and 80). Although intraoperative recognition of ureteral injury is possible, the diagnosis is usually delayed (76).

Ureteral lacerations may be confirmed intraoperatively visually or with the intravenous injection of indigo carmine. Thermal injury presents up to 14 days after surgery with fever, abdominal or flank pain, and peritonitis. Leukocytosis may be present, and intravenous pyelography shows extravasation of urine or a urinoma. Mechanical obstruction from staples or a suture can be recognized intraoperatively only by direct visualization. Ureteral obstruction presents a few days to 1 week after surgery with flank pain and often fever (80).

Abdominal ultrasound may be helpful, but intravenous pyelography can more precisely identify the site and degree of the obstruction.

Discharge or continuous incontinence is a delayed sign of ureterovaginal or vesicovaginal fistulas. A bladder fistula can be confirmed by detecting dye on a tampon previously placed in the vagina after filling the bladder with methylene blue. With a ureterovaginal fistula, the methylene blue will not pass into the vagina, but it can be detected with the intravenous injection of indigo carmine.

Knowledge of the course of the ureter through the pelvis is a prerequisite to reducing the risk for injury. The ureter can usually be seen through the peritoneum of the pelvic sidewall between the pelvic brim and the attachment of the broad ligament. However, because of variation from one patient to another or the presence of disease, the location of the ureter can become obscured, making it necessary to enter the retroperitoneal space. The techniques used for retroperitoneal dissection are also important factors in reducing the risk for ureteric injury. Blunt and sharp dissection with scissors is preferred, although hydrodissection can be used (81). The selective placement of ureteral stents may also be helpful.

Ureteral injury can be treated immediately if it is diagnosed intraoperatively. Although very limited damage may heal over a ureteral stent left in place for 10 to 21 days, repair is indicated in most patients. Although laparoscopic repair of ureteric lacerations and transections has been performed, most injuries require laparotomy (76,82).

When the diagnosis of ureteral injury is delayed, the bladder should be drained with a catheter. Incomplete or small obstructions or lacerations may be treated successfully with either a retrograde or anterograde ureteral stent. Urinomas may be drained percutaneously. If a stent cannot be placed successfully, a percutaneous nephrostomy should be performed before operative repair is undertaken.

**Neurologic Injury**

Peripheral nerve injury is usually related either to poor positioning of the patient or to excessive pressure exerted by the surgeons. Nerve injury may also occur as a result of the surgical dissection.

In the extremities, the trauma may be direct, such as when the common peroneal nerve is compressed against the stirrups. The femoral nerve or the sciatic nerve or its branches may be overstretched and damaged by inappropriate positioning of the hip or the knee joint (83,84). Brachial plexus injuries may occur secondary to the surgeon or assistants leaning against the abducted arm during the procedure. If the patient is placed in a steep Trendelenburg position, the brachial plexus may be damaged because of the pressure exerted on the shoulder joint (85). In most cases, sensory or motor deficits are found as the patient emerges from anesthesia. The likelihood of brachial plexus injury can be reduced with adequate padding and support of the arms and shoulders or by placing the patient's arms in an adducted position.

Most injuries to peripheral nerves resolve spontaneously. The time to recovery depends on the site and severity of the lesion. For most peripheral injuries, full sensory nerve recovery occurs in 3 to 6 months. Recovery may be facilitated by physical therapy, appropriate braces, and electrical stimulation of the affected muscles. Open microsurgery should be performed for transection of major intraperiosteal nerves.

**Incisional Hernia and Wound Dehiscence**

Incisional hernia after laparoscopy has been reported in more than 900 cases (51). Although no incision is immune to the risk, defects that are larger than 10 mm in diameter are particularly vulnerable (86,87). In most cases, these defects can be prevented by proper technique and closure of large defects. All ancillary cannulas should be removed under direct vision to ensure that bowel is not drawn into the incision. For incisions larger than 10 mm in diameter, the fascia should be closed while viewing the defect with the laparoscope to minimize the risk for intestinal injury. A small-diameter laparoscope should be used through a narrow cannula to facilitate incisional closure.

The most common defect is when intestinal hernia develops in the immediate postoperative period. The hernia may be asymptomatic or, within the first postoperative week, may cause pain, fever, periumbilical mass, obvious eversion, and the symptoms and signs of mechanical bowel obstruction.

Because Richter's hernias contain only a portion of the intestine in the defect, the diagnosis is often delayed. Hernias most often occur in incisions lateral to the midline. The initial symptom is usually pain because the incomplete obstruction still allows the passage of intestinal contents. Fever can be present if incarceration occurs, and peritonitis may result from subsequent perforation. The condition is difficult to diagnose, requires a high index of suspicion, and may be confirmed with an ultrasound or a CT scan (88).

The management of laparoscopic incisional defects depends on the time of presentation and the presence and condition of entrapped bowel. Evisceration always requires surgical intervention. If the condition is diagnosed immediately, the intestine is replaced into the peritoneal cavity (if there is no evidence of necrosis or intestinal defect), and the incision is repaired, usually with laparoscopic guidance. If the diagnosis is delayed or the bowel is incarcerated or at risk for perforation, laparotomy is necessary to repair or resect the intestine.

**Infection**

Wound infections after laparoscopy are uncommon; most are minor skin infections that can be treated successfully with expectant management, drainage, or antibiotics (89). Severe necrotizing fasciitis can occur rarely (90). Bladder infection, pelvic cellulitis, and pelvic abscess have been reported (91).

The risk for infection associated with laparoscopy is much lower than that for infection associated with open abdominal or vaginal surgery. Prophylactic antibiotics should be offered to selected patients (e.g., those with enhanced risk for bacterial endocarditis and those for whom hysterectomy is planned). Patients should be instructed to monitor their body temperature after discharge and to report immediately a temperature higher than 38°C.

**Hysteroscopy**

The hysteroscopic lysis of intrauterine adhesions was first described in 1973 (92). The technique of endoscopically guided electrosurgical resection was adapted from urology to gynecology for the removal of uterine leiomyomas (93). Hysteroscopic division of uterine septa was developed using a technique in which scissors are passed along the outside of the endoscope (93). Hysteroscopic destruction of the endometrium has been reported using Nd:YAG laser vaporization, electrosurgical
resection, and electrosurgical coagulation (95,96 and 97).

The use of diagnostic and operative hysteroscopy has been limited by the difficulties in obtaining a consistently acceptable image (as a result of inadequate distention, bleeding) and the perception that its therapeutic potential is low. Although hysteroscopic technology and techniques are still being developed, the current quality of the images is excellent because smaller-diameter endoscopes have been made possible by improvements in fiber technology. The concomitant use of ultrasound imaging can provide a view of the myometrial wall during resectoscopic procedures.

Because diagnostic hysteroscopy can be performed in an office or clinic setting without anesthetic, its widespread use has been advocated to investigate abnormal uterine bleeding. Hysteroscopic surgical procedures include removal of polypye, excision of leiomyomas, endometrial ablation, and division of adhesions and uterine septa. Some of these procedures are well established; others, although promising, require more clinical investigation. Hysteroscopy has been suggested as a method to replace blind sampling of the uterine cavity because it may provide better results at a lower cost (98,99).

### Diagnostic Hysteroscopy

Diagnostic hysteroscopy can provide information that cannot be obtained by blind endometrial sampling (98,99,100,101,102,103 and 104). In most cases, the additional findings visible with hysteroscopy are endometrial polyps or submucous leiomyomas (101,102,104,105). Malignant or hyperplastic processes can be identified with hysteroscopy and directed biopsy (103). Hysteroscopic examination is probably superior to hysteroscopy in the evaluation of the endometrial cavity (106-107). However, in some situations (e.g., endometritis, hyperplasia), curettage provides information not otherwise available by hysteroscopic evaluation, even when it is combined with directed biopsy (101,102,104,108). The principal advantage of diagnostic hysteroscopy is that structural anomalies (congenital or acquired) are more easily detected and defined. Potential indications for diagnostic hysteroscopy are as follows.

1. Unexplained abnormal uterine bleeding
   - Premenopausal
   - Postmenopausal
2. Selected infertility cases
   - Abnormal hysteroscopy
   - Unexplained infertility
3. Recurrent spontaneous abortion

In most patients, diagnostic hysteroscopy can be performed in an office or clinic with minimal discomfort and at a much lower cost than in an operating room. For some patients, concerns about patient comfort or a preexisting medical condition may preclude office hysteroscopy.

Although hysteroscopy can, in many patients, provide more information than blind curettage, it should still be used prudently. For most patients, other investigative or therapeutic measures can be undertaken before, or instead of, diagnostic hysteroscopy. For women with perimenopausal and postmenopausal bleeding, office endometrial biopsy or curettage should be performed before diagnostic hysteroscopy. If a satisfactory diagnosis cannot be established, or if bleeding continues without explanation, office hysteroscopy and directed biopsy or repeat curettage is appropriate. For women in their reproductive years, medical or expectant management may be used initially, depending on the severity and inconvenience of the bleeding. For those who do not respond to medical regimens such as oral contraceptives, office hysteroscopy with biopsy or curettage can be performed for diagnosis (109).

For women with infertility, hysterosalpingography is the best initial imaging step because it provides information about the patency of the oviducts. In the presence of a suspicious or identified abnormality in the endometrial cavity, hysteroscopy can be performed to confirm the diagnoses, to define the abnormality, and perhaps to direct the removal of the lesion. Some consider hysteroscopy mandatory for these patients because of the high occurrence of false-negative radiologic images in those with intrauterine anomalies. However, there has been no evidence that identification and treatment of these "missed" anomalies improves pregnancy rates. Confirmation of patency of the oviduct is unnecessary in women who have recurrent abortions; therefore, these patients can be evaluated primarily with hysteroscopy.

### Operative Hysteroscopy

Adhesiolysis, division of a uterine septum, resection of myomas, and endometrial destruction through resection, electrosurgical desication, or vaporization with the Nd:YAG laser can be performed hysteroscopically. Hysteroscopy may also be used to remove foreign bodies or to position instruments in the fallopian tube.

### Foreign Body

If the string of an intrauterine device is absent, the device usually can be removed with a specially designed hook or a toothed curette (e.g., Novak). When removal is difficult or impossible, the location of the device may be confirmed by hysteroscopy, allowing removal with a grasping forceps.

### Septum

When a single uterus with a divided cavity is present, hysteroscopic division of uterine septa improves reproductive outcome at a rate comparable to abdominal metroplasty, with reduced morbidity and cost (110,111,112 and 113). The procedure may be performed mechanically with scissors or with energy-based techniques such as the Nd:YAG laser or an electro surgical knife or loop. Because most septa have few vessels, scissors can be used easily, and the minimal risk for thermal damage is avoided.

### Endometrial Polyps

Although endometrial polyps can be removed with blind curettage, many are missed (101,102,104,105). Therefore, known or suspected endometrial polyps are more successfully treated with hysteroscopic guidance, which can often be performed in a clinic or office using local anesthesia. Hysteroscopy may be used either to evaluate the result of blind curettage, or preferably, to guide a grasping forceps. Alternatively, for larger polyps, a uterine resectoscope may be used to sever the stalk or morcellate the lesion.

### Leiomyomas

Hysteroscopy may be used to remove intracavitary leiomyomas in women with menorrhagia or infertility (114,115,116,117,118,119,120 and 121). However, this approach is limited by the location and size of the leiomyomas. In some patients, excision is relatively easy, whereas in others, laparotomy is necessary.

Pediculated leiomyomas may be removed by transecting the stalk with scissors or a resectoscope. For larger lesions, electrosurgical morcellation or a resectoscope may be necessary before removal. In some patients, hysteroscopy can be used to direct the attachment of a tenaculum so that the lesion can be twisted off. Although preferable, it is not absolutely necessary to remove the leiomyoma because it will be expelled spontaneously.

Selected submucous leiomyomas that extend into the uterine wall may be resected using a loop electrode. The extent of intramural involvement may be evaluated by performing abdominal ultrasound with saline instilled into the endometrial cavity (i.e., sonohysterosgraphy) (123). If the leiomyoma is too deeply imbedded in the myometrium, it may not be resectable, or the uterus might be perforated if overzealous attempts are made to remove the tumor. Selected intramural leiomyomas may be removed completely during a second procedure performed after a suitable interval (119). Instead of a second procedure, the Nd:YAG laser or bipolar electrosurgery can be used to desiccate the remaining portion of the leiomyoma, although the efficacy of this approach is unclear (115). Preoperative gonadotropin-releasing hormone (GnRH) agonists may help shrink submucous myomas, facilitating their complete removal (122,123 and 124).

### Menorrhagia

Menorrhagia that does not respond to medications may be managed by endometrial ablation or resection (95,96 and 97, 117, 124,125,126,127,128,129,130,131 and
Ablation may be performed with the laser (95,125,126), by electrosurgical desiccation using a uterine resectoscope equipped with a blunt ball- or barrel-shaped electrode (97,132), or by thermal balloon ablation. Resection is performed with an electrosurgical loop electrode that can shave the endometrium (96,127,128). Complications of the procedure include fluid overload, electrolyte imbalances, bleeding, perforation, and intestinal injury (130). The risk for uterine perforation can be reduced by using a combination of resection and electrosurgical ablation; the latter is most suitable for the thinner areas of the myometrium in the cornu and on the lateral walls of the endometrial cavity (117). The preoperative use of GnRH analogues or danazol may reduce operating time, bleeding, and the amount of fluid required (134,135).

For many women, these procedures are successful in reducing or eliminating menses without hysterectomy or long-term medical therapy (136). Success rates vary and depend on the duration of follow-up and the definition of success. For many patients, amenorrhea is the goal, whereas for others, it is normalization of menses. About 75% to 95% of patients are satisfied with the surgical procedure after 1 year, and 30% to 90% of patients have amenorrhea. In comparative studies, there is no advantage of laser over electrosurgical techniques (125,130).

The long-term efficacy and impact of ablation or resection on women with adenomyosis is unknown. Because some endometrium inevitably cannot be ablated, there is the potential for endometrial cancer; therefore, postmenopausal women who have undergone ablation or resection should take progestin as part of hormonal replacement therapy (136).

Sterilization

Hysteroscopic sterilization can be performed without entering the peritoneal cavity. Because the tubal ostia are usually visible during hysteroscopy, there are several potential options for sterilization: insertion of a plug, injection of a sclerosing agent, or destruction of the intramural portion of the oviduct. These procedures are being developed and should be performed only as part of an approved clinical trial (36).

Synechiae

Asherman’s syndrome is the presence of adhesions in the endometrial cavity resulting in infertility or recurrent spontaneous abortion with or without amenorrhea. These synechiae may be detected on a hystogram but are best shown with diagnostic hysteroscopy. Relatively thin, fragile synechiae may be divided with the tip of a rigid diagnostic hysteroscope (137). Thicker lesions may require division by semirigid or rigid scissors or energy-based instruments such as a resectoscope or an operative hysteroscope with an Nd:YAG laser. Reproductive outcome depends on the extent of the preoperative endometrial damage (138,139) and (140).

Patient Preparation

Most diagnostic hysteroscopy procedures are performed in the office or clinic, whereas operative hysteroscopy is performed in an operating room or hospital surgicenter. The patient should understand the rationale for either procedure as well as the anticipated discomfort, the potential risks, and the expectant medical and surgical alternatives. The patient must understand the nature of the procedure and the chance of therapeutic success. A realistic estimate of success based on the operator’s experience must be presented to the patient.

Diagnostic Hysteroscopy

Diagnostic hysteroscopy is designed to identify or exclude the presence of anatomic or structural abnormalities in the endometrial cavity that may contribute to bleeding, infertility, or recurrent pregnancy loss. The risks of diagnostic hysteroscopy are few, and they rarely have severe consequences. However, those related to anesthesia, perforation, bleeding, and the distention media should be discussed. After diagnostic hysteroscopy, most patients have slight vaginal bleeding and lower abdominal cramps. Severe cramps, dyspnea, and upper abdominal and right shoulder pain can develop if CO₂ passes into the peritoneal cavity. Consequently, the patient should be accompanied by a friend or relative who will escort her home.

Operative Hysteroscopy

Counseling before operative hysteroscopy varies depending on the planned procedure and the type of anesthesia used. The risks of operative hysteroscopy are higher and are potentially more dangerous than those of diagnostic hysteroscopy. Failure to purge air sufficiently from inflow lines or cervical dilation and insertion of operative instruments into the uterine cavity may be sufficient to cause a clinically significant air embolus. The risk for emboli as room air or gas from electrosurgical combustibles increases with higher intracavitary pressures, longer procedures, and invasion into the deeper myometrial vasculature. The use of large volumes of hypotonic distention media may not be tolerated in some patients if there is significant intravascular absorption, especially in patients with underlying cardiovascular disease. The patient must be aware of the risk for damage to the intestines or to the urinary tract. If damage occurs during the procedure, it may not be possible to complete the surgery, and laparotomy may be necessary to repair the problem.

Equipment and Technique

The equipment required depends on the reason for the procedure. The surgeon must be knowledgeable about the equipment, its mechanisms, and the technical specifications to facilitate efficiency, optimal clinical outcome, and a decreased probability of complications (Fig. 21.18). A typical hysteroscopy setup for diagnostic and minor operative procedures is shown in Fig. 21.19. Core competencies required for hysteroscopy are as follows:
**Patient Positioning and Exposure**

Hysteroscopy is performed in a modified dorsal lithotomy position; the patient is supine, and the legs are held in stirrups. For hysteroscopic procedures performed while the patient is conscious, comfort must be considered in conjunction with the need to gain good exposure of the perineum. Stirrups that hold and support the knees, calves, and ankles permit prolonged procedures. “Candy cane” stirrups should be avoided for hysteroscopic surgery on conscious patients.

The smallest speculum possible should be used to expose the cervix. A bivalve speculum hinged on only one side allows its removal without disturbing the other instruments needed. The use of weighted specula should be avoided in conscious patients.

**Anesthesia**

The anesthetic requirements for hysteroscopy vary greatly, depending on the patient's level of anxiety, the status of her cervical canal, the procedure, and the outside diameter of the hysteroscope or sheath. In some patients, diagnostic hysteroscopy is possible without anesthesia, especially if the patient is parous or if narrow-caliber (<3 mm in inside diameter) hysteroscopes are used. The pain of cervical dilation also is avoided or minimized by inserting a laminaria tent in the cervix 3 to 8 hours before the procedure. However, if left in place too long (e.g., longer than 24 hours), the cervix may overdistend, which is counterproductive for CO₂ insufflation.

For most diagnostic procedures, effective cervical anesthesia is obtained with an intracervical block. A spinal needle can be used to instill about 3 mL of 0.5% to 1% lidocaine into the anterior lip of the cervix. An intracervical block is administered evenly around the circumference of the internal os. A paracervical block may also be injected into the uterosacral ligaments at the 4- and 8-o’clock positions, if necessary. Care must be taken to avoid intravascular injection. Additional topical anesthesia may be given by injecting 5 mL of 2% mepivacaine into the endometrial cavity with a syringe. Many operative procedures can be performed with this technique combined with intravenous anxiolytics or analgesics, as necessary. Alternatively, regional or general anesthesia may be used.

**Cervical Dilation**

Dilation of the cervix, although apparently simple, can be incorrectly performed in a way that compromises the whole procedure. If the objective lens of the hysteroscope cannot be placed in the endometrial cavity, the hysteroscopy cannot be done. The cervix should be dilated asatraumatically as possible. A uterine sound should not be used because it can traumatize the canal or the endometrium, causing unnecessary bleeding and uterine perforation.

**Uterine Distention**

Distention of the endometrial cavity is necessary to create a viewing space. The choices include CO₂ gas, high-viscosity 32% dextran 70, and a number of low-viscosity fluids, including glycine, sorbitol, saline, and dextrose in water. A pressure of 45 mm Hg or higher is required for adequate distention of the uterine cavity. To minimize extravasation, this pressure should not exceed the mean arterial pressure. For each of the fluids, there are several methods used to create this pressure by infusion into the endometrial cavity.

**Sheaths**

A rigid hystroscope is passed into the endometrial cavity through an external sheath. The design and diameter of the sheath reflect both the dimensions of the endoscope and the purpose of the instrument. Diagnostic hystoscopes have a sheath slightly wider than the telescope, allowing infusion of the distention media. Sheaths for operative hystoscopes have one or two additional channels that permit the passage or efflux of distention media or the insertion of semirigid instruments or laser fibers. These sheaths are usually 7 to 8 mm in diameter, and some allow continuous flow of distention media in and out of the endometrial cavity (Fig. 21.16).

**Media**

CO₂ provides an excellent view for diagnostic purposes, but it is unsuitable for operative hysteroscopy and for diagnostic procedures when the patient is bleeding because there is no effective way to remove blood and other debris from the endometrial cavity. To prevent CO₂ embolus, the gas must be instilled by an insufflator that is specially designed for the procedure—the intrauterine pressure is kept below 100 mm Hg, and the flow rate is maintained at less than 100 mL/min.

Normal saline is a useful and safe medium for procedures that do not require electricity. Even if there is absorption of a significant volume of solution, saline does not cause electrolyte imbalance. Therefore, saline is a good fluid for minor procedures performed in the office.

Dextran 70 is useful for patients who are bleeding, because it does not mix with blood. However, it is expensive and tends to “caramelize” on instruments, which must be disassembled and thoroughly cleaned in warm water immediately after each use. Anaphylactic reactions, fluid overload, and electrolyte disturbances can occur.

For operative hysteroscopy, low-viscosity, nonconductive fluids such as 1.5% glycine and 3% sorbitol are used most often. These solutions can be used with electricity because there are no electrolytes to disperse the current and impede the electrosurgical effect. Both 1.5% glycine and 3% sorbitol are inexpensive and are readily available in 3-L bags suitable for continuous-flow hysteroscopy. Because each fluid is hypotonic, extravasation into the systemic circulation can be associated with fluid and electrolyte disturbances. Therefore, uterine “absorption” must be monitored continuously by collecting outflow from the sheath and subtracting it from the total infused volume. Absorbed volumes greater than 1 L mandate the measurement of electrolyte levels. If there is more than 2 L of extravasated fluid, the procedure should be stopped. Excessive circulating sorbitol may cause hyperglycemia, and large volumes of glycine may elevate levels of ammonia in the blood.

**Delivery Systems**

Syringes can be used for office diagnostic procedures and are especially good for infusing dextran solution. The syringe can be operated by the surgeon and is either connected directly to the sheath or attached by connecting tubing. Because this technique is so tedious, it is suited only for simple operations.

Continuous hydrostatic pressure is effectively achieved by elevating the vehicle containing the distention media above the level of the patient's uterus. The achieved pressure is the product of the weight of the connecting tubing and the elevation—for operative hysteroscopy with 10-mm tubing, intrauterine pressure ranges from 70 to 100 mm Hg when the bag is between 1 and 1.5 m above the uterine cavity.

A pressure cuff may be placed around the infusion bag to elevate the pressure in the system. Caution must be exercised, however, because this technique causes...
extravasation if intrauterine pressure rises above the mean arterial pressure.

A variety of infusion pumps are available, ranging from simple devices to instruments that maintain a preset intrauterine pressure. Simple pump devices continue to press fluid into the uterine cavity regardless of resistance, whereas the pressure-sensitive pumps reduce the flow rate when the preset level is reached, thereby impeding the efflux of blood and debris and compromising the view.

**Imaging**

**Endoscopes**

Hysteroscopes are available in two basic types—flexible and rigid. Flexible hysteroscopes have lower resolution than rigid instruments of a similar diameter and are most useful for cannulation of the fallopian tube. For other uses, rigid hysteroscopes are more durable and provide a superior image. The most commonly used hysteroscopes are 4 mm in diameter, although those smaller than 3 mm in diameter are available. Small-diameter endoscopes have a somewhat lower resolution but are easier to pass through the cervix.

Oblique endoscopes are more useful for hysteroscopy than laparoscopy and are available in zero-degree, 12- to 15-degree, and 25- to 30-degree models (Fig. 21.20). The zero-degree telescope provides a panoramic view and is best for diagnostic procedures. Hysteroscopes with 25- to 30-degree angles are most often used for both diagnosis and therapy, although the 12- to 15-degree types are a suitable compromise useful for diagnosis, ablation, and resection.

**Light Sources and Cables**

Adequate illumination of the endometrial cavity is essential. Because it runs from a standard 110- or 220-volt wall outlet, the light source requires no special electrical connections. For most cameras and endoscopes, the element must have at least 150 watts of power for direct viewing and preferably 250 watts or more for video and operative procedures (143).

**Video Imaging**

Although diagnostic hysteroscopy may be performed with direct visualization, it is best to use video guidance for prolonged operations. Video imaging is important for teaching and recording pathology and procedures. The cameras used for operative hysteroscopy often have greater technical requirements than those used for laparoscopy. The camera must be more sensitive because of the narrow diameter of the endoscope and the frequently dark background of the endometrial cavity, particularly when it is enlarged (Fig. 21.18).

**Intrauterine Manipulation**

The instruments available for use through operative hysteroscopes include grasping, cutting, and punch-biopsy devices. These tools are narrow and flexible enough to navigate the 1- to 2-mm diameter operating channel (Fig. 21.21). Their value is limited by their small size and flimsy construction. However, the scissors can be used to divide adhesions, the biopsy forceps can be used to sample targeted lesions, and the grasping forceps can be used to remove small polyps or intrauterine devices. Some operative hysteroscopes are designed to allow passage of fibers for the conduction of Nd:YAG laser.

**Figure 21.20 Hysteroscope optics.** Panoramic (08) and oblique (158 and 308) viewing angles.

**Figure 21.21 Hysteroscopy hand instruments.** From top: biopsy forceps, grasping forceps, and scissors, each of which passes through the instrument channel of an operating hysteroscope. Bottom: a rigid sheath with integrated scissors.

The uterine resectoscope is similar to the one used in urology and is designed to apply electrical energy in the endometrial cavity (Fig. 21.22). An understanding of the principles of electrosurgery is mandatory for safe and effective use of this instrument. By sliding the "working element," one of a variety of electrode tips can be manipulated back and forth within the cavity. Tissue can be divided with a pointed electrode, excised with a loop, or desiccated with a rolling ball or bar. A clear operative field is maintained by the continuous flow of nonconductive distending media in and out of the cavity. Although basic design modifications have made the resectoscope more useful in gynecology, extraction of resected fragments is time consuming. The most effective approach is the periodic use of a uterine curette or polyp forceps inserted after removal of the hysteroscope.
Dextran 70

be especially designed for hysteroscopy; it is difficult to set laparoscopic insufflator flow rates below 1,000 mL/min.

procedures and by ensuring that the insufflation pressure is always lower than 100 mm Hg and that the flow rate is lower than 100 mL/min. The insufflator used must

are damaged, laparotomy is indicated to repair the damage (146). Most perforations do not need to be repaired. However, the pelvic sidewalls, the bladder, and the small and large bowel should be carefully inspected. If the intestines

vessels are at risk. An activated electrode or fiber should never be advanced, but if an activated electrode has penetrated the uterine wall, direct examination of the

of the myometrium (146). However, if an activated electrode or laser fiber penetrates the uterus, surrounding structures such as bowel, urinary tract, and blood

vessels are at risk. An activated electrode or fiber should never be advanced, but if an activated electrode has penetrated the uterine wall, direct examination of the

Thermal Trauma

The temperature of the uterine serosa does not rise significantly during electrosurgical coagulation of the endometrium, even at the cornu, which is the thinnest area of the myometrium (146). However, if an activated electrode or laser fiber penetrates the uterus, surrounding structures such as bowel, urinary tract, and blood

Bleeding

Bleeding that occurs during or after hysteroscopy results from trauma to the vessels in the myometrium or injury to other vessels in the pelvis. Myometrial vessels can

be lacerated during the resectoscopic procedures.

In planning operations that involve deep resection, autologous blood can be obtained before surgery. The risk for bleeding may be reduced by the preoperative

injection of diluted vasopressin into the cervical stroma (145). The risk for injury to branches of the uterine artery can be lowered by minimizing the depth of resection in the lateral endometrial cavity near the uterine isthmus, where ablative techniques should be used. When bleeding is encountered during resectoscopic procedures, the ball electrode can be used to desicate the vessel electrosurgery. Intractable bleeding may respond to the injection of diluted vasopressin or to the inflation of a 30-mL Foley catheter balloon in the endometrial cavity (117).

Thermal Trauma

The temperature of the uterine serosa does not rise significantly during electrosurgical coagulation of the endometrium, even at the cornu, which is the thinnest area of the myometrium (146). However, if an activated electrode or laser fiber penetrates the uterus, surrounding structures such as bowel, urinary tract, and blood

vessels are at risk. An activated electrode or fiber should never be advanced, but if an activated electrode has penetrated the uterine wall, direct examination of the pelvic viscera is mandatory. Laparoscopy is the appropriate first step. The site of the perforation should be examined to exclude the presence of significant bleeding. Most perforations do not need to be repaired. However, the pelvic sidewalls, the bladder, and the small and large bowel should be carefully inspected. If the intestines are damaged, laparotomy is indicated to repair the damage (147).

Thermal injury to the intestine or ureter may be difficult to diagnose, and symptoms may not occur for several days to 2 weeks. Therefore, the patient should be

advised of the symptoms that could indicate peritonitis.

Distention Media

Carbon Dioxide

CO₂ can cause emboli and result in serious intraoperative morbidity and death (149,149 and 150). These risks can be eliminated by not using CO₂ with operative

procedures and by ensuring that the insufflation pressure is always lower than 100 mm Hg and that the flow rate is lower than 100 mL/min. The insufflator used must be

especially designed for hysteroscopy; it is difficult to set laparoscopic insufflator flow rates below 1,000 mL/min.

Dextran 70

Dextran 70 is a hyperosmolar medium that can induce an allergic response, coagulopathy, and, if sufficient volumes are infused, vascular overload and heart failure
Before undertaking a procedure using the resectoscope, baseline serum electrolyte levels should be measured. Women with cardiopulmonary disease should be evaluated carefully. The selective preoperative use of agents such as GnRH agonists may reduce operating time and media absorption.

In the operating room, media infusion and collection should take place in a closed system to allow accurate measurement of the “absorbed” volume. The volume should be calculated every 5 minutes or at least every 15 minutes.

The lowest intrauterine pressure necessary for adequate distention should be used to complete the operation, usually at a level that is below the mean arterial pressure. A pressure range is 70 to 80 mm Hg, which can be achieved with a specially designed pump or by maintaining the meniscus of the infusion bag 1 m above the level of the patient’s uterus.

Deficits of more than 1 L require measurement of electrolyte levels. The procedure should be completed expeditiously. If the deficit is more than 2 L, the procedure should be terminated, and a diuretic such as mannitol or furosemide should be used as needed. In patients with cardiovascular compromise, deficits must be avoided (36).

References
Hysterectomy is one of the most common surgical procedures performed. After cesarean delivery, it is the second most frequently performed major surgical procedure in the United States. In 1965, there were 426,000 hysterectomies performed in the United States, with an average length of hospital stay of 12.2 days. This number reached its peak in 1985, when 724,000 procedures were reported, with the length of stay decreasing to 9.4 days. The number of hysterectomies performed in the United States declined to 544,000 in 1991, with an average length of stay of 4.5 days. Of these 544,000 hysterectomies, 408,000 (75%) were performed abdominally, and 136,000 (25%) were performed vaginally. However, by 1998, the number of hysterectomies performed had increased to more than 600,000. Using 1987 age-specific hysterectomy rates and the population projections supplied by the U.S. Census Bureau, it has been projected that there will be 824,000 hysterectomies in the year 2005.

The rate of hysterectomy has varied between 6.1 and 8.6 per 1,000 women of all ages. A woman's chance of having a hysterectomy is dependent on a variety of factors, including her age, race, and where she lives, and the sex of her physician. Women between the ages of 20 and 49 years constituted the largest segment of women undergoing the procedure. The average age of a woman undergoing hysterectomy is 42.7 years and the median age is 40.9 years, which has remained constant since the 1980s. About 75% of all hysterectomies are performed in women between the ages of 20 and 49 years. The rates of hysterectomy vary by region of the country. The highest overall rate is in the southern states, where the rate tends to be higher for women aged 15 to 44 years. The lowest rates have consistently been in the northeastern portion of the United States. Hysterectomy is more often performed in African American than in white women and is performed more frequently by male gynecologists than by female gynecologists.

**Indications**

The indications for hysterectomy are listed in Table 22.1. In virtually all studies, uterine leiomyomas are consistently the leading indication for hysterectomy. As expected, the indications differ with the patient's age. For instance, whereas pelvic relaxation accounts for 16% of hysterectomies in women older than 55 years of age, this diagnosis is responsible for more than 33% of hysterectomies in women older than 55 years of age. More complete discussions of these indications are presented in the specific chapters indicated.

**Leiomyomas**

Uterine leiomyomas are the most common pelvic tumors in women; therefore, this condition is responsible for a large number of hysterectomies. Hysterectomy for uterine leiomyomas should be considered only in patients who do not desire future fertility. Otherwise, fertility-preserving surgical management (myomectomy) is possible in most patients with leiomyomas. The decision to perform a hysterectomy for leiomyomas is usually based on the need to treat symptoms—abnormal uterine bleeding, pelvic pain, or pelvic pressure. Other indications for intervention have included "rapid" uterine enlargement (although this finding is poorly defined), ureteral compression, or uterine growth after menopause. The concept of rapid growth has been challenged because such patients have not been shown clearly to have...
malignant conditions. Furthermore, there is no clearly reproducible definition of rapid growth.

The removal of the uterus because it reaches a certain size is widely debated. In the past, surgeons removed the uterus if its size reached that approximating 12 weeks' gestation or greater, even if it was asymptomatic. The reasons given for such an intervention include the inability to palpate the ovaries on bimanual examination and the notion that, as the uterus enlarges, the morbidity for hysterectomy incurs, the method for endometriosis treatment increases. Malignancy is uncommon in premenopausal patients, however, and adnexal palpation is not possible in many patients whose ovaries are of normal size. No difference in surgical morbidity exists between patients with a 12-week-sized uterus and those with a 20-week-sized uterus if the procedures are performed abdominally (12). Therefore, hysterectomy for leiomyomas should be considered only in symptomatic patients who do not desire future fertility (12).

To reduce uterine size before hysterectomy, patients with large leiomyomas may be pretreated with a gonadotropin-releasing hormone (GnRH) agonist (13,14) and corticosteroids (15). In many cases, the reduction of uterine size is sufficient to permit vaginal hysterectomy when otherwise an abdominal hysterectomy would have been necessary. In one prospective trial, premenopausal patients with leiomyomas the size of 14 to 18 weeks of gestation were randomized to receive either 2 months of preoperative depot GnRH agonist or no GnRH agonist (15). Treatment with a single dose of leuprolide acetate before surgery enabled patients' procedures to be performed safely from an abdominal approach to a vaginal hysterectomy. This preoperative regimen was associated with a rise in hematocrit before surgery and, because patients were more likely to have vaginal than abdominal hysterectomy, shortening the patient's hospital stay and convalescent period.

Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding is the indication for about 20% of hysterectomies. Because dysfunctional uterine bleeding usually is the result of anovulation, the bleeding can be controlled by medical interventions with progestin, estrogen, a combination of progestin and estrogen, oral contraceptives, or nonsteroidal antiinflammatory agents (see Chapter 13). In most patients, the bleeding requires no therapy unless anemia is present or bleeding is excessive and interferes with the patient's quality of life. In patients older than 35 years of age, endometrial sampling should be performed before hysterectomy. Dilatation and curettage is not an effective means of controlling bleeding and is not necessary before hysterectomy (16). Therefore, hysterectomy should be reserved for patients who do not respond to or who cannot tolerate medical therapy. Alternatives to hysterectomy (e.g., endometrial ablation or resection) should be considered in selected patients because these operations may be cost-effective and have a lower morbidity rate (see Chapter 21).

Intractable Dysmenorrhea

About 10% of adult women are incapacitated for up to 3 days per month as a result of dysmenorrhea (see Chapter 14) (17). Dysmenorrhea can be treated with nonsteroidal antiinflammatory agents used alone or in combination with oral contraceptives or other hormone agents to reduce or ablate menstrual flow (18,19). Hysterectomy is rarely required for the treatment of primary dysmenorrhea. In patients with secondary dysmenorrhea, the underlying condition (e.g., leiomyomas, endometriosis) should be treated primarily. Nonsteroidal antiinflammatory agents may be effective. Hysterectomy should be considered only if medical therapy fails or if the patient does not want to preserve fertility (20-22).

Pelvic Pain

In a review of 418 women in whom hysterectomy was performed for a variety of nonmalignant conditions, 18% had chronic pelvic pain. Preoperative laparoscopy was performed in only 66% of these patients. After hysterectomy, there was a significant reduction in symptoms associated with an improvement in the patient's quality of life (23). Stovall and colleagues reviewed 104 patients who underwent hysterectomy for chronic pelvic pain that was believed to be of uterine origin. Patients were followed for a mean of 21.6 months after hysterectomy, and 78% experienced improvement in their pain (24). However, 22% of patients had no improvement or exacerbation of their pain. Hysterectomy should be performed only in those patients whose pain is of uterine origin and does not respond to nonsurgical treatments (18) (see Chapter 14).

Cervical Intraepithelial Neoplasia

In the past, hysterectomy was performed as primary surgical treatment of cervical intraepithelial neoplasia. However, the maximum depth of dysplasia at the squamocolumnar junction is 5.2 mm; 99.7% of dysplasias (including carcinoma in situ) are located within 3.8 mm of the epithelial surface (25). Therefore, more conservative treatments such as cryotherapy, laser, or a loop electrosurgical excision procedure can be effective in treating the disease, making hysterectomy unnecessary in most women with these conditions (see Chapter 16). For patients with recurrent high-grade dysplasia who do not desire to preserve fertility, hysterectomy is an appropriate treatment option. Even after hysterectomy, however, patients are at increased risk for vaginal intraepithelial neoplasia.

Genital Prolapse

Hysterectomy is performed for symptomatic genital prolapse accounts for about 15% of hysterectomies performed in the United States (71). Unless there is an associated condition requiring an abdominal incision, vaginal hysterectomy is the preferred approach for genital prolapse. Uterine prolapse typically is not an isolated event and is most often associated with a variety of pelvic support defects (see Chapter 20). Each defect must be corrected to optimize the surgical outcome and decrease the chance for future development of pelvic support defects.

Obstetric Emergency

Most emergency hysterectomies are performed because of postpartum hemorrhage resulting from uterine atony. Other indications include uterine rupture that cannot be repaired or a pelvic abscess that does not respond to medical therapy. Hysterectomy may be required for patients with placenta accreta or placenta increta.

Pelvic Inflammatory Disease

Pelvic inflammatory disease can generally be successfully treated with antibiotics. The uterus, tubes, and ovaries should not be removed in a patient with pelvic inflammatory disease unless the patient has not responded to intravenous antibiotic therapy (see Chapter 15). Whether one proceeds with conservative surgical management, abscess drainage, or organ removal is a subjective decision that must be based on the individual. If accessible, some pelvic abscesses may be drained successfully by percutaneous catheter drainage guided by ultrasonography or computed tomography (CT) scanning. Surgical intervention also is necessary if the patient has had an abdominal findings associated with peritonitis and signs of sepsis in the presence of a ruptured tuboovarian abscess. For the patient who desires future fertility, consideration should be given to unilateral adnexitomy or partial bilateral adnexitomy without hysterectomy. For the patient in whom bilateral adnexitomy is required, the uterus can be left in place for possible ovum donation and in vitro fertilization (see Chapter 27).

Endometriosis

Medical and conservative surgical procedures generally are successful for treatment of endometriosis (see Chapter 26). Therefore, adnexitomy with or without hysterectomy should be performed only in patients who do not respond to conservative surgical (resection or ablation of endometriotic implants) or medical therapy. Most patients with endometriosis who require hysterectomy have unremitting pelvic pain or dysmenorrhea. Other less common situations include patients who do not desire future fertility and who have endometriosis involving other pelvic organs, such as the ureter or colon.

Cancer

Metastases from nongynecologic sites may cause symptoms requiring hysterectomy. As a primary procedure, hysterectomy with bilateral salpingo-oophorectomy should be considered for patients with colorectal carcinoma because these patients are at risk for either synchronous pelvic cancers or occult metastases (26,27).
Benign Ovarian Tumor

Benign ovarian tumors that are persistent or symptomatic require surgical treatment. Obviously, if the patient desires fertility, the uterus should be conserved. If fertility is not an issue, however, or if the patient is perimenopausal or postmenopausal, a decision must be made regarding whether the uterus should be removed. Gambone and colleagues reviewed 100 patients who underwent adnexectomy plus hysterectomy for benign adrenal disease and compared these patients with a group of risk-matched women who underwent adnexectomy without hysterectomy for the same indication (29). There was a significant increase in operative morbidity, estimated blood loss, and the length of hospital stay for patients in whom hysterectomy was performed.

Vaginal Versus Abdominal Hysterectomy

The proportion of abdominal versus vaginal hysterectomies has not changed significantly since the 1980s—about 75% of hysterectomies are abdominal (30,31). There are no specific indications for the use of vaginal hysterectomy. The route chosen should be individualized. Absolute and relative contraindications have been proposed (27,28 and 29). In a large, multicenter retrospective study conducted by the U.S. Centers for Disease Control between 1978 and 1981, and the risks and outcome of abdominal and vaginal hysterectomy were compared (32). The study included 1,851 patients aged 15 to 44 years in whom hysterectomy was performed for benign gynecologic disorders (568 vaginal, 1,283 abdominal). Surgical complications were classified into six categories. The overall complication rate was 24.5 per 100 for vaginal hysterectomy compared with 42.8 per 100 women for abdominal hysterectomy. The risk for one or more complications after abdominal hysterectomy was 1.7 times the risk after vaginal hysterectomy. The two major categories of complications were febrile morbidity and hemorrhage requiring transfusion. The risk for febrile morbidity was 2.1 times higher for abdominal hysterectomy than for vaginal hysterectomy, and the risk for transfusion was 1.9 times higher for abdominal surgery. Since the collection of these data, transfusion practices within the United States have changed as a result of increased awareness of the human immunodeficiency virus. Although only one fourth of hysterectomies are performed vaginally, this proportion could probably be increased substantially. In a recent study of 817 hysterectomies, 548 were performed vaginally, laparoscopic assistance was used in 63 patients, and an abdominal approach was required in only 6 patients (33). If feasible, vaginal hysterectomy is the preferred approach.

Supracervical Hysterectomy

The indications for supracervical hysterectomy are somewhat vague. Among potential indications are endometriosis with obliteration of the anterior and posterior cul-de-sac, cesarean hysterectomy when the cervix is fully dilated and difficult to identify, and concern for sexual function. During a technically difficult surgical procedure, the presence of the cervix could create a significant morbidity associated with the removal of the cervix. However, the cervix can almost always be removed. Some women desire to conserve the cervix because they believe that it is important for sexual satisfaction, although there are no sound scientific data to prove this perception. Some authors (currently representing the minority view) believe that the cervix should not be removed unless there is a specific reason. They suggest that removal of the cervix leads to a decrease in sexual pleasure, increased operative and postoperative morbidity, vaginal shortening, vault prolapse, abnormal cuff granulations, and the potential for oviductal prolapse (34-35).

There is some debate about the effects of leaving the cervix in situ. Kilkku and associates reported on a group of 210 patients who underwent hysterectomy, of whom half had total abdominal hysterectomy and half had supracervical hysterectomies (36). Studies of the same population disclosed an increase in psychiatric symptoms in both groups (34-35 and 36). Sexual desire and functioning was unchanged, although there was a decrease in dyspareunia in both groups. Patients undergoing supracervical hysterectomy were reported to have increased orgasmic frequency when compared with patients in whom the cervix was left intact (36,37,38 and 39). Regardless of the reason for leaving the cervix at the time of hysterectomy, preoperative Papanicolaou (Pap) test results must be normal, and appropriate consent must be obtained from the patient.

Laparoscopically Assisted Hysterectomy

Laparoscopy has been used diagnostically before hysterectomy (see Chapter 21). Kovac (33) performed laparoscopy in 46 patients who had been advised to have abdominal hysterectomy, and the findings suggested that uterine size had been overestimated and that uterine mobility had been underestimated by the referring physicians. All 14 patients who were referred for assessment of adnexal pathology had none. In 91% (42 of 46) of the patients, a vaginal hysterectomy was completed. In another study of seven patients who were candidates for vaginal hysterectomy, except that they had a history suggestive of adhesions, six of the patients underwent laparoscopy, which did not reveal any adhesive disease (30). Studies of the same population disclosed an increase in psychiatric symptoms in both groups (34-35 and 36). Sexual desire and functioning was unchanged, although there was a decrease in dyspareunia in both groups. Patients undergoing supracervical hysterectomy were reported to have increased orgasmic frequency when compared with patients in whom the cervix was left intact (36,37,38 and 39). Regardless of the reason for leaving the cervix at the time of hysterectomy, preoperative Papanicolaou (Pap) test results must be normal, and appropriate consent must be obtained from the patient.

The use of operative laparoscopy to complete some or all of the hysterectomy has been widely reported (42,43,44,45,46,47,48,49,50,51 and 52) (see Chapter 21). However, in most of these studies, the patient population was neither randomized nor defined. Furthermore, the reasons the patient would require an abdominal approach are unclear. The criteria for patient selection for laparoscopy-assisted vaginal hysterectomy (LAVH) versus abdominal hysterectomy have not been clearly established.

Summitt and co-workers (49) published a randomized, prospective, controlled trial in which patients who were candidates for vaginal hysterectomy were randomized to either LAVH or a standard vaginal approach. All procedures were performed on an outpatient basis; included were patients who had uterine leiomyomas up to the size of 16 weeks of gestation. There was no difference between the groups in terms of uterine weight, febrile morbidity, or the need for transfusion. Patients undergoing LAVH had a lower hematocrit value on the first and second postoperative days and required more pain medication on the second postoperative day. Patients undergoing LAVH had a lower hematocrit value on the first and second postoperative days and required more pain medication on the second postoperative day.

It has been suggested that LAVH may be helpful in treating patients with documented endometriosis, known pelvic adhesive disease, an adnexal mass that requires hysterectomy, and lack of uterine mobility (see Chapter 21). Depending on the circumstances, LAVH may be appropriate in some patients with stage I/II endometrial cancer or previous episodes of multiple major pelvic surgery. For example, if the patient has had endometriosis that has been treated previously or adhesions that have been lysed previously and now require hysterectomy, a vaginal approach can most likely be taken. Davis and associates reported on a group of patients with stage III or IV endometrial cancer, in whom the procedure was successful in 40 of 46 patients (43). Even in the hands of expert laparoscopic surgeons, however, the rate of complications was high.

It is uncertain whether LAVH is preferable in patients with limited uterine mobility, and there is no standard method to assess the best approach. The major supporting structures of the uterus are the uterosacral ligaments and lower cardinal complex (55), which are not generally transected with a laparoscopic approach. Transection of the uterosacral ligament, round ligament, and broad ligament does not improve mobility.

Both LAVH and pelvic lymphadenectomy may be useful in selected patients with endometrial carcinoma (56). The data suggest that a lymphadenectomy can be performed safely and that hospital stay and morbidity are decreased when compared with the standard transabdominal approach. Long-term prospective studies are needed to address these questions.

Concurrent Surgical Procedures

Oophorectomy at the Time of Hysterectomy

A laparoscopic approach should not be used in conjunction with hysterectomy solely for the purpose of accomplishing ovarian removal. Although not every ovary can be removed through the vagina, it has been shown clearly that most can be removed in this manner (57).
Prophylactic oophorectomy is the most common surgical procedure performed concurrently with hysterectomy. Oophorectomy is performed prophylactically to prevent ovarian cancer and to eliminate the potential need for further surgery for either benign or malignant disease. Arguments against prophylactic oophorectomy center around the need for earlier and more prolonged hormone replacement. Although hormone replacement therapy is generally well tolerated and provides good symptomatic relief, it may not be as effective as normal ovarian function, and the implications of long-term replacement therapy are not fully known. Therefore, the decision to proceed with oophorectomy should be considered carefully after the patient has been informed of the risks and benefits.

The strength of the healed wound and cosmesis of the healed incision are important considerations. The potential need for enlarging the incision and the need for exposure are also significant. Elevation of the Uterus often. The Bookwalter retractor has a variety of adjustable blades that can be helpful, particularly in obese patients.

Retractor Choice and Placement

Abdominal Exploration

Incision

The choice of incision should be determined by the following considerations:

1. Simplicity of the incision
2. The need for exposure
3. The potential need for enlarging the incision
4. The strength of the healed wound
5. Coagness of the healed incision
6. The location of previous surgical scars

The skin is opened with a scalpel, and the incision is carried down through the subcutaneous tissue and fascia. With traction applied to the lateral edges of the incision, the fascia is divided. The peritoneum is opened similarly. This technique minimizes the possibility of inadvertent enterotomy, entering the abdominal cavity.

Abdominal Hysterectomy

Preoperative Preparation

Although not mandatory, a cleansing tap water or soap enema given on the evening before or the morning of the scheduled hysterectomy is preferred by some surgeons. To reduce the colony count of skin bacteria, the patient is asked to shower. Hair surrounding the incision area may be removed at the time of surgery or up to 2 days before surgery using a depilatory agent. Hair clipping is preferable to shaving because it decreases the incidence of incisional infection.

Patient Positioning

The patient is placed in the dorsal supine position for the procedure. After the patient is anesthetized adequately, her legs are placed in the stirrups and a pelvic examination is performed to validate the in-office pelvic examination findings. A Foley catheter is placed in the bladder, and the vagina is cleansed with an iodine solution. The patient's legs are then straightened.

Skin Preparation

Several methods for skin cleaning can be recommended, including a 5-minute iodine solution scrub followed by application of iodine solution, iodine solution scrub followed by alcohol with application of an iodine-impregnated occlusive drape, or an iodine-alcohol combination with or without application of an iodine-impregnated occlusive drape.

Surgical Technique

Incision

The uterus is elevated by placing broad ligament clamps at each cornu so that it crosses the round ligament. The clamp tip may be placed...
close to the internal os. This placement provides uterine traction and prevents backbleeding (Fig. 22.1).

**Figure 22.1** The uterus is elevated by placement of clamps across the broad ligament. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

**Round Ligament Ligation** The uterus is deviated to the patient's left side, stretching the right round ligament. With the proximal portion held by the broad ligament clamp, the distal portion of the round ligament is ligated with a suture ligature or simply transected with Bovie cautery (Fig. 22.2). The distal portion can be grasped with forceps, and the round ligament is cut to separate the anterior and posterior leaves of the broad ligament. The anterior leaf of the broad ligament is incised with Metzenbaum scissors or electrocautery along the vesicouterine fold, separating the peritoneal reflection of the bladder from the lower uterine segment (Fig. 22.3).

**Figure 22.2** The round ligament is transected and the broad ligament is incised and opened. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996.)

**Figure 22.3** The incision in the anterior broad ligament is extended along the vesicouterine fold. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

**Ureter Identification** The retroperitoneum is entered by extending the incision cephalad on the posterior leaf of the broad ligament. Care must be taken to remain lateral to both the infundibulopelvic ligament and iliac vessels. The external iliac artery courses along the medial aspect of the psoas muscle and is identified by bluntly dissecting the loose alveolar tissue overlying it. By following the artery cephalad to the bifurcation of the common iliac artery, the ureter is identified crossing the common iliac artery. The ureter should be left attached to the medial leaf of the broad ligament to protect its blood supply (Fig. 22.4).

**Figure 22.4** Identification of the ureter in the retroperitoneal space on the medial leaf of the broad ligament. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

**Uteroovarian or Infundibulopelvic Ligament Ligation** If the ovaries are to be preserved, the uterus is retracted toward the pubic symphysis and deviated to one side, placing tension on the contralateral infundibulopelvic ligament, the tube, and the ovary. With the ureter under direct visualization, a window is created in the peritoneum of the posterior leaf of the broad ligament under the uteroovarian ligament and fallopian tube. The tube and uteroovarian ligament are clamped on each side with a curved Heaney or Ballentine clamp, cut, and ligated with both a free-tie and a suture ligature. The medial clamp at the uterine cornu should control backbleeding; if it does not, the clamp should be repositioned to do so (Fig. 22.5).

**Figure 22.5** Identification of the ureter in the retroperitoneal space on the medial leaf of the broad ligament. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)
If the ovaries are to be removed, the peritoneal opening is enlarged and extended cephalad to the infundibulopelvic ligament and caudad to the uterine artery. This opening allows proper exposure of the uterine artery, the infundibulopelvic ligament, and the ureter. In this manner, the ureter is released from its proximity to the uterine vessels and the infundibulopelvic ligament.

A curved Heaney or Ballentine clamp is placed lateral to the ovary (Fig. 22.6); care is taken to ensure that the entire ovary is included in the surgical specimen. The infundibulopelvic ligament on each side is cut and doubly ligated (Fig. 22.7). Alternatively, free ties can be passed around the infundibulopelvic ligament, two cephalad and one caudad, before the ligament is cut.

Bladder Mobilization Using Metzenbaum scissors, with the tips pointed toward the uterus, the bladder is sharply dissected from the lower uterine segment and cervix. Alternatively, Bovie electrocautery can be used. An avascular plane, which exists between the lower uterine segment and the bladder, allows for this mobilization. Tonsil clamps may be placed on the bladder edge to provide countertraction and easier dissection (Fig. 22.8).

Uterine Vessel Ligation The uterus is retracted cephalad and deviated to one side of the pelvis, stretching the lower ligaments. The uterine vasculature is dissected or “skeletonized” from any remaining areolar tissue, and a curved Heaney clamp is placed perpendicular to the uterine artery at the junction of the cervix and body of the uterus. Care is taken to place the tip of the clamp adjacent to the uterus at this anatomic narrowing. The vessels are cut, and the suture is ligated. The same procedure is repeated on the opposite side (Fig. 22.9).
Incision of Posterior Peritoneum If the rectum is to be mobilized from the posterior cervix, the posterior peritoneum between the uterosacral ligaments just beneath the cervix and rectum may be incised (Fig. 22.10). A relatively avascular tissue plane exists in this area, allowing mobilization of the rectum inferiorly out of the operative field. A sponge may be placed to control the venous oozing that often occurs.

Cardinal Ligament Ligation The cardinal ligament is divided by placing a straight Heaney clamp medial to the uterine vessel pedicle for a distance of 2 to 3 cm parallel to the uterus. The ligament is then cut, and the pedicle suture is ligated. This step is repeated on each side until the junction of the cervix and vagina is reached (Fig. 22.11).

Removal of the Uterus The uterus is placed on traction cephalad and the tip of the cervix is palpated. Curved Heaney clamps are placed bilaterally, incorporating the uterosacral ligament and upper vagina just below the cervix. Care should be taken to avoid foreshortening the vagina. The uterus is then removed with heavy curved scissors (Fig. 22.12).

Vaginal Cuff Closure Several techniques of vaginal cuff closure have been described. A figure-of-eight suture of 0-0 braided absorbable material is placed between the tips of the two clamps. The suture is used for both traction and hemostasis. Sutures are also placed at the tip of each clamp, and the pedicles are sutured with a Heaney stitch, thereby incorporating the uterosacral and cardinal ligament at the angle of the vagina (Fig. 22.13). Alternatively, the vaginal cuff can be left open to heal secondarily. If this method is used, a running-locked suture is used for hemostasis along the cuff edge (Fig. 22.14).
Small bowel injuries are the most common intestinal injuries in gynecologic surgery. Bowel injury to the dome of the bladder is performed similarly postoperatively. A more conservative practice is to continue drainage until the patient is ready for discharge, usually a total of 3 to 4 days. Elective incision into the bladder is controversial. If the bladder is not compromised, drainage should be continued at least until gross hematuria clears, which may occur as soon as 48 hours. If bleeding persists, a braided absorbable suture such as a 3-0 polyglycolic acid is adequate. The bladder should be drained postoperatively. The length of time that drainage is required is governed by the amount and persistence of bleeding. Unless there is involvement of the bladder trigone, a bladder laceration is easily repaired. In the nonirradiated bladder, a one- or two-layer closure with a small-caliber monofilament absorbable suture is adequate. The bladder should be drained postoperatively. The length of time that drainage is required is governed by the amount and persistence of bleeding. If the bladder is not involved, the bladder can be repaired with interrupted sutures, bites should be taken about 1 cm from the cut edge of the fascia and about 1 cm apart to prevent wound dehiscence.

Irrigation and Hemostasis

The pelvis is thoroughly irrigated with saline or lactated Ringer's solution. Meticulous care is taken to ensure hemostasis throughout the pelvis, particularly of the vascular pedicles. Ureteral position and integrity are checked again to ensure that they are intact and do not appear dilated.

Peritoneal Closure

The parietal peritoneum is not reapproximated as a separate layer. Fascia can be closed with an interrupted or a continuous 0-0 or 1-0 monofilament absorbable suture. A continuous suture may reduce the risk for necrosis, which may occur when interrupted sutures are tied too tightly. As with interrupted sutures, bites should be taken about 1 cm from the cut edge of the fascia and about 1 cm apart to prevent wound dehiscence.

Skin Closure

If the ovaries have been retained, they may be suspended to the pelvic sidewall to minimize the risk of becoming retroperitoneal or adherent to the vaginal cuff. It is essential to be aware of the proximity of the ureter to the other pelvic structures at all times. Ureteral position and integrity are checked again to ensure that they are intact and do not appear dilated.

Intraoperative Complications

Most intraoperative injuries during abdominal hysterectomy can be traced to poor lighting, unsatisfactory assistance, undue haste, anatomic variants, or involvement of the injured organ in the disease process. Some of these factors can be eliminated with careful attention to detail and use of proper surgical technique. However, some operative injuries cannot be avoided by even the most skilled surgeons. The surgeon, therefore, must be prepared to recognize and repair these injuries. Even with a high level of attention to detail, injuries and complications, recognized and unrecognized, can still occur.

Ureteral Injuries

Injury to the pelvic ureter is one of the most formidable complications of hysterectomy. Because of the risk for subsequent renal impairment, injury to the ureter is far more serious than injury to the bladder or bowel. Most ureteral injuries can be avoided by opening the retroperitoneum and directly identifying the ureter. The use of ureteral catheters as a substitute for direct visualization is often of little help in patients with extensive fibrosis or scarring resulting from endometriosis, pelvic inflammatory disease, or ovarian cancer. In these instances, a false sense of security may actually increase an already high risk for ureteral injury. The use of ureteral catheters can also be associated with hematuria and acute urinary retention. Their complications are usually transitory in nature.

Direct visualization is accomplished by opening the retroperitoneum lateral to the external iliac artery. Blunt dissection of the loose areolar tissue is performed to visualize the artery directly. The artery may then be traced cephalad to the bifurcation of the internal and external iliac arteries. The ureter crosses the common iliac artery at its bifurcation and may be followed throughout its course in the pelvis.

Despite these precautions, ureteral injuries may occur. Prompt consultation is necessary if the surgeon has not been trained in ureteral repair. If a ureteral obstruction is suspected, confirmation may be obtained by intravenous injection of 1 ampule of indigo carmine dye, opening the dome of the bladder, and observing the presence or absence of bilateral spill of tinted urine. Alternatively, ureteral patency may be established by opening the dome of the bladder and positioning retrograde ureteral stents. Cystoscopic evaluation may replace opening the bladder to evaluate the spill of tinted urine.

Bladder Injury

Because of the close anatomic relationship of the bladder, uterus, and upper vagina, the bladder is the segment of the lower urinary tract that is most vulnerable to injury. Bladder injury may occur on opening the peritoneum or, more frequently, during the dissection of the bladder off the cervix and upper vagina. Unless there is involvement of the bladder trigone, a bladder laceration is easily repaired. In the nonirradiated bladder, a one- or two-layer closure with a small-caliber braided absorbable suture such as a 3-0 polyglycolic acid is adequate. The bladder should be drained postoperatively. The length of time that drainage is required is controversial. If the bladder is not compromised, drainage should be continued at least until gross hematuria clears, which may occur as soon as 48 hours postoperatively. A more conservative practice is to continue drainage until the patient is ready for discharge, usually a total of 3 to 4 days. Elective incision into the dome of the bladder is performed similarly. If the trigone is involved, a surgeon trained in complicated urologic repair should be consulted.

Bowel Injury

Small bowel injuries are the most common intestinal injuries in gynecologic surgery. Small defects of the serosa or muscularis may be repaired using a single...
layer of continuous or interrupted 3-0 braided absorbable suture. Although single-layer closure of the small bowel has proved adequate, it is safer to close defects involving the lumen in two layers using a 3-0 braided absorbable suture. The defect should be closed in a direction perpendicular to the intestinal lumen. If a large area has been injured, resection with reanastomosis may be necessary (85.87).

Because the bacterial flora of the ascending colon is similar to that of the small bowel, injuries can be repaired in a similar manner. The transverse colon rarely is injured in normal gynecologic procedures because it is well outside the operative field. However, the descending colon and the rectosigmoid colon are intimately involved with the pelvic structures and are at significant risk for injury during gynecologic surgery. Injuries not involving the mucosa may be repaired with a single running layer of 2-0 or 3-0 braided absorbable suture. If the laceration involves the mucosa, it may be closed as with small bowel injuries if the colon has been prepared adequately. Otherwise, diverting colostomy may be necessary in some patients to protect the repair site from fecal contamination, especially if the defect is larger than 5 cm or if there is spillage of the bowel contents (85.87).

Hemorrhage

Significant arterial bleeding usually arises from the uterine arteries or the ovarian vessels near the insertion of the infundibulopelvic ligaments (88). Blind clamping of these vessels presents a risk for ureteral injury; therefore, the ureters should be identified in the retroperitoneal space and traced to the area of bleeding to avoid inadvertent ligation. It is best to apply a pressure pack to tamponade the bleeding and then slowly remove the pack in an effort to visualize, isolate, and individually clamp the bleeding vessels. Mass ligatures should be avoided. The use of surgical clips may be helpful. Venous bleeding, while less dramatic, is often more difficult to manage, particularly in the presence of extensive adhesions and fibroids. This type of bleeding can be controlled with pressure alone or with suture ligation. Bleeding from peritoneal edges or denuded surfaces may be controlled with pressure, application of topical agents such as thrombin or collagen, or cautery with the Bovie. A variety of laser techniques have been used to control bleeding.

Postoperative Management

Bladder Drainage Overdistention of the female bladder resulting from bladder trauma or the patient's reluctance to initiate the voluntary phase of voiding is one of the most common complications after abdominal hysterectomy (89). For this reason, an indwelling bladder catheter should be used for the first few postoperative hours until the patient is able to urinate and ambulate.

If retropubic urethropexy has been performed, consideration should be given to using a suprapubic catheter, which allows postrvoid residual levels to be checked without repetitive catheterizations. This catheter may be removed when satisfactory postvoid residual levels of less than 100 mL have been obtained.

Diet In anticipation of the rare case in which the patient must be returned to the operating room, the patient is allowed only ice chips and liquids on the day of surgery. On the first postoperative day, assuming bowel sounds are present, diet is resumed, beginning with a soft diet and advancing to solid foods as tolerated. This dietary regimen assumes minimal intraoperative bowel manipulation and dissection. Early postoperative feeding has been shown not only to be safe but also to speed return of bowel function and recovery. In patients who have undergone pelvic and paraaortic lymph node dissection, bowel surgery, or other extensive dissections, clear liquids should not be given until flatus has been passed. The diet should be advanced only as tolerated.

Activity Early ambulation decreases the incidence of thrombophlebitis and pneumonia. Patients are encouraged to begin ambulation on their first postoperative day if possible and to increase progressively their time out of bed as their strength improves. On discharge, the patient is instructed to avoid lifting more than 20 pounds for 6 weeks, thereby minimizing stress on fascia to allow full healing. Sexual intercourse is not recommended until 6 weeks after surgery, when the vaginal cuff is fully healed. Patients are instructed to avoid driving until full mobility returns because postoperative pain and tenderness may hinder sudden braking or steering maneuvers in emergency situations. With these exceptions, the patient is encouraged to return to normal activities as soon as she feels comfortable doing so.

Wound Care The abdominal incision normally requires little attention, except for ordinary hygienic measures. The wound is kept covered with a sterile bandage for the first 24 hours after surgery, by which time the incision has sealed itself. After the bandage has been removed, the incision should be cleaned daily with mild soap and water and kept dry.

Vaginal Hysterectomy

Preoperative Evaluation

Evaluation of Pelvic Support The most important observation in determining the feasibility of a vaginal hysterectomy is the demonstration of uterine mobility (85.89). A vaginal approach should not be chosen if the uterus is not freely mobile. Pelvic support structures are elevated at the initial pelvic examination. In patients with no apparent prolapse, poor pelvic support can often be demonstrated by observing descent of the uterus with a series of Valsalva maneuvers. Although vaginal hysterectomy is easier to perform when the uterine supporting ligaments are lax, it is not an absolute requirement. Some gynecologists advocate the application of a tenaculum to the anterior cervical lip, with subsequent traction applied as the patient bears down. Although this exercise may give some indication of uterine mobility, it is uncomfortable and not necessarily predictive of the success of vaginal hysterectomy. Therefore, the practice of applying traction to the cervix with a tenaculum to demonstrate descent of an apparently well-supported uterus is not recommended.

Evaluation of the Pelvis After assessment of pelvic support, the bony pelvis should be evaluated. Ideally, the angle of the pubic arch should be 90 degrees or greater, the vaginal canal should be ample, and the posterior vaginal fornix should be wide and deep. The surgeon may use a closed fist to approximate the bituberous diameter, which should exceed 10 cm. The size and shape of the female pelvis contributes to increased exposure.

Surgical Considerations

Patient Positioning Once the patient is in the dorsal lithotomy position, the buttocks should be positioned just over the table’s edge. Several strtip types are available, including those that support the entire leg and those that suspend the legs in straps. To avoid nerve injury, adequate padding should be used; marked flexion of the thigh and pressure points should be avoided. Trendelenburg (10- to 15-degree) positioning aids in the intravaginal visualization needed during surgery.

Vaginal Preparation A povidone-iodine solution is applied to the vagina, the bladder is drained, and the catheter is removed. Several methods for draping have been proposed, including individual or single-piece drapes; the method chosen is at the surgeon’s discretion. There is usually no need to shave or clip the pubic hair. Individual drapes with an adhesive barrier should be used to hold the drapes in place and prevent the pubic hair from compromising the field.

Instruments Instruments specific to and useful in performing a vaginal hysterectomy include right-angled retractors, narrow Deaver retractors, weighted specula, Heaney needle holders, and an assortment of Briesky-Navratil vaginal retractors. Heaney and Heaney-Ballentine hysterectomy clamps are preferable. Several other clamps also are commonly used, including the Masterson clamp.

Lighting Overhead high-intensity lamps should be used and positioned to direct light over the operator’s shoulder. In addition, the surgeon may prefer a headlight, which can be worn to provide direct horizontal lighting. Although not routinely used, a fiberoptic-lighted irrigating suction system can provide additional light and transilluminate tissue planes.

Suture Material Various suture materials have been advocated for gynecologic surgery. The type of suture material chosen should be based on the surgeon’s preference. A synthetic delayed absorbable polyglactin or polyglycolic acid suture and atrumatic needles are generally preferable.

Procedure

The patient is examined while anesthetized to confirm prior findings and to assess uterine mobility and descent. The decision is then made whether to proceed vaginally or abdominally.

Grasping and Circumscribing the Cervix The anterior and posterior lips of the cervix are grasped with a single- or double-toothed tenaculum. With downward
traction applied on the cervix, a circumferential incision is made in the vaginal epithelium at the junction of the cervix (Fig. 22.15).

Figure 22.15 Circumferential incision in the vagina to infiltrate a vaginal hysterectomy. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

**Dissection of Vaginal Mucosa** After the initial incision is made, the vaginal epithelium may be dissected sharply from the underlying tissue or pushed bluntly with an open sponge (Fig. 22.16). If the initial incision is made too close to the external cervical os, there is a greater amount of dissection required and associated bleeding. Therefore, this circumscribing incision should be made just below the bladder reflection. It is important to continue the dissection in the correct cleavage plane because dissection in the wrong plane will increase blood loss.

Figure 22.16 Dissection of the vaginal mucosa. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

**Posterior Cul-de-Sac Entry** The peritoneal reflection of the posterior cul-de-sac (cul-de-sac of Douglas) can be identified by stretching the vaginal mucosa and underlying connective tissue with forceps (Fig. 22.17). If difficulty is encountered (e.g., if the cervix is elongated and the peritoneum is not evident), the vaginal mucosa may be incised vertically to the point at which the cul-de-sac becomes more apparent.

Figure 22.17 Entry into the posterior cul-de-sac. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

If the vaginal mucosa has been dissected in the wrong plane, the hysterectomy may be begun extraperitoneally by clamping and cutting the uterosacral and cardinal ligaments close to the cervix. The posterior cul-de-sac will then become readily identifiable.

If the peritoneal reflection of the posterior cul-de-sac still cannot be identified, entry into the anterior peritoneum is attempted, and a finger is hooked into the posterior cul-de-sac to place tension on the peritoneum. The peritoneum is opened with Mayo scissors. An interrupted suture is placed to approximate the peritoneum and vaginal cuff and thus provide hemostasis (Fig. 22.18).

Figure 22.18 Interrupted suture is placed on posterior vaginal cuff and peritoneum for hemostasis. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

The posterior pelvic cavity is examined for pathologic alterations of the uterus or adhesive disease of the cul-de-sac. The weighted speculum is placed into the
Uterosacral Ligament Ligation With retraction of the lateral vaginal wall and countertraction on the cervix, the uterosacral ligaments are clamped, with the tip of the clamp incorporating the lower portion of the cardinal ligaments (Fig. 22.19). The clamp is placed perpendicular to the uterine axis, and the pedicle is cut close to the clamp and sutured. A small pedicle (0.5 cm) distal to the clamp is optimal because a larger pedicle becomes necrotic and the tissue sloughs, which may present culture medium for microorganisms. The pedicle should be incised no more than one half to three fourths of the way around the tip of the clamp. Limiting the incision prevents the next pedicle, which may be vascular, from being cut.

![Figure 22.19 Ligation of the uterosacral ligaments.](From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

When suturing any pedicle, the needle point is placed at the tip of the clamp, and the needle is passed through the tissue by a rolling motion of the operator's wrist. Once ligated, the uterosacral ligaments may be transfixed to the posterolateral vaginal mucosa (Fig. 22.20).

![Figure 22.20 Transfixion of the uterosacral ligament to the posterolateral vaginal mucosa.](From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

This suture may lend additional support to the vagina and provides hemostasis at this point on the vaginal mucosa. This suture is held with a hemostat to facilitate location of any bleeding at the completion of the procedure and to aid in the closure of vaginal mucosa.

Entry versus Nonentry into the Vesicovaginal Space (Cul-de-Sac) Downward traction is placed on the cervix. Using either Mayo scissors, with the points directed toward the uterus, or an open moistened 4 × 4 gauze sponge, the bladder is advanced. If the vesicovaginal peritoneal reflection is easily identified at this point, the vesicovaginal space may be entered. Otherwise, it may be preferable to delay entry. There is no danger in delaying entry so long as the operator has ascertained that the bladder has been advanced.

After the bladder has been advanced, a curved Deaver or Heaney retractor is placed in the midline, holding the bladder out of the operative field. This process precedes each step of the vaginal hysterectomy until the vesicovaginal space is entered.

Cardinal Ligament Ligation With traction on the cervix continued, the cardinal ligaments are identified, clamped, and cut. The suture is ligated (Fig. 22.21).

![Figure 22.21 Ligation of the cardinal ligament.](From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

Advancement of Bladder The bladder again is advanced out of the operative field. A blunt dissection technique may be used; however, sharp dissection may be helpful if the patient has had previous surgery such as cesarean delivery, which may have scarred the bladder reflection.

Uterine Artery Ligation Contralateral and downward traction is placed on the cervix. With an effort to incorporate the anterior and posterior leaves of the visceral peritoneum, the uterine vessels are identified, clamped, and cut, and the suture is ligated (Fig. 22.22). A single suture and single clamp technique is adequate and decreases the potential risk for ureteral injury. When the uterus is large or when a fibroid distorts the anatomic relationships, a second suture may be required to ligate any remaining branches of the uterine artery.
Entry into the Vesicovaginal Space  The anterior peritoneal fold usually can be identified readily just before or after clamping and suture ligation of the uterine arteries. The anterior peritoneal cavity should not be opened blindly because of the increased risk for bladder injury (Fig. 22.23). The peritoneum is grasped with forceps, tented, and opened with scissors with the tips pointed toward the uterus. A Heaney or Deaver retractor is then placed, and the peritoneal contents are identified. This retractor serves to keep the bladder out of the operative field.

Delivery of the Uterus  A tenaculum is placed onto the uterine fundus in a successive fashion to deliver the fundus posteriorly (Fig. 22.24). The operator’s index finger is used to identify the uteroovarian ligament and aid in clamp placement.

Uteroovarian and Round Ligament Ligation  With the posterior and anterior peritoneum opened, the remainder of the broad ligament and uteroovarian ligaments are clamped, cut, and ligated (Fig. 22.25). The uteroovarian and round ligament complexes are double ligated with a suture tie followed by a ligature medial to the first suture. A hemostat is placed on the second suture to aid in the identification of any bleeding and to assist with peritoneal closure. A hemostat should not be placed on the first suture or any other vascular pedicle in order to avoid the risk for loosening the tie.

Removal of the Ovaries  When the adnexa are removed, the round ligaments should be removed separately from the adnexal pedicles. Traction is placed on the uteroovarian pedicle. The ovary is drawn into the operative field by grasping it with a Babcock clamp. A Heaney clamp is placed across the infundibulopelvic ligament, and the ovary and tube are excised (Fig. 22.26). A transfixion tie and suture ligature are placed on the infundibulopelvic ligament. The surgeon should not be reluctant to remove the fallopian tube separately from the ovary if taking them together risks loss of the tissue pedicle or injury to the ureter or nearby blood vessels.
Hemostasis A retractor or tagged sponge is placed into the peritoneal cavity, and each of the pedicles is visualized and inspected for hemostasis. If additional sutures are required, they should be placed precisely with care to avoid the ureter or bladder.

Peritoneal Closure Because the pelvic peritoneum does not provide support and reforms in 24 hours after surgery, the peritoneum need not be reapproximated routinely. If it is believed to be important, the anterior peritoneal edge is identified and grasped with forceps. A continuous absorbable 0-0 suture is begun at the 12-o’clock position. The suture is continued in a pursestring fashion and incorporates the distal portion of the left upper pedicle and the left uterosacral ligament (Fig. 22.27). Tension is applied to the suture placed at the beginning of the procedure that incorporates the posterior peritoneum and vaginal mucosa. This allows for high posterior reperitonealization, which shortens the cul-de-sac and thus helps to prevent future enterocoele formation. The right uterosacral ligament and the distal portion of the right upper pedicle are incorporated, and this continuous suture ends at the point on the anterior peritoneum where it was begun.

Vaginal Mucosa Closure The vaginal mucosa can be reapproximated in a vertical or horizontal manner, using either interrupted or continuous sutures (Fig. 22.28). The vaginal mucosa is, in this case, reapproximated horizontally with interrupted absorbable sutures.

Bladder Drainage After completion of the procedure, the bladder is drained. Unless an anterior or posterior colporrhaphy or other reconstructive procedure is performed, a bladder catheter or vaginal packing is not mandatory.

Surgical Techniques for Selected Patients

Injection of Vaginal Mucosa The use of paracervical and submucosal injection of 20 to 30 mL of 0.5% lidocaine with 1:200,000 epinephrine before incision of the vaginal mucosa is believed by some to decrease postoperative pain and facilitate identification of surgical planes. There is no need to inject the cervix. Areas to be injected include the bladder pillars, lower portion of the cardinal ligament, uterosacral ligaments, and paracervical tissue. However, it has been shown that the incidence of cuff cellulitis and cuff abscess formation is increased when epinephrine is injected into the cervicovaginal mucosa.

Morcellation of the Large Uterus

Uterine morcellation is a well-known but often underutilized surgical procedure whereby the uterus is removed piecemeal. Several methods of uterine morcellation have been described (91), including hemisection or bivalving, wedge or “V” incisions, and intramyometrial coring. Before beginning any morcellation procedure, the uterine vessels must be ligated, and the peritoneal cavity must be entered.

When uterine hemisection or bivalving is performed, the cervix is split at the midline, and the uterus is cut into halves, which are removed separately (92,93). This method seems best suited for fundal, midline leiomyomas.

Wedge morcellation is best suited for anterior or posterior fibroids or for fibroids in the other broad ligaments (i.e., when the fibroids are away from the midline).
The cervix is amputated, and the myometrium is grasped with clamps. Wedge-shaped portions of myometrium are removed from the anterior or posterior uterine wall. The apex of the wedge is kept in the midline, thereby reducing the bulk of the myometrium. This process is repeated until the uterus can be removed or until a pseudocapsule of a fibroid can be grasped with a Leahy clamp or towel clip. Traction is then applied, and a "myomectomy" is performed.

When the intramyometrial coring technique is used, the myometrium above the site of the ligated vessels is incised parallel to the axis of the uterine cavity and serosa of the uterus. This incision is continued around the full circumference of the uterine body in a symmetrical fashion beneath the uterine serosa. Traction is maintained on the cervix, and the avascular myometrium is cut to allow the undisturbed endometrial cavity, with a thick layer of myometrium, to be delivered with the cervix. As a result, the inside of the uterus with its unopened endometrial cavity is brought closer to the operator. Incision of the lateral portions of the myometrium medial to the remaining attachment of the broad ligament results in considerable additional descent of the uterus and greatly increases the mobility of the uterine fundus. The uterus is converted from a globular to an elongated tissue mass. The cored uterus is removed by clamping the uteroovarian pedicle and fallopian tubes.

**McCall Culdoplasty**

A McCall culdoplasty has been thought by some surgeons to help decrease future enterocele formation (96). Whether this is accurate remains open to debate. An absorbable suture is placed through the full thickness of the posterior vaginal wall at the point of the highest portion of the vaginal vault. The patient’s left uterosacral ligament pedicle is grasped and sutured. The suture then incorporates the posterior peritoneum, between the uterosacral ligaments and the right uterosacral ligament. The suture is completed by passing the needle from the inside to the outside at the same point at which it was begun. The suture is tied, thereby approximating the uterosacral ligaments and the posterior peritoneum.

**Schuchardt Incision**

When vaginal exposure is difficult, the Schuchardt incision may be used (96). If the surgeon is right-handed, the incision is made on the patient’s left side. To decrease blood loss, the area can be infiltrated with lidocaine-containing epinephrine. The incision follows a curved line from the 4-o’clock position at the hymenal margin to a point halfway between the anus and the ischial tuberosity. The incision may be continued as high as necessary in the vaginal vault to gain exposure. The depth of the incision is the medial portion of the pubococcygeus muscle, which may be divided in extreme cases. The incision must be closed in layers at the completion of the procedure.

**Intraoperative Complications**

**Bladder Injury**

Injury to the urinary bladder is one of the most common intraoperative complications associated with hysterectomy. If the bladder is inadvertently entered, repair generally should be performed when the injury is discovered and not delayed until completion of surgery (84). When bladder injury is recognized, the edges of the wound should be mobilized to assess the full extent of the injury and to allow repair without tension. This assessment should include visualization of the trigone to exclude injury to that area. The bladder may then be repaired with a single- or double-layered closure with a small-caliber absorbable suture. Methylene blue or a dye of sterile milk formula can be instilled into the bladder to ensure that the repair is adequate.

**Bowel Injury**

Because patients with suspected pelvic adhesions or obvious pelvic disease are excluded as candidates for vaginal hysterectomy, bowel injuries do not often occur. Bowel injuries more often are associated with the performance of a posterior colporrhaphy and are usually confined to the rectum (84,96).

If the rectum is entered, the injury is repaired with a single- or double-layer closure using a small-caliber absorbable suture, followed by copious irrigation. Postoperatively, the patient should be given a stool softener and a low-residue diet.

**Hemorrhage**

Intraoperative hemorrhage invariably is the result of failure to ligate securely a significant blood vessel, bleeding from the vaginal cuff, slippage of a previously placed ligature, or avulsion of tissue before clamping (96). Most intraoperative bleeding can be avoided with adequate exposure and good surgical technique. Using square knots with attention to proper knot-tying mechanisms will prevent bleeding in most cases. Likewise, the use of Heaney-type sutures minimizes ligature slippage and subsequent bleeding. When bleeding does occur, blind clamping, which may endanger the ureter, should be avoided. The bleeding vessel should be identified and precisely ligated with visualization of the ureter if necessary. If the location of the ureter is in question, it should be visualized before suturing a bleeding vessel. Although excessive blood loss occasionally occurs despite these precautions, it should be infrequent.

**Perioperative Care**

**Bladder Drainage** Postoperative bladder drainage should be employed after any procedure in which spontaneous, complete voiding is not anticipated. Reasons to consider closed bladder drainage include significant local pain, additional vaginal reparative procedures, surgery for stress incontinence, the use of a vaginal pack, and patient anxiety.

After vaginal hysterectomy without additional repair, most patients can void spontaneously, and therefore, catheter drainage is not required. The relative amount of pain after a vaginal hysterectomy is less than with abdominal hysterectomy and, in the absence of additional repairs or a pack, no obstructive effect should be present.

If the patient does not tolerate pain well postoperatively or is extremely anxious, the transurethral insertion of a 16-Fr. catheter after completing surgery is warranted. A McCall culdoplasty has been thought by some surgeons to help decrease future enterocele formation (96). Measurements believed to reduce the incidence of wound infections include a preoperative shower, no removal of hair, or if hair removal is necessary, removal of hair with clippers in the operating room, use of adhesive drapes and prophylactic antibiotics, and delayed primary closure (see Chapter 19).

**Hemorrhage**

Immediately after hysterectomy, hemorrhage may become apparent in one of two ways (88). First, bleeding from the vagina may be noted by the nursing staff or physician within the first few hours after surgery. Second, and less commonly, the patient may be noted to have little bleeding from the vagina but deteriorating vital signs.
signs manifested by low blood pressure and rapid pulse, falling hematocrit level, and flank or abdominal pain. The first presentation usually is in the form of bleeding from the vaginal cuff or one of the pedicles. The second presentation may be a retroperitoneal hemorrhage. Each situation is approached differently in its evaluation and treatment, but both involve the same general principles of rapid diagnosis, stabilization of vital signs, appropriate fluid and blood replacement, and constant surveillance of the patient's overall condition (98).

After vital signs are assessed, attention should be directed to the amount of bleeding. A small amount of bleeding is expected after any vaginal hysterectomy. However, steadily bleeding 2 to 3 hours after surgery suggests lack of hemostasis. The patient should be taken promptly to the examining room, where the operative site is viewed using a large speculum and good lighting. If bleeding is not excessive, the vaginal cuff can be inspected, and in many instances, bleeding from the cuff edge will be found. Hemostasis can easily be achieved with one or two sutures placed through the mucosa.

If bleeding is excessive or appears to be coming from above the cuff, or if the patient is too uncomfortable to tolerate adequate examination, she should be taken to the operating room. General anesthesia should be administered and the vaginal operative site should be thoroughly explored. Any bleeding point may be sutured or ligated. However, bleeding that is coming from above the cuff or is extremely brisk usually cannot be controlled through the vaginal route. An exploratory laparotomy is necessary to examine the pelvic floor, identify and isolate the bleeding vessel, and achieve hemostasis. The ovarian vessels and uterine arteries should be thoroughly inspected because they often are the source of excessive vaginal bleeding. If it is difficult to localize bleeding to a specific pelvic vessel, ligation of the hypogastric artery may be necessary.

In the patient with little vaginal bleeding in whom vital signs have deteriorated, retroperitoneal hemorrhage should be suspected. Input and output should be monitored. Hematocrit assessment, along with cross-matching, should be performed immediately. Examination may reveal tenderness and dullness in the flank. In cases of intraperitoneal bleeding, abdominal distention may occur. Diagnostic radiologic studies can be used to confirm the presence of retroperitoneal or intraabdominal bleeding. Ultrasonography is one option for viewing low pelvic hematomas. CT provides better visualization of retroperitoneal spaces, however, and can delineate a hematoma.

If the patient's condition stabilizes rapidly with intravenous fluids, one of two approaches may be used for continued care. The first is to give the patient a transfusion and follow serial hematocrit assessments and vital signs. In many instances, retroperitoneal bleeding will tamponade and stop, forming a hematoma that may eventually be resorbed. The risk with this approach is that the hematoma will later become infected, necessitating surgical drainage. In some instances when the patient's condition is stable, radiologic embolization may be considered.

Another option is to perform abdominal exploratory surgery while the patient's condition is stable. This approach adds the morbidity of a second procedure but avoids the possibility of the patient's condition deteriorating with continued delay or the formation of a pelvic abscess. Once adequate exposure is obtained, the peritoneum over the hematoma should be opened, and the blood should be evacuated. All bleeding vessels should be identified and ligated. Again, if control of bleeding is difficult, consideration should be given to unilateral or bilateral ligation of the anterior division of the internal iliac artery. Once hemostasis is achieved, the pelvis should be drained using a closed system.

Urinary Tract Complications

Urinary Retention

Urinary retention after hysterectomy is an uncommon occurrence (32). If the urethra is unobstructed and retention occurs, it is usually the result of either pain or bladder atony resulting from anesthesia. Both are temporary effects.

If a catheter was not placed after surgery, retention can be relieved initially with the insertion of a Foley catheter for 12 to 24 hours. Most patients are able to void after the catheter is removed 1 day later. If the patient still has trouble voiding and urethral spasm is suspected, success often can be achieved with a skeletal muscle relaxant such as diazepam (2 mg twice a day). In most cases, waiting is the best course, and voiding usually occurs spontaneously.

Ureteral Injury

In patients who develop flank pain soon after vaginal hysterectomy, ureteral obstruction should be suspected. The incidence of ureteral injury is lower with vaginal hysterectomy than with abdominal hysterectomy (83). One risk factor for its occurrence is total uterine prolapse, in which the ureters are drawn outside the bony pelvis.

In a patient with flank pain in whom ureteral obstruction is suspected, intravenous pyelography and urinalysis should be performed (80). If obstruction is noted on intravenous pyelography, it is usually present near the ureterovesical junction. The first immediate step should be attempted passage of a catheter through the ureter under cystoscopic guidance. If a catheter can be passed through the ureter, it should be left in place for at least 4 to 6 weeks, allowing sutures to absorb and the obstruction to resolve. If the catheter cannot be passed through the ureter, the best course is to perform abdominal exploratory surgery and repair the ureter at the site of obstruction (79,80,81,82,83) and (84).

Vesicovaginal Fistula

Vesicovaginal fistulas occur most often after total abdominal hysterectomy for benign gynecologic disease (83). Intraoperative steps to avoid the formation of a vesicovaginal fistula include correct identification of the proper plane between the bladder and cervix, sharp rather than blunt dissection of the bladder, and care in clamping and suturing the vaginal cuff. The development of a postoperative vesicovaginal fistula after hysterectomy is rare; the incidence is as low as 0.2% (82,83).

Patients who have a postoperative vesicovaginal fistula develop a watery vaginal discharge 10 to 14 days after surgery. Some fistulas resulting from surgery are noted as early as the first 48 to 72 hours after surgery (84). After vaginal examination with a speculum, the diagnosis can usually be confirmed with the insertion of a cotton tampon into the vagina followed by the instillation of methylene blue or indigo carmine dye through a transurethral catheter. If the tampon stains blue, a vesicovaginal fistula is present. If no staining occurs, however, the presence of a ureterovaginal fistula must be ruled out by the intravenous injection of 5 mL of indigo carmine dye. Within 20 minutes, the tampon should stain blue if a ureterovaginal fistula is present. Intravenous pyelography should also be performed to rule out ureteral obstruction.

If a vesicovaginal fistula is diagnosed, a Foley catheter should be inserted for prolonged drainage. As many as 15% of fistulas spontaneously close with 4 to 6 weeks of continuous bladder drainage. If closure has not occurred by 6 weeks, operative correction is necessary. Waiting 3 to 4 months from the time of diagnosis before operative repair is recommended to allow reduction of inflammation and to improve vascular supply. After vaginal hysterectomy, the fistula site is above the bladder trigone and away from the ureters. Vaginal repair can be anticipated in most patients. The surgical correction is generally undertaken in a four-layered closure: the bladder mucosa, the seromuscular layer, the endopelvic fascia, and the vaginal epithelium.

Incidental cystotomy at the time of hysterectomy is more common than vesicovaginal fistula. When repaired correctly, cystotomy rarely results in the development of a fistula (82).

Prolapse of the Fallopian Tube

Posthysterectomy prolapse of the fallopian tube is a rare event and is often confused with granulation tissue at the vaginal apex (32). Predisposing factors for the development of fallopian tube prolapse include development of a hematoma and an abscess at the vaginal apex. As many as half of patients undergoing vaginal hysterectomy form some granulation tissue at the vaginal vault. In patients in whom granulation tissue persists after attempts to cauterize it or pain is experienced with attempts to remove it, fallopian tube prolapse should be suspected. A biopsy of the area is warranted and usually reveals tubal epithelium if a fallopian tube is present.

If fallopian tube prolapse is diagnosed, it should be repaired with surgery. In general, the surrounding vaginal mucosa should be opened and undermined widely. The tube is then ligated high and removed, followed by closure of the vaginal mucosa.
Discharge Instructions

Before discharging the patient, instructions should be reviewed. Printed postoperative instructions are helpful to the patient and should include the following information:

1. Avoid strenuous activity for the first 2 weeks and increase activity level gradually.
2. Avoid heavy lifting, douching, or sexual intercourse until instructed by the physician.
3. Bathe as needed using shower or tub baths.
4. Follow a regular diet.
5. Avoid straining for a bowel movement or urination. For constipation, use Copenhaver EH.
6. Call the physician if excessive vaginal bleeding or fever occurs.
7. Schedule a return appointment at the time specified by the physician.

The physician should provide telephone numbers for emergencies both during and after office hours. Typically, the first postoperative visit is scheduled about 4 weeks after discharge from the hospital. At the time of that visit, the patient should be ambulating well, and vaginal discharge or bleeding should be minimal. Speculum examination of the cervical margin is not necessary, but the patient should be assured that the healing process is proceeding normally. Finally, the patient's questions should be answered, and advice should be given on increasing her activity level, including sexual activity, work, and normal household activity.

Psychosomatic Aspects

The decision to proceed with hysterectomy should be made jointly by the patient and her physician. Factors leading a patient or her physician to choose hysterectomy and reasons that patients with similar conditions choose different treatments are uncertain. For many patients, the decision to undergo hysterectomy may be sudden. They face the potential risks of anesthesia and surgery, and, if premenopausal, they must also cope with the loss of menstruation and the ability to procreate. Many women are concerned that the procedure will result in a loss of femininity, a decrease in sexual satisfaction, or an increase in interpersonal problems with their spouses. The concern over the loss of the reproductive tract is greater than that related to the loss of other intraabdominal organs (99). To minimize the possibility that the patient has a poor outcome, preoperative counseling and preparation are essential.

Drellich and Bierer studied 23 women after hysterectomy. Most of these women regretted the loss of menstruation, which was true even for women who had experienced dysmenorrhea (110). Several of these women viewed the menstrual cycle as a way to “rid itself of waste,” and they felt better after the menstrual phase of their cycle.

Depression

There is wide variation in women’s responses to hysterectomy. Most studies suggest that there is little evidence that hysterectomy increases the risk for depression. Some investigators have observed an increased incidence of psychiatric symptoms and an increased incidence of psychiatric symptoms and depression after hysterectomy (101,102). Hollander reported that almost twice as many women were admitted to a psychiatric hospital after pelvic operations compared with other types of surgery (103). However, other authors have not found such an association (104), and some report a decrease in symptoms after hysterectomy (105,106,107,108 and 109). The impact of hysterectomy on the development of depression is unknown because most studies are retrospective and not well controlled for preoperative depression (see Chapter 12).

Patients who had a moderate amount of preoperative anxiety do much better postoperatively than patients with little or no anxiety or patients who had an exaggerated response (109). Both long delays before surgery and a very short time before surgery increase patients’ anxiety. Thus, women should be scheduled for surgery several weeks in advance to avoid this problem (110). Women who planned to have children in the future had more problems during the immediate postoperative period. The patient’s response to previous loss (e.g., death of family members) predicted her response after hysterectomy (111).

Sexuality

The incidence of sexual dysfunction after hysterectomy ranges from 10% to 40%. Estimates vary based on study variations, cultural definitions, and the definitions used to determine the diagnosis. Some report a decrease in libido after hysterectomy, whereas others suggest that libido is increased because of caused by the reduced fear of unwanted pregnancy (102,112). Humphreys found that most patients do not have a change in their sexual practices after hysterectomy (113), whereas others report a deterioration of sexual relations (114). Preoperative anxiety about sexual functioning is often associated with an overall deterioration of sexual relations (115).

The literature supports that hysterectomy does not cause psychiatric sequelae or diminished sexual functioning in most patients. The best predictor of satisfaction after hysterectomy is the patient’s preoperative understanding of the procedure. The best predictor of postoperative sexual functioning is the patient’s preoperative sexual satisfaction. Preoperatively, these issues should be discussed with the patient, and her questions and concerns should be addressed to decrease the fear and anxiety associated with surgery.

9. Drellich and Bieber studied 23 women after hysterectomy. Most of these women regretted the loss of menstruation, which was true even for women who had experienced dysmenorrhea (110). Several of these women viewed the menstrual cycle as a way to “rid itself of waste,” and they felt better after the menstrual phase of their cycle.
Puberty is defined as the period during which secondary sexual characteristics begin to develop and the capability of sexual reproduction is attained. The physical changes accompanying pubertal development result directly or indirectly from maturation of the hypothalamus, stimulation of the sex organs, and secretion of sex steroids. Hormonally, puberty in humans is characterized by the resetting of the classic negative gonadal steroid feedback loop, alterations in circadian and ultradian (frequent) gonadotropin rhythms, and the acquisition in the woman of a positive estrogen feedback loop, which controls the monthly rhythm as an interdependent expression of gonadotropins and ovarian steroids.

The ability to evaluate and treat aberrations of pubertal development requires an understanding of the normal hormonal and physical changes that occur at puberty. An understanding of these changes is also important in evaluating young women with amenorrhea.

Normal Pubertal Development

Factors Affecting Time of Onset

The major determinant of the timing of the onset of puberty is no doubt genetic, but a number of other factors appear to influence both the age at onset and the progression of pubertal development. Among these influences are nutritional state, general health, geographic location, exposure to light, and psychological state (1). The concordance of the age of menarche in mother–daughter pairs and between sisters and in ethnic populations illustrates the importance of genetic factors (1). Typically, the age of menarche is earlier than average in children with moderate obesity (up to 30% above normal weight for age), whereas delayed menarche is common in those with severe malnutrition. Children who live in urban settings, closer to the equator, and at lower altitudes typically begin puberty earlier than those who live in rural areas, farther from the equator, and at higher elevations. Blind girls apparently undergo menarche earlier than sighted girls, suggesting some influence of light (2).

In western Europe, the age of menarche declined 4 months each decade between 1850 and 1960 (1). Recent data suggest that the trend toward earlier pubertal development is continuing among girls (but not boys) who live in the United States (3). It has been presumed that these changes represent improved nutritional status and healthier living conditions.

One of the more controversial hypotheses has centered on the role of total body weight and body composition on the age of menarche. Frisch has argued that a girl must reach a critical body weight (47.8 kg) before menarche (4). More importantly, body fat must increase to 23.5% from the typical 16% of the prepubertal state, which presumably is influenced by nutritional status (5). This hypothesis is supported by observations that menarche occurs earliest in obese girls, followed by normal-weight girls, then underweight girls, and lastly anorectic girls (Fig. 23.1). The importance of other factors is indicated by observations that menarche is often delayed in morbidly obese girls, those with diabetes, and those who exercise intensely but are of normal body weight and body fat percentage. Moreover, girls with precocious puberty may undergo menarche even if they have a low body fat percentage, and other girls show no pubertal development with a body fat percentage of 27% (6). The hypothesis linking menarche to body weight and composition does not always seem valid because menarche is a late event in pubertal development.

Figure 23.1 Normal twins at 12 years of age. The heavier twin (weighing 143 lb) is clearly more advanced in puberty than the lighter twin (weighing 87 lb). Anecdotal photographs and data such as these served to provide the basis for the theory that body fat, body mass, and menarche are linked. (From Wilkins L. The diagnosis and treatment of endocrine disorders in childhood and adolescence. 3rd ed. Springfield, IL:Charles C. Thomas, 1965:216, with permission.)
Physical Changes during Puberty

The changes associated with puberty occur in an orderly sequence over a definite time frame. Any deviation from this sequence or time frame should be regarded as abnormal. Moreover, the pubertal changes, their relationships to each other, and the ages at which they occur are distinctly different in girls and in boys. Although this chapter focuses on girls, changes in boys are considered briefly as well.

Tanner Stage

In girls, pubertal development typically requires 4.5 years (Fig. 23.2). Although generally the first sign of puberty is accelerated growth, breast budding is usually the first recognized pubertal change, followed by the appearance of pubic hair, peak growth velocity, and menarche. The stages initially described by Marshall and Tanner are often used to describe breast and pubic hair development.

With regard to breast development (Fig. 23.3), Tanner stage 1 refers to the prepubertal state and includes no palpable breast tissue, with the areolae generally less than 2 cm in diameter. The nipples may be inverted, flat, or raised. In stage 2, breast budding occurs, with a visible and palpable mound of breast tissue. The areolae begin to enlarge, the skin of the areolae thins, and the nipple develops to varying degrees. Stage 3 is reflected by further growth and elevation of the entire breast. When the individual is seated and viewed from the side, the nipple is generally at or above the midplane of breast tissue. In most girls, stage 4 is defined by projection of the areola and papilla above the general breast contour in a secondary mound. Breast development is incomplete until Tanner stage 5, in which the breast is mature in contour and proportion. In most women, the nipple is more pigmented at this stage than earlier in development, and Montgomery’s glands are visible around the circumference of the areola. The nipple is generally below the midplane of breast tissue when the woman is seated and viewed from the side. Full breast development usually occurs over 3 to 3.5 years but may occur in as little as 2 years or not progress beyond stage 4 until the first pregnancy. Breast size is no indication of breast maturity.

Pubic hair staging is related both to quantity and distribution (Fig. 23.4). In Tanner stage 1, there is no sexually stimulated pubic hair present, but some nonsexual hair may be present in the genital area. Tanner stage 2 is characterized by the first appearance of coarse, long, crinkly pubic hair along the labia majora. In Tanner stage 3, coarse, curly hair extends onto the mons pubis. Tanner stage 4 is characterized by adult hair in thickness and texture, but the hair is not distributed as widely as in adults and typically does not extend onto the inner aspects of the thighs. Except in certain ethnic groups, including Asians and American Indians, pubic hair extends onto the thighs in Tanner stage 5.

The staging of male pubertal sexual maturation is based on genital size and pubic hair development. Tanner stage 1 is prepubertal. Tanner stage 2 of genital growth begins when testicular enlargement is first evident. Testis length along the longitudinal axis ranges from 2.5 to 3.2 cm. The size of the penis increases as well. Pigmented, curly pubic hair is first visible around the base of the penis. In Tanner stage 3, there is further growth of the penis in both length and diameter, the scrotum
develops further, and testis length increases to 3.3 to 4 cm. Thicker, curly hair extends above the penis. Tanner stage 4 involves further growth of the genitalia, with testis length ranging from 4 to 4.5 cm. Extension of pubic hair over the genital area continues, but the volume is less than in the adult. At this stage, the prostate gland is palpable by rectal examination. In Tanner stage 5, the genitalia are within the adult range in size. Stretched penile length measured along the dorsum averages 15.7 cm in adult men. Pubic hair spreads laterally onto the medial thighs. Hair may or may not extend from the pubic area toward the umbilicus and anus.

Pigmented pubic hair is often the first recognized sign of male puberty even though it typically occurs 6 months after genital growth begins. Tanner stage 3 puberty is often accompanied by symmetric or asymmetric gynecomastia, and mature sperm first can be identified with microscopic urinalysis.

Height and Growth Weight

Plotting height increments (i.e., growth velocity) against the phases of puberty allows one to see relationships during puberty (Fig. 23.2). Girls reach peak height velocity early in puberty before menarche. As a consequence, they have limited growth potential after menarche. In contrast, boys reach peak height velocity about 2 years later than girls. Boys grow an average of 28 cm during the growth spurt, in comparison to a mean of 25 cm for girls. Adult men eventually are an average of 10 cm taller than adult women largely because they are taller at the onset of the growth spurt. Hormonal control of the pubertal growth spurt is complex. Growth hormone, insulin-like growth factor 1 (IGF-1), and gonadal steroids play major roles. Adrenal androgens appear to be less important.

During the growth spurt associated with puberty, the long bones in the body lengthen, and the epiphyses ultimately close. The bone or skeletal age of any individual can be estimated closely by comparing x-rays documenting the development of bones in the nondominant hand (most commonly), knee, or elbow to standards of maturation for the normal population. The Greulich and Pyle atlas (8) is used most often for this purpose. Skeletal age is more closely correlated with pubertal stage than with chronologic age during puberty. With height and chronologic age, an individual's bone age can be used to predict final adult height using the Bayley-Pinneau tables (9).

Another practical clinical approach to predicting adult height uses midparental height. The adjusted midparental height is calculated by adding 13 cm to the mother's height (for boys) or subtracting 13 cm from the father's height (for girls) and then determining the mean of the heights of the parents, including the adjusted height of the opposite-sex parent. Adding and subtracting 6.5 cm to the calculated predicted height approximates the target range of the third to the ninety-seventh percentile for the anticipated adult height of the child. This quick calculation can be of assistance in evaluating individuals with delayed or precocious pubertal development and those with short stature.

Several changes in body composition also occur during pubertal development. Although lean body mass, skeletal mass, and body fat are equal in prepubertal boys and girls, by maturity, men have 1.5 times the lean body mass and almost 1.5 times the skeletal mass of women, whereas women have twice as much body fat as men (1). The changes in body contour in girls, with accumulation of fat at the thighs, hips, and buttocks, occur during the pubertal growth spurt. Voice and other changes also are associated with the changes in body composition.

Hormonal Changes

By 10 weeks of gestation, gonadotropin-releasing hormone (GnRH) is present in the hypothalamus, and luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are present in the pituitary gland (10). Gonadotropin levels are elevated in both female and male fetuses before birth; the levels of FSH are higher in females. At birth, gonadotropin and sex steroid concentrations are still high, but the levels decline during the first several weeks of life and remain low during the prepubertal years. The hypothalamic–pituitary–pituitary unit appears to be suppressed by the extremely low levels of gonadal steroids present in childhood. Gonadal suppression of gonadotropin secretion is demonstrated by higher gonadotropin levels in children with gonadal dysgenesis and those who undergo gonadectomy before puberty (11).

Several of the hormonal changes associated with pubertal development begin before any of the physical changes are obvious. Early in puberty, there is increased sensitivity of LH to GnRH. Sleep-entrained increases in both LH and FSH can be documented early in puberty (12). In boys, the nocturnal increases in gonadotropin levels are accompanied by simultaneous increases in circulating testosterone levels (13). In contrast, in girls, the nighttime increases in circulating gonadotropin levels are followed by increased secretion of estradiol the next day (14) (Fig. 23.5). This delay in estradiol secretion is believed due to the additional synthetic steps required in the aromatization of estrogens from androgens. Basal levels of both FSH and LH increase through puberty. The patterns differ in boys and girls, with LH levels (measured in mIU/mL) eventually becoming greater than FSH levels (15) (Fig. 23.6). Although it now appears that gonadotropins are always secreted in an episodic or pulsatile fashion, even before puberty, the pulsatile secretion of gonadotropins is more easily documented as puberty progresses and basal levels increase (16).

Figure 23.5 Patterns of circulating luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol in a stage 3 pubertal girl over a 24-hour period with the encephalographic stage of sleep indicated. (From Boyar RM, Wu RHK, Roffwarg H, et al. Human puberty: 24-hour estradiol patterns in pubertal girls. J Clin Endocrinol Metab 1976;43:1418–1421, with permission.)

Figure 23.6 Increases ± standard error) in circulating levels of gonadotropins and adrenal and gonadal steroids through puberty in girls. DHEA, dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulfate. (From Emans SJH, Goldstein DP. The physiology of puberty. In: Emans SJH, Goldstein DP, eds. Pediatric and adolescent gynecology. 3rd ed. Boston: Little, Brown, 1990:95, with permission.)

Increased adrenal androgen secretion is important in stimulating adrenarche, the appearance of pubic and axillary hair, in both boys and girls. Pubarche specifically refers to the appearance of pubic hair. Progressive increases in circulating levels of the major adrenal androgens, dehydroepiandrosterone (DHEA) and its sulfate (DHEAS), begin as early as 2 years of age, accelerate at 7 to 8 years of age, and continue until 13 to 15 years of age (17,18 and 19). The accelerated
Asynchronous pubertal development

Precocious puberty is characterized by pubertal development that deviates from the normal pattern of puberty. Although, as noted, increases in estradiol first appear during the daytime hours, basal levels increase during both the day and night. Estrone, which is secreted in part by the ovaries and arises in part from extraglandular conversion of estradiol and androstenedione, also increases early in puberty but plateaus by midpuberty. Thus, the ratio of estrone to estradiol decreases throughout puberty, indicating that ovarian production of estradiol becomes increasingly important and peripheral conversion of androgens to estrone becomes less important during maturation.

In boys, most of the testosterone in the circulation arises from direct secretion by the Leydig cells of the testis. Testosterone induces development of a male body habitus and voice change, whereas dihydrotestosterone (DHT), produced following 5α reduction within target cells, induces enlargement of the penis and prostate gland, beard growth, and temporal hair recession during puberty. Mean plasma testosterone levels rise progressively during puberty, with the greatest increase occurring during Tanner stage 2.

Mechanisms Underlying Puberty

The mechanisms responsible for the numerous hormonal changes that occur during puberty are poorly understood, although it is recognized that a “central nervous system program” must be responsible for initiating puberty. It appears that the hypothalamic–pituitary–gonadal axis in girls develops in two distinct stages during puberty. First, sensitivity to the negative or inhibitory effects of the low levels of circulating sex steroids present in childhood decreases early in puberty. Second, late in puberty, there is maturation of the positive or stimulatory feedback response to estrogen, which is responsible for the ovulatory midcycle surge of LH.

Current evidence suggests that the central nervous system inhibits the onset of puberty until the appropriate time. Based on this theory, the neuroendocrine control of puberty is mediated by GnRH-secreting neurons in the medial basal hypothalamus, which act together as an endogenous pulse generator. At puberty, the GnRH pulse generator is reactivated (i.e., disinhibited), leading to increased amplitude and frequency of GnRH pulses. In turn, the increased GnRH secretion results in increased gonadotropin and then gonadal steroid secretion. What causes this “disinhibition” of GnRH release is unknown.

Aberrations of Pubertal Development

Classification

Several aberrations of pubertal development, as detailed in Table 23.1, can occur in girls. Pubertal aberrations can be classified in four broad categories:

<table>
<thead>
<tr>
<th>Table 23.1. Aberrations of Pubertal Development</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Delayed or interrupted puberty exists in girls who fail to develop any secondary sex characteristics by age 13, have not had menarche by age 16, or have not attained menarche 5 or more years since the onset of pubertal development.</td>
</tr>
<tr>
<td>2. Asynchronous pubertal development is characterized by pubertal development that deviates from the normal pattern of puberty.</td>
</tr>
<tr>
<td>3. Precocious puberty has been defined as pubertal development beginning before the age of 7 years in white girls and before the age of 6 years in African American girls. This new definition is controversial and has been challenged because some feel that evaluation for breast or pubic hair development before 8 or 9 years of age, respectively, may be warranted. It is clear that in most cases, development nearer to the mean age of puberty is less likely to have a pathologic basis. Precocious pubertal development is characterized in several ways. In isosexual precocious puberty, the early changes are common to the phenotypic sex of the individual. In heterosexual precocious puberty, the development is characteristic of the opposite sex. Precocious puberty is sometimes termed “true” when it is of central origin with activation of the hypothalamic–pituitary–gonadal unit. In precocious pseudopuberty, also known as precocious puberty of peripheral origin, secretion of hormones in the periphery (commonly by neoplasms) stimulates pubertal development.</td>
</tr>
<tr>
<td>4. Heterosexual puberty is characterized by a pattern of development that is typical of the opposite sex occurring at the expected age of normal puberty.</td>
</tr>

</table>

Delayed or Interrupted Puberty

Disorders of sexual development and amenorrhea may be considered in relation to this classification of the aberrations of puberty. It is very helpful to document the growth of the individual and to plot the individual’s height and weight on one of several commonly available growth charts.

Figure 23.7 Growth chart showing stature by age percentiles for girls aged 2 to 18 years. Weight can be plotted in a similar fashion. Several excellent growth charts are available to clinicians, including those from Ross Laboratories (Columbus, OH), Serono Laboratories (Randolph, MA), and Genentech, Inc. (South San Francisco, CA). (From Hamill PVV, Drizd TA, Johnson CL, et al. Physical growth: National Center for Health Statistics percentiles. Am J Clin Nutr 1979;32:607–629, with permission; based on data from the National Center for Health Statistics.)
An approach to evaluation is depicted in Fig. 23.8.

**Figure 23.8 Flow diagram for the evaluation of delayed or interrupted pubertal development, including primary amenorrhea, in phenotypic girls.** Girls with asynchronous development often present because of failure to menstruate. (From Rebar RW. Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al, eds. Gynecology and obstetrics: a longitudinal approach. New York: Churchill Livingstone, 1993: 97–133.)

**Anatomic Abnormalities of the Genital Outflow Tract**

Those girls who have mature secondary sex characteristics and any of a number of disorders of the outflow tract and uterus, often termed müllerian agenesis and dysgenesis, are most often identified on examination (Fig. 23.9). One of the most logical classification schemes that has been proposed is shown in Table 23.2. The incidence of these anomalies was estimated to be 0.02% of the female population several years ago (24), but the incidence may have increased as a result of the maternal ingestion of diethylstilbestrol (DES) and the resultant increase in anomalies of the lumen of the uterus (class VI) (25). Of the disorders unrelated to drugs, the septate uterus (class V) is most common.

**Figure 23.9 Hysterosalpingograms of normal and abnormal female genital tracts.** The radiographic photographs have been reversed to accentuate the uterine cavities. A: Normal study with bilateral spill. B: Bicornuate uterus. C: Uterus didelphis. D: Uterus didelphis with double vagina. (Courtesy of Dr. A. Gerbie; from Spitzer IB, Rebar RW. Counselling for women with medical problems: ovary and reproductive organs. In: Hollingsworth D, Resnik R, eds. Medical counselling before pregnancy. New York: Churchill Livingstone, 1988:213–248, with permission.)

**Table 23.2. Classification of Müllerian Anomalies**

Disorders of the outflow tract and uterus often occur as a part of a syndrome of malformations that include abnormalities of the skeletal and renal systems (Rokitansky-Küster-Hauser syndrome). Familial aggregates of the most common disorders of müllerian differentiation in females—müllerian aplasia and incomplete müllerian fusion—are best explained on the basis of polygenic and multifactorial inheritance (26). It is clear that the HOX genes, a family of regulatory genes that encode for transcription factors, are essential for proper development of the müllerian tract in the embryonic period (27), and HOX A 13 has been found to be altered in hand–foot–genital syndrome.

The most common single anatomic disorder of puberty is the imperforate hymen, which prevents the passage of endometrial tissue and blood. These products can accumulate in the vagina (hydrocolpos) or uterus (hydrometrocolpos) and result in a bulging hymen that is often bluish in color. The affected individual often has a history of vague abdominal pain with approximately monthly exacerbations. It is sometimes difficult to distinguish an imperforate hymen from a transverse vaginal septum, and in most situations, examination under anesthesia is required.

Regardless of the cause, uterine anomalies not involving segmental müllerian agenesis or hypoplasia (class I) are compatible with normal pregnancy. However, increased fetal wastage has been reported (28). Uterine malformations have been associated with spontaneous abortion, premature labor, abnormal presentations, and complications of labor (i.e., retained placenta). Many of these uterine anomalies can be identified with hysterosalpingography (Fig. 23.9). Hysterosalpingography, laparoscopy, and hysteroscopy have been used to differentiate a septate uterus (class V) from a bicornuate uterus (class IV). It is now clear that magnetic resonance imaging (MRI) and endovaginal ultrasonography (sometimes with sonohysterography) are as accurate as these invasive techniques in identifying the abnormality (29).

Obstruction or malformation of the distal genital tract must be distinguished from androgen insensitivity. Individuals with androgen insensitivity have breast development in the absence of significant pubic and axillary hair development; the vagina may be absent or foreshortened in these women.

**Hypergonadotropic and Hypogonadotropic Hypogonadism**

Basal levels of FSH and prolactin should be determined in individuals in whom secondary sex characteristics have not developed to maturity (Fig. 23.8). Bone age should be estimated from x-rays of the nondominant hand. If prolactin levels are elevated, thyroid function should be assessed to determine whether the individual has primary hypothyroidism. Paradoxically, primary hypothyroidism can result in precocious puberty as well. If thyroid function is normal, a hypophalamic or pituitary
neoplasm is possible, and careful evaluation of the hypothalamic and pituitary area by MRI or computed tomography (CT) is indicated.

The karyotype should be determined in any individual with delayed puberty and increased basal FSH concentrations. Regardless of the karyotype, the individual with hypergonadotropic hypogonadism has some form of ovarian "failure."

**Forms of Gonadal Failure**

**Turner's Syndrome** Most affected individuals have a 45X karyotype and Turner's syndrome; still others have mosaic karyotypes (i.e., 45X/46XX; 45X/46XY) and may present with the Turner's phenotype as well. Intrauterine growth restriction is common in infants with a 45X karyotype. After birth, these patients generally grow slowly, beginning in the second or third year of life. They typically have many of the associated stigmata, including lymphedema at birth; a webbed neck; multiple pigmented nevi; disorders of the heart, kidneys (most commonly horseshoe), and great vessels (most commonly coarctation of the aorta); and small hyperconvex fingernails (32) (Fig. 23.10). Diabetes mellitus, thyroid disorders, essential hypertension, and other autoimmune disorders are often present in individuals with 45X karyotypes. Most 45X patients have normal intelligence, but many affected individuals have an unusual cognitive defect characterized by an inability to appreciate the shapes and relations of objects with respect to one another (i.e., space-form blindness). As they grow older, affected children typically are shorter than normal. Although they do not develop breasts at puberty, some pubic or axillary hair may develop because appropriate adrenarche can occur with failure of thelarche (i.e., breast development). Although less severe short stature and some adolescent development may occur with chromosomal mosaicism, it is reasonable to assume that any short, slowly growing, sexually infantile girl has Turner's syndrome until proved otherwise because this disorder is so prevalent (about 1 in 2,500 newborn phenotypic females). In fact, the 45X karyotype is the single most frequent chromosomal disorder in humans, but most affected fetuses are aborted spontaneously early in pregnancy. However, trisomy is the most common chromosomal type or category of abnormality in first-trimester losses.

![Figure 23.10 Typical appearance of two individuals with 45X gonadal dysgenesis. A: This 16-year-old individual has obvious short stature, a webbed neck, shortened fourth metatarsals, and a thoracotomy scar from the repair of the coarctation of the aorta that was performed at 13 years of age. B: This 13-year-old individual had evidence of adrenarche with some pubic and axillary hair development. She is quite short, but the stigmata of Turner's syndrome are less obvious than in the patient in A.](image)

Even in the presence of typical Turner stigmata, a karyotype is indicated to eliminate the possibility of any portion of a Y chromosome. If a Y chromosome is identified, surgical extirpation of the gonads is warranted to eliminate any possibility of a germ cell neoplasm (estimated 20% to 30% prevalence) (31,32). In individuals in whom there is no evidence of neoplastic dissemination, the uterus may be left in situ for donor in vitro fertilization and embryo transfer. The evaluation of other commonly involved organ systems should include a careful physical examination, with special attention to the cardiovascular system, and thyroid function tests (including antibody assessment), fasting blood glucose, renal function tests, and intravenous urography or a renal ultrasonography.

**Treatment of Turner's Syndrome** To increase final adult height, treatment strategies using exogenous growth hormone (GH) are commonly accepted (33). It is not yet known what dose of GH is optimal or if an anabolic steroid such as oxandrolone will provide additional growth. However, GH in doses 25% greater than those recommended for GH deficiency are proving safe and effective, with a net increase in height of about 8.1 cm over the average height of about 146 cm in untreated individuals.

The treatment of patients with Turner's syndrome is as follows:

1. To promote sexual maturation, therapy with exogenous estrogen should be initiated when the patient is psychologically ready, at about 12 to 13 years of age, and after GH therapy is completed.
2. Because the intent is to mimic normal pubertal development, therapy with low-dose estrogen alone (such as 0.3 to 0.625 mg conjugated estrogens orally each day) should be initiated.
3. Progestins (5 to 10 mg medroxyprogesterone acetate or 200 mg micronized progesterone orally for 12 to 14 days every 1 to 2 months) can be added to prevent endometrial hyperplasia after the patient first experiences vaginal bleeding or after 6 months of unopposed estrogen use if the patient has not yet had any bleeding.
4. The dose of estrogen is increased slowly over 1 to 2 years until the patient is taking about twice as much estrogen as is administered to postmenopausal women.
5. Girls with gonadal dysgenesis must be monitored carefully for the development of hypertension with estrogen therapy.
6. The patients and their parents should be counseled regarding the emotional and physical changes that will occur with therapy.

**Mosaic Forms of Gonadal Dysgenesis** Individuals with rare mosaic forms of gonadal dysgenesis may develop normally at puberty. The decision to initiate therapy with exogenous estrogen should be based mainly on circulating FSH levels because FSH levels in the normal range for the patient's age imply the presence of functional gonads.

Pregnancies can be achieved in these individuals, with success rates of more than 50%, by using donor oocytes (34).

**Pure Gonadal Dysgenesis** The term, pure gonadal dysgenesis refers to 46XX or 46XY phenotypic females who have streak gonads. This condition may occur sporadically or may be inherited as an autosomal recessive trait or as an X-linked trait in XY gonadal dysgenesis (Fig. 23.11). Affected girls are typically of average height and have none of the stigmata of Turner's syndrome, but they have elevated levels of FSH because the streak gonads produce neither steroid hormones nor inhibit. When gonadal dysgenesis occurs in 46XY individuals, it is sometimes termed Swyer's syndrome. Surgical extirpation is warranted in individuals with a 46XY karyotype to prevent development of germ cell neoplasms. Both 46XX and 46XY forms of gonadal dysgenesis benefit from exogenous estrogen and are potential candidates for donor oocytes.
Several different tumors of the hypothalamic and pituitary regions may also lead to hypogonadotropic hypogonadism. The small amount of breast development (Tanner stage 2) is unusual, but some pubertal development may occur in such patients.

**Figure 23.12**

A 16-year-old individual with 46XX gonadal dysgenesis and primary amenorrhea. Circulating follicle-stimulating hormone (FSH) levels were markedly elevated. The small amount of breast development (Tanner stage 2) is unusual, but some pubertal development may occur in such patients. B: A 16-year-old individual with 46XY gonadal dysgenesis who presented with primary amenorrhea and markedly elevated FSH levels. Most affected individuals do not present with as much pubic and axillary hair development. The right gonad contained a dysgerminoma, but there was no evidence of metastases. (From Rebar RW. Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al, eds. Gynecology and obstetrics: a longitudinal approach. New York: Churchill Livingstone, 1993:97–133, with permission.)

In early gonadal failure, the ovaries appear to develop normally but contain no oocytes by the expected age of puberty. These disorders are considered further in the discussion delineating the evaluation of amenorrhea (see [Chapter 24](#)).

### Hypogonadotropic Hypogonadism

**Hypothalamic–pituitary disturbances** are usually associated with low levels of circulating gonadotropins (with both LH and FSH <10 mIU/mL) ([35](#)). There are both sporadic and familial causes of hypogonadotropic hypogonadism, and the differential diagnosis is extensive. Mutations in several genes have been shown to cause hypogonadotropic hypogonadism in humans ([36](#)). This condition can arise from abnormalities in hypothalamic GnRH secretion, impaired release of gonadotropins from the pituitary gland, or both. At least four genes have been identified as causes of hypogonadotropic hypogonadism: (a) KAL, (b) DAX 1 (the gene for X-linked congenital adrenal hypoplasia), (c) GNRIHR (the gene for the GnRH receptor), and (d) PC1 (the gene for prohormone convertase 1) ([37](#)). Because defects in these four genes account for less than 20% of all cases of isolated hypogonadotropic hypogonadism, additional mutations probably exist but have yet to be identified. It is important to remember, however, that low levels of LH and FSH are normally present in the prepubertal years; thus, girls with constitutionally delayed puberty may mistakenly be presumed to have hypogonadotropic hypogonadism. In fact, constitutional delay is the most common cause of delayed puberty. Constitutional delayed growth and adolescence can be diagnosed only after careful evaluation excludes other causes of delayed puberty and longitudinal follow-up documents normal sexual development. The farther below the third percentile for height that the young girl is, the less likely it is that the cause is constitutional.

**Kallmann’s Syndrome** As originally described in 1944 ([38](#)), Kallmann’s syndrome consisted of the triad of anosmia, hypogonadism, and color blindness in men. Women may be affected as well, and other associated defects may include cleft lip and palate, cerebellar ataxia, nerve deafness, and abnormalities of thirst and vasopressin release. Because autopsy studies have shown partial or complete agenesis of the olfactory bulb, the term olfactogenital dysplasia has also been used to describe the disorder. These anatomic findings coincide with embryologic studies documenting that GnRH neurons originally develop in the epithelium of the olfactory placode and normally migrate into the hypothalamus ([39](#)). In some affected individuals, gene defects have been found in one protein, anosmin, that facilitates this neuronal migration, thus leading to an absence of GnRH neurons in the hypothalamic and olfactory bulbs and consequent hypogonadotropic hypogonadism and anosmia (Kallmann’s syndrome) ([40](#)). The gene defect resulting in loss of this facilitatory adhesion protein has been localized to the X chromosome in an X-linked form of the syndrome, and this locus has been designated KAL1. Because confirmed mutations in the coding sequence of the KAL1 gene occur only in a minority of individuals with Kallmann’s syndrome ([41](#)), other mutations no doubt will be identified in the future. Moreover, the disorder is so heterogeneous that it appears likely that this disorder forms a structural continuum with other midline defects. Septo-optic dysplasia represents the most severe disorder.

Clinically, affected individuals typically present with sexual infantilism and an eunuchoid habitus, but some degree of breast development may occur ([Fig. 23.12](#)). Primary amenorrhea is the rule. The ovaries are usually small, with follicles seldom developing beyond the primordial stage. Circulating gonadotropin levels are usually very low but are almost invariably measurable. Affected individuals respond readily to pulsatile administration of exogenous GnRH, and clearly this is the most physiologic approach to ovulation induction ([34](#)). For women not seeking pregnancy, replacement therapy with exogenous estrogen and progestin is indicated.

**Isolated gonadotropin deficiency** can also occur in association with the Prader-Labhart-Willi syndrome, which is characterized by obesity, short stature, hypogonadism, small hands and feet (acromicria), mental retardation, and infantile hypotonia; and in association with the Laurence-Moon-Bardet-Biedl syndrome, which is characterized by retinitis pigmentosa, postaxial polydactyly, obesity, and hypogonadism. Prader-Labhart-Willi syndrome apparently results from rearrangements of chromosome 15q11 to q13, an imprinted region of the human genome ([42](#)). Laurence-Moon-Bardet-Biedl syndrome, inherited in an autosomal recessive manner, is apparently heterogeneous, with at least four involved gene loci having been mapped to date ([43](#)).

Multiple pituitary hormone deficiencies, which are usually hypothalamic in origin, may be congenital and either part of an inherited constellation of findings or sporadic. If growth hormone (GH) or thyroid-stimulating hormone (TSH) concentrations are subnormal, growth and pubertal development will be affected. Thus, the condition should be diagnosed before the age of puberty. Because individuals with hypogonadism may have a high mortality rate, predominantly caused by vascular and respiratory disease ([44](#)), it is important to identify affected individuals. Later age at diagnosis, female sex, and above all craniohypophysealgioma have been identified as significant independent risk factors. Untreated gonadotropin deficiency also is an important risk factor for early mortality.

**Tumors of the Hypothalamus and Pituitary** Several different tumors of the hypothalamic and pituitary regions may also lead to hypogonadotropic hypogonadism ([45](#)), except for craniopharyngiomas, these tumors are relatively uncommon in children. Craniopharyngiomas are usually suprasellar in location and may be asymptomatic well into the second decade of life. Such tumors may present as headache, visual disturbances, short stature or growth failure, delayed puberty, or diabetes insipidus. Visual field defects (including bilateral temporal hemianopsia), optic atrophy, or papilledema may be seen on physical examination. Laboratory evaluation should document hypogonadotropinism and may also reveal hyperprolactinemia as a result of interruption of hypothalamic dopamine inhibition of prolactin release. Radiographically, the tumor may be either cystic or solid and may show areas of calcification. Appropriate therapy for hypothalamic–pituitary tumors may involve surgical excision or radiotherapy (with adequate pituitary hormone replacement therapy) and is best decided by a team of physicians that includes an endocrinologist, a neurosurgeon, and a radiotherapist.
Obsessive-compulsive personality often characterized by overachievement. Relentless pursuit of thinness. Amenorrhea, sometimes preceding the weight loss. Distorted and bizarre attitude toward eating, food, or weight. Distorted body image.

Extreme inanition. Asynchronous Puberty

Figure 23.13 A: A 16-year-old girl with delayed puberty. Breast budding began at 11 years of age, but there was no further development. During the year before presentation, her scholastic performance in school deteriorated, she gained 25 lb, she became increasingly lethargic, and nocturia and polydypsia were noted. Initial evaluation documented low follicle-stimulating hormone, elevated prolactin, and a bone age of 10.5 years. Computed tomography scanning documented a large hypophthalmic neoplasm that proved to be an ectopic germinoma. The patient was also documented to be hypothyroid and hypoadrenale and to have diabetes insipidus. Despite the elevated prolactin, she had no galactorrhea because of the minimal breast development. (From Rebar RW. Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al, eds. Gynecology and obstetrics: a longitudinal approach. New York: Churchill Livingstone, 1993:97–133, with permission.) B: A 16-year-old girl with primary amenorrhea who progressed in puberty until about 12 years of age. Breast budding occurred at about 10 years of age. The patient’s short stature is obvious. She proved to have hypopituitarism. Classic radiographic findings established the diagnosis of Langerhans cell–type histiocytosis (Hand-Schüller-Christian disease).

Other Central Nervous System Disorders

Other central nervous system disorders that may lead to delayed puberty include infiltrative diseases, such as Langerhans-type histiocytosis, particularly the form known previously as Hand-Schüller-Christian disease (Fig. 23.13B). Diabetes insipidus is the most common endocrinopathy (because of infiltration of the supraoptic nucleus in the hypothalamus), but short stature resulting from GH deficiency, and delayed puberty caused by gonadotropin deficiency are not uncommon in this disorder (46). Irradiation of the central nervous system for treatment of any neoplasm or leukemia may result in hypothalamic dysfunction. Although GH deficiency occurs most often, partial or complete gonadotropin deficiency may develop in some patients. Severe chronic illnesses, often accompanied by malnutrition, may also lead to slowed growth in childhood and delayed adolescence. Regardless of the cause, weight loss to less than 80% to 85% of ideal body weight often results in hypothalamic GnRH deficiency. If adequate body weight and nutrition are maintained in chronic illnesses such as Crohn’s disease or chronic pulmonary or renal disease, sufficient gonadotropin secretion usually is present to initiate and maintain pubertal development.

Anorexia Nervosa and Bulimia

Significant weight loss and psychological dysfunction occur simultaneously with anorexia nervosa (47,48). Although many anorectic girls experience amenorrhea after pubertal development has begun, if the disorder begins sufficiently early, pubertal development may be delayed or interrupted (Fig. 23.14). The following constellation of associated findings confirms anorexia nervosa in most individuals:

1. Relentless pursuit of thinness
2. Amenorrhea, sometimes preceding the weight loss
3. Extreme anarthria
4. Obsessive-compulsive personality often characterized by overachievement
5. Disturbed and bizarre attitude toward eating, food, or weight
6. Disturbed body image

Because normal body weight is commonly maintained in bulimia, it is unusual for bulimic patients to experience either delayed development or amenorrhea. Girls with anorexia nervosa may have, in addition to hypogonadotropic hypogonadism, partial diabetes insipidus, abnormal temperature regulation, chemical hypothyroidism with low serum triiodothyronine (T3) and high reverse T3 levels, and elevated circulating cortisol levels in the absence of evidence of hypercortisolism (49).

Fear of obesity, a syndrome of self-induced malnutrition common among teenage gymnasts and ballet dancers, also may slow growth and delay pubertal development (50). These children voluntarily reduce their caloric intake as much as 40%, leading to nutritional growth retardation. Any additive role for endurance training in the delayed development is possible, but the mechanisms are unclear at this point. These conditions are essentially severe forms of hypothalamic amenorrhea. It is clear, however, that delayed puberty will occur inevitably unless adequate caloric intake is provided.

Hyperprolactinemia

Low levels of LH and FSH may be associated with hyperprolactinemia. As noted, galactorrhea cannot occur in the absence of complete breast development. Pituitary prolactinomas are rare during adolescence but must be considered when certain signs and symptoms are present. Many individuals with prolactinomas have a history of delayed menarche. The association between the ingestion of certain drugs (most often psychotropic agents and opiates in this age group) is well established. Primary hypothroidism also is associated with hyperprolactinemia because increased levels of thyrotropin-releasing hormone (TRH) stimulate secretion of prolactin. The empty sella syndrome, in which the sella turcica is enlarged but has been replaced by cerebrospinal fluid, may also be associated with hyperprolactinemia.

Asynchronous Puberty
Asynchronous pubertal development is characteristic of androgen insensitivity (i.e., testicular feminization). Affected individuals typically present with breast development (usually only to Tanner stage 3) out of proportion with the amount of pubic and axillary hair (Fig. 23.15). In this disorder, 46XY individuals have bilateral testes, female external genitalia, a blindly ending vagina (often foreshortened and sometimes absent), and no müllerian derivatives (i.e., uterus and fallopian tubes) (51). Infrequently, patients may have clitoral enlargement and labioscrotal fusion at puberty, which is referred to as incomplete androgen insensitivity.

Because the Sertoli cells of the testis make antimüllerian hormone (AMH), müllerian derivatives are absent in this disorder; thus, müllerian regression occurs normally. The testes may be normal in size and may be located anywhere along the path of embryonic testicular descent—in the abdomen, inguinal canal, or labia. Half of all individuals with androgen insensitivity develop inguinal hernias. Recognizing that most such girls will be 46XX, it is important to determine the karyotype in prepubertal girls with inguinal hernias, especially if a uterus cannot be detected with certainty by ultrasound.

The frequency of gonadal neoplasia is increased with this condition, but the extent is uncertain (31). Most clinicians believe the risk for neoplasia is low before 25 years of age; thus, the testes should be left in place until after pubertal feminization, especially because the risk for neoplasia appears to increase with age. Exogenous estrogen should be provided after gonadectomy.

The diagnosis is often suspected by the typical physical findings and strongly suggested by normal (or even somewhat elevated) male levels of testosterone, normal or somewhat elevated levels of LH, and normal levels of FSH. The diagnosis is confirmed by a 46XY karyotype.

Interacting with the patient and family requires sensitivity and care. It may be inadvisable to begin by informing the patient of the karyotype; the psychological implications may be devastating because the patient has been reared as a female. Family members should be informed initially that müllerian aplasia occurred and that the risk for neoplasia mandates gonadectomy after puberty. Because the disorder can be inherited in an X-linked recessive fashion, families should undergo appropriate genetic counseling and screening to identify the possible existence of other affected family members.

Precocious Puberty

Although precocious pubertal development may be classified in several ways, it is perhaps simplest to think of the development as gonadotropin dependent (in which case it is almost invariably of central origin) or gonadotropin independent (of peripheral origin). The evaluation of precocious puberty is as follows:

1. Measurement of basal gonadotropin levels is the first step in the evaluation of a child with sexual precocity (Fig. 23.16).

2. Thyroid function should also be evaluated to rule out primary hypothyroidism as the cause of precocious development.

3. High levels of LH (which really may be human chorionic gonadotropin detected because of cross-reactivity with LH in immunoassays) suggest a gonadotropin-producing neoplasm, most often a pinealoma (ectopic germinoma) or choriocarcinoma or, less often, a hepatoblastoma. (Gonadotropin-producing neoplasms are the only causes of precocious puberty in which the gonadotropin dependence does not equate with central precocious puberty.)

4. Low or pubertal levels of gonadotropins indicate the need to determine circulating estradiol concentrations in girls with heterosexual development and to assess androgen levels, specifically testosterone, dehydroepiandrosterone sulfate, and 17a-hydroxyprogesterone in girls with heterosexual development.

5. Increased estradiol levels suggest an estrogen-secreting neoplasm, probably of ovarian origin.

6. Increased testosterone levels suggest an androgen-producing neoplasm of the ovary or the adrenal gland. Such neoplasms may be palpable on abdominal or rectal examination. Increased 17a-hydroxyprogesterone levels are diagnostic of 21-hydroxylase deficiency (i.e., congenital adrenal hyperplasia [CAH]).

7. If the estradiol levels are compatible with the degree of pubertal development observed, evaluation of the central nervous system by MRI or CT scanning is warranted.

8. Bone age should always be assessed in evaluating an individual with sexual precocity.

Perhaps the most difficult decision for the gynecologist is determining how much evaluation is warranted for the young girl brought in by her mother for precocious breast budding only (precocious thelarche) or the appearance of pubic or axillary hair alone (precocious pubarche or adrenarche). In such cases, it is acceptable to many clinicians to follow the patient at frequent intervals and to proceed with evaluation if there is evidence of pubertal progression. The feasibility of this approach may depend on the concerns of the parents. Premature thelarche may be caused by increased sensitivity of the breasts to low levels of estrogen or to increased...
Constitutional sexual precocity is the most common cause of precocious puberty. It is often familial and represents the so-called “tail” of the gaussian curve (i.e., the early 2.5% for the age distribution for the onset of puberty).

Central (True) Precocious Puberty

In central precocious puberty, GnRH prematurely stimulates increased gonadotropin secretion. Central precocious puberty may occur in children in whom there is no structural abnormality, in which case it is termed constitutional or idiopathic. Alternatively, central precocious puberty may result from a tumor, infection, congenital abnormality, or traumatic injury affecting the hypothalamus. Tumors of the hypothalamus include hamartomas and, less frequently, neurogliomas and pinealomas. It appears that hamartomas control GnRH in a pulsatile manner and thus stimulate gonadotropin secretion (54) (Fig. 23.17). A number of congenital malformations, including hydrocephalus, crianiostenosis, arachnoid cysts, and septo-optic dysplasia, also can be associated with precocious puberty (as well as with sexual infantilism).

Figure 23.17 A 7½-year-old girl with Tanner stage 4 pubertal development who began menstruating 1 month earlier. She was 57 inches tall (above the ninety-fifth percentile). Luteinizing hormone and follicle-stimulating hormone levels were consistent with her development. A large neoplasm that proved to be a hypothalamic hamartoma was present on computed tomography scan. Pubertal development began at about 5 years of age.

Precocious Puberty of Peripheral Origin

In gonadotropin-independent precocious puberty, production of estrogens or androgens from the ovaries, adrenals, or rare steroid-secreting neoplasms leads to early pubertal development. Small functional ovarian cysts, typically asymptomatic, are common in children and may cause transient sexual precocity (55). Simple cysts (with a benign ultrasonographic appearance) can be observed and usually resolve over time. Of the various ovarian neoplasms that can secrete estrogens, granulosa-theca cell tumors occur most frequently but are still rare (56). Although such tumors may grow rapidly, more than two thirds are benign.

The McCune-Albright syndrome is characterized by polyostotic fibrous dysplasia of bone, irregular café-au-lait spots on the skin, and hyperfunctioning endocinopathies. Girls develop sexual precocity as a result of functioning ovarian cysts. Other endocinopathies may include hyperthyroidism, hypercortisolism, hyperprolactinemia, and acromegaly. It is now known that mutations of the GSβ subunit of the G protein, which couples extracellular hormonal signals to the activation of adenylate cyclase, are responsible for the autonomous hyperfunction of the endocrine glands and, presumably, for the other defects present in this disorder (57). Exposure to exogenous estrogens can mimic gonadotropin-independent precocious puberty. Ingestion of oral contraceptives, other estrogen-containing pharmaceutical agents, and estrogen-contaminated foods and the topical use of estrogens have been implicated in cases of precocious development in infants and children. Severe primary hyperprolactinism has also been associated with sexual precocity; associated hyperprolactinemia may result in galactorrhea in affected individuals.

Congenital Adrenal Hyperplasia

Heterosexual precocious puberty is always of peripheral origin and is most often caused by CAH. Three adrenal enzyme defects—21-hydroxylase deficiency, 11b-hydroxylase deficiency, and 3b-hydroxysteroid dehydrogenase deficiency—can lead not only to heterosexual precocity but also to virilization of the external genitalia because of increased androgen production beginning in utero (58). The clinical presentation of the various forms of CAH depend on (a) the affected enzyme, (b) the extent of residual enzymatic activity, and (c) the physiologic consequences of deficiencies in the end products and excesses of precursor steroids.

21-Hydroxylase Deficiency Most patients with classic CAH have 21-hydroxylase deficiency (Fig. 23.18). Neonatal screening suggests an incidence of about 1 in 15,000 births. This disorder is inherited as an autosomal recessive trait closely linked to the human leukocyte antigen (HLA) major histocompatibility complex on the short arm of chromosome 6. Thus, siblings with 21-hydroxylase deficiency usually have identical HLA types. There are various forms of 21-hydroxylase deficiency, including simple virilizing or classic (typically identified at birth because of genital ambiguity), salt-wasting (in which there is impairment of mineralocorticoid as well as glucocorticoid secretion), and late-onset or nonclassic (in which heterosexual development occurs at the expected age of puberty). All types involve alleles at the same locus. The nonclassic form is discussed in the following section on heterosexual pubertal development.

Figure 23.18 Left: A 10½-year-old girl with 21-hydroxylase deficiency before treatment. 17-Ketosteroid (KS) excretion was 34 mg/day. Right: The same patient after 9 months of therapy with cortisone (17-KS excretion: 4.6 mg/day). (From Wilkins L. The diagnosis and treatment of endocrine disorders in childhood and adolescence. 3rd ed. Springfield, IL: Charles C. Thomas, 1965:439, with permission.)

Deficiency of 21-hydroxylase results in the impairment of the conversion of 17α-hydroxyprogesterone to 11-deoxycorticisol and of progesterone to deoxycorticosterone (Fig. 23.19). As a consequence, precursors accumulate, and there is increased conversion to adrenal androgens. Because the development of the external genitalia is controlled by androgens, in the classic form of this disorder, girls are born with ambiguous genitalia, including an enlarged clitoris, fusion of the labioscrotal folds, and the urogenital sinus. The internal female organs (including the uterus, fallopian tubes, and ovaries) develop normally because they are not affected by the increased androgen levels. Almost two thirds of affected newborns rapidly develop salt-wasting 21-hydroxylase deficiency, hypokalemia, hyperkalemia, and hypertension. During childhood, untreated girls with either the classic or salt-wasting form grow rapidly but have advanced bone ages, enter puberty early, experience early closure of their epiphyses, and ultimately are short in stature as adults. CAH, with appropriate therapy, is the only inherited disorder of sexual
Some degree of insulin resistance may be present, even in the absence of overt glucose intolerance (62). Because circulating levels of estrogens are not diminished in PCO and androgen levels are only mildly elevated, affected girls become both feminized and somewhat overweight. In anovulatory women, estrone levels are typically greater than estradiol levels.

In some cases, menarche may be delayed, and primary amenorrhea also may occur. Some clinicians advocate measurement of 17a-hydroxyprogesterone in all women who develop hirsutism. Although values of 17a-hydroxyprogesterone are commonly elevated more than 100-fold in individuals with classic 21-hydroxyase deficiency, they may or may not be elevated in nonclassic late-onset forms of PCO. Because the normal menstrual cycle and the control of ovulation. In: Becker KL, ed. Principles and practice of endocrinology and metabolism. 2nd ed. Philadelphia: JB Lippincott, 1995:868–880, with permission.

Distinguishing PCO from the nonclassic forms of CAH is problematic and controversial (63, 64). The evaluation is as follows:

1. Some clinicians advocate measurement of 17a-hydroxyprogesterone in all women who develop hirsutism. Although values of 17a-hydroxyprogesterone are commonly elevated more than 100-fold in individuals with classic 21-hydroxyase deficiency, they may or may not be elevated in nonclassic late-onset forms of PCO.
the disorder.

2. Measurement of 17α-hydroxyprogesterone also can identify women with various forms of 11-hydroxylase deficiency.

3. Basal levels of DHEAS as well as 17α-hydroxyprogesterone may be moderately elevated in patients with PCO, making the diagnosis even more difficult.

4. To screen for CAH, 17α-hydroxyprogesterone should be measured in early morning.

5. In women with regular cyclic menses, it is important to measure 17α-hydroxyprogesterone only in the follicular phase because basal levels increase at midcycle and in the luteal phase.

Measurements of 17α-hydroxyprogesterone appear to be of value in populations at high risk for nonclassic late-onset 21-hydroxylase deficiency. In the white population, the gene occurs in only about 1 in 1,000 individuals, but it occurs in 1 in 27 Ashkenazi Jews, 1 in 40 Hispanics, 1 in 90 Yugoslavs, and 1 in 300 Italians (58). The incidence is also increased among Eskimos and French Canadians. Alternatively, screening might be restricted to hirsute teenagers presenting with the more “typical” features of nonclassic 21-hydroxylase deficiency, including severe hirsutism beginning at puberty, “flattening” of the breasts (i.e., defeminization), shorter stature than other family members, and increased DHEAS levels (between 5,000 and 7,000 ng/mL). Women with a strong family history of hirsutism or hypoplasia might be screened as well (35) (Fig. 23.21).

Figure 23.21 A 19-year-old girl with secondary amenorhea and severe acne and hirsutism beginning at the normal age of puberty. Stimulatory testing with corticotropin documented nonclassic 21-hydroxylase deficiency. Flattening of the breasts is apparent. She was shorter than her one sister and her mother.

**Basal Levels of 17α-Hydroxyprogesterone** Basal levels of 17α-hydroxyprogesterone higher than 800 ng/dL are virtually diagnostic of CAH. Levels between 300 and 800 ng/dL require stimulatory testing with corticotropin to distinguish between PCO and CAH. To complicate the situation even further, nonclassic 21-hydroxylase deficiency may occur even when basal levels of 17α-hydroxyprogesterone are below 300 ng/dL, thus requiring stimulatory testing in those cases as well.

**Cosyntropin Stimulation Test** The most commonly used stimulatory test involves measurement of 17α-hydroxyprogesterone 30 minutes after administration of a bolus of 250 mg of synthetic cosyntropin (Cortrosyn) (65). In normal women, this value seldom exceeds 400 ng/dL. Patients with classic 21-hydroxylase deficiency achieve peak levels of 3,000 ng/dL or higher. Patients with nonclassic 21-hydroxylase deficiency commonly achieve levels of 1,500 ng/dL or more. Heterozygous carriers achieve peak levels up to about 1,000 ng/dL. In hirsute women with hypertension, 11-deoxycortisol levels can be determined during the test. If both 11-deoxycortisol and 17α-hydroxyprogesterone levels are increased, the rare 11-hydroxylase deficiency is present. Only measurements of several steroid precursors after corticotropin stimulation can identify individuals with nonclassic forms of 3b-HSD deficiency.

The elevated levels of 17α-hydroxyprogesterone present in all forms of 21-hydroxylase deficiency are rapidly suppressed by administration of exogenous corticoids. Even a single dose of a glucocorticoid such as dexamethasone will suppress 17α-hydroxyprogesterone in CAH but not in virilizing ovarian and adrenal neoplasms.

**Hirsutism** It has been suggested that androgen-receptor blockade may be preferable to glucocorticoids as primary treatment of nonclassic 21-hydroxylase deficiency (66). Although menses usually (but not always) become regular shortly after beginning therapy with glucocorticoids, the hirsutism in this disorder has proved to be remarkably refractory to glucocorticoids.

Distinguishing nonclassic forms of CAH from idiopathic hirsutism also may be problematic. Individuals with idiopathic hirsutism have regular ovulatory menses, thus effectively eliminating PCO from consideration. Confusion can be created by the fact that some women with nonclassic CAH may continue to ovulate. Basal levels of 17α-hydroxyprogesterone are normal in idiopathic hirsutism, as is the response to ACTH stimulation. Idiopathic hirsutism represents enhanced androgen action at the hair follicle (67).

**Mixed Gonadal Dysgenesis**

The term mixed gonadal dysgenesis is used to designate those individuals with asymmetric gonadal development, with a germ cell tumor or a testis on one side and an undifferentiated streak, rudimentary gonad, or no gonad on the other side. Most individuals with this rare disorder have a mosaic karyotype of 45X/46XY and are raised as females who then virilize at puberty. Gonadectomy is indicated to remove the source of androgens and eliminate any risk for neoplasia.

**Reifenstein’s Syndrome**

Individuals who have rare forms of male pseudohermaphroditism, especially 5α-reductase deficiency (the so-called “penis at 12” syndrome) and the Reifenstein’s syndrome, generally have ambiguous female genitalia with variable virilization at puberty. Cushing syndrome, too, may occur rarely during the pubertal years, as may adrenal or ovarian androgen-secreting neoplasms.

**Genital Ambiguity at Birth**

Because of the concerns of the parents and the need to prevent life-threatening complications, the infant with genital ambiguity should be evaluated promptly. Evaluation and treatment is best conducted by a team of physicians. The initial evaluation is as follows:

1. Cytogenetic and endocrine studies should be initiated promptly. Use of specific probes for the Y chromosome and fluorescent in situ hybridization can assist in obtaining a karyotype within 48 hours. Probes for many specific inherited disorders are now available.

2. To exclude CAH, the most common cause of genital ambiguity, serum levels of sodium, potassium, and 17α-hydroxyprogesterone and urinary excretion of 17-ketosteroids, pregnanetriol, and tetrahydrodeoxycortisol should be measured. Infants should be monitored closely to prevent development of dehydration, hyponatremia, and hyperkalemia.

3. It has been suggested that antimüllerian hormone be measured in infants with genital ambiguity because it is elevated in males and undetectable in females in the first several years of life (68).

**Physical Signs**

During the 3 to 4 days required for evaluation, it is important to be supportive of the parents. Many clinicians believe that it is important not to attach any unusual significance to the genital ambiguity and to treat the abnormality as just another “birth defect.” Physicians should emphasize that the child should undergo normal psychosexual development regardless of the sex-of-rearing selected. Either a name compatible with either sex should be chosen or the naming of the infant should be delayed until the studies have been completed.

Although the diagnosis is not usually obvious on examination, there are some helpful distinguishing features (Fig. 23.22). In normal males, there is only a single
midline frenulum on the ventral side of the phallus; in normal females, there are two frenula lateral to the midline. A female with clitoral enlargement still has two frenula, and a male with hypospadias has a single midline frenulum or several irregular fibrous bands (chordee).

Figure 23.22 Two newborn girls with 46XX karyotypes and genital ambiguity. Both had clitoral hypertrophy, paired frenula, so-called scrotaization of the labia, and a common urogenital sinus (shown by the probe in B). Both were shown to have 21-hydroxylase deficiency. (From Rebar NW, Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al, eds. Gynecology and obstetrics: a longitudinal approach. New York: Churchill Livingstone, 1993:97–133, with permission.)

It is important to determine whether any müllerian derivatives are present. Recent studies suggest that MRI may be the most effective way of evaluating the infant for the presence of müllerian tissue (69).

The location or consistency of the gonad may be helpful in deducing its composition. A gonad located in the labial or inguinal regions almost always contains testicular tissue. A testis is generally softer than an ovary or a streak gonad and is more apt to be surrounded by blood vessels imparting a reddish cast. An ovary is more often white, fibrous, and convoluted. A gonad that varies in consistency may be an ovotestis or a streak gonad that has undergone neoplastic transformation. If a well-differentiated fallopian tube is present on only one side, the side without the tube probably contains a testis or ovotestis.

Diagnosis and Management

Although genital ambiguity is usually identified at birth, it may not be recognized for several years. Questions about changing the sex-of-rearing may arise. It has been believed that sex-of-rearing may be changed before 2 years of age without psychologically damaging the child, but experience with individuals with 5α-reductase deficiency, as well as other cases (e.g., McCune-Albright syndrome), indicates that surgery may be made after 2 years of age in certain instances (70). In any case, surgery for genital ambiguity to make the external genitalia (and development) compatible with the sex-of-rearing of the child is warranted but has not always been proved successful. Clitoral recession and clitorectomy are the most frequently performed surgical procedures.

It is possible to diagnose prenatally 21-hydroxylase deficiency in patients known to be at risk (58). The diagnosis is established by documenting elevated levels of 17α-hydroxyprogesterone or 21-deoxycortisol in amniotic fluid. Genetic diagnosis using specific probes and cells obtained by chorionic villus sampling or amniocentesis is also possible. Unfortunately, prenatal treatment of the fetus by administering dexamethasone to the mother is usually but not always successful in preventing genital ambiguity (71). Moreover, maternal complications, including hypertension, massive weight gain, and overt Cushing's syndrome, have been noted in about 1% of pregnancies in which low doses of dexamethasone were administered. Despite the risks and the nonuniformity of beneficial outcome to affected female fetuses, many parents may choose prenatal medical treatment because of the psychological impact of ambiguous genitalia.

Teratogens

It is important to recognize that ambiguous genitalia can result from the maternal ingestion of various teratogens, most of which are synthetic steroids (Table 23.3). Exposure to the teratogen must occur early in pregnancy, during genital organogenesis. Moreover, not all exposed fetuses manifest the same anomalies or even the presence of any anomalies. In principle, most synthetic steroids with androgenic properties, including weakly androgenic progestins, can affect female genital differentiation. However, the doses required to produce genital ambiguity are generally so great that the concern is only theoretical. The one agent that clearly can lead to genital ambiguity when ingested in clinically used quantities is danazol. There is no evidence that inadvertent ingestion of oral contraceptives, which contain relatively low doses of either mestranol or ethinyl estradiol and a 19-nor-steroid, results in virilization (72,73).

References

A complex hormonal interaction must take place in order for normal menstruation to occur. The hypothalamus must secrete gonadotropin-releasing hormone (GnRH) in a pulsatile fashion, which is modulated by neurotransmitters and hormones. The GnRH stimulates secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary, which promotes ovarian follicular development and ovulation. A normally functioning ovarian follicle secretes estrogen; after ovulation, the follicle is converted to a corpus luteum and progesterone is secreted in addition to estrogen. These hormones stimulate endometrial development. If pregnancy does not occur, estrogen and progesterone secretion decrease, and withdrawal bleeding begins. If any of the components (hypothalamus, pituitary, ovary, outflow tract, and feedback mechanism) are nonfunctional, bleeding cannot occur.

Primary amenorrhea is defined as the absence of menses by 16 years of age in the presence of normal secondary sexual characteristics, or by 14 years of age when there is no visible secondary sexual characteristic development. The definition represents approximately two standard deviations from the mean age when secondary sexual characteristic development and menstruation should occur. A woman who has previously menstruated can develop secondary amenorrhea, which is defined as absence of menstruation for three normal menstrual cycles or 6 months.

Patients may develop slight alterations in the hypothalamic–pituitary–ovarian axis that are not severe enough to cause amenorrhea but instead cause anovulation. Anovulatory patients usually have irregular menses and may bleed excessively during menstruation because estrogen is unopposed. This often occurs at the beginning and end of the reproductive years. Luteal phase defect is caused by minimal alterations in the hypothalamic–pituitary–ovarian axis, and patients have regular menses along with infertility or recurrent pregnancy loss. Except for amenorrhea from anatomic and chromosomal etiologies, luteal phase defects and anovulation have causes similar to those of amenorrhea, but the hypothalamic, pituitary, or ovarian hormonal dysfunction is less severe or of shorter duration than with amenorrhea.

In order to detect the cause of amenorrhea, it is useful to determine whether secondary sexual characteristics are present (Fig. 24.1). The absence of secondary sexual characteristics indicates that a woman has never been exposed to estrogen stimulation.

Amenorrhea without Secondary Sexual Characteristics

Although the diagnosis and treatment of disorders associated with hypogonadism have been discussed in Chapter 23, they will also be mentioned here because these conditions may cause primary amenorrhea. Abnormal findings on physical examination may suggest certain enzyme deficiencies (Fig. 24.1). Because these conditions are very rare, however, it is more clinically relevant to discuss the causes of amenorrhea on the basis of gonadotropin status.

Causes of Primary Amenorrhea

Hypergonadotropic Hypogonadism

Primary gonadal failure and the resulting impaired secretion of gonadal steroids is manifested by elevated levels of LH and FSH that result from decreased negative feedback. Gonadal failure as well as primary amenorrhea are most often associated with genetic abnormalities (Table 24.1). Approximately 30% of patients with primary amenorrhea have an associated genetic abnormality (1). The syndrome of gonadal dysgenesis, or Turner’s syndrome, and its variants represent the most common form of hypogonadism in women (see Chapter 23). Other disorders associated with primary amenorrhea include structurally abnormal X chromosomes, mosaicism, pure gonadal dysgenesis (46,XX and 46,XY with gonadal streaks), and 17a-hydroxylase deficiency. Individuals with these conditions have gonadal failure and cannot synthesize ovarian steroids. Therefore, gonadotropin levels are elevated because of the lack of negative estrogen feedback on the hypothalamic–pituitary axis. Patients with 17a-hydroxylase deficiency have primordial follicles, but gonadotropin levels are elevated because the enzyme deficiency...
In six Finnish families, an autosomal recessive single amino acid substitution in the extracellular domain of the FSH receptor gene has been identified. This mutation results in the absence of functional FSH receptors, leading to primary amenorrhea

Other Causes of Primary Ovarian Failure

Amenorrhea and premature ovarian failure can occur in association with irradiation of the ovaries, chemotherapy with alkylating agents, or combinations of radiation and other chemotherapeutic agents. In girls, galactosemia is often associated with premature ovarian failure, but usually it is

### Table 24.1 Amenorrhea Associated with a Lack of Secondary Sexual Characteristics

**Genetic Disorders**

**Gonadal Dysgenesis**

Turner's syndrome (45,X) is the most common chromosomal abnormality causing gonadal failure and primary amenorrhea. Turner's syndrome is discussed in Chapter 23.

**Partial Deletions of the X Chromosome**

Individuals with partial deletions of the X chromosome have the karyotype 46,XX with part of one of the X chromosomes missing. The phenotype is variable, depending on the amount and location of the missing genetic material. Patients with a deletion of part of the long arm of the X chromosome (Xq-) often exhibit sexual infantilism, normal stature, no somatic abnormalities, and streak gonads. Some patients may be eunuchoid in appearance and have delayed epiphyseal closure. Patients with a deletion of the short arm of the X chromosome (Xp) and patients with isochromosome of the long arm of the X chromosome, with or without mosaicism, usually are phenotypically similar to individuals with Turner's syndrome.

**Mosaicism**

Primary amenorrhea is associated with various mosaic states, the most common of which is 45,X/46,XX. As discussed in Chapter 23, the clinical findings in patients with 45,X/46,XX and 45,X/46,XX/47,XXX are similar to those in 45,X/46,XX and vary in estrogen and gonadotropin production, depending on the number of follicles in the gonads. When compared with the pure 45,X cell line, individuals with 45,X/46,XX are taller and have fewer abnormalities, although 80% of those with 45,X/46,XX mosaics are shorter than their peers and 66% have some somatic abnormalities. Spontaneous menstruation occurs in approximately 20% of these patients.

**Pure Gonadal Dysgenesis**

Pure gonadal dysgenesis refers to phenotypically female individuals who have sexual infantilism, primary amenorrhea, normal stature, and no chromosomal abnormalities (46,XX or 46,XY). The gonads are usually streaks, but there may be some development of secondary sexual characteristics as well as a few episodes of uterine bleeding. Mutations in the SRY (sex-determining region gene on the Y chromosome) have been identified in some XY females with gonadal dysgenesis.

**Enzyme Deficiencies**

**Congenital Lipoid Adrenal Hyperplasia**

Patients with this autosomal recessive disorder have an inability to convert cholesterol to pregnenolone, which is the first step in steroid hormone biosynthesis. A defect has not been found in the P450scc gene, which is the conversion enzyme responsible for this step in the pathway. Instead, 15 different mutations have been identified in the sterologenic acute regulatory protein that facilitates the transport of cholesterol from the outer to the inner mitochondrial membrane. This protein appears to be the rate-limiting step for steroid biosynthesis stimulated by tropic hormones. These patients in infancy suffer from hyperanorexia, hyperkalemia, and acidosis. Both XX and XY individuals are phenotypically female. With appropriate mineralocorticoid and glucocorticoid replacement, these patients can survive into adulthood. Patients who are XY do not have a uterus and remain sexually infantile without hormone replacement, whereas XX patients may acquire some secondary sexual characteristics at puberty but develop early ovarian failure as a result of accumulation of cholesterol in the ovaries.

**17a-Hydroxylase Deficiency**

17a-Hydroxylase deficiency may be associated with either 46,XX or 46,XY karyotypes. The uterus is absent in individuals with 46,XY karyotype, a feature distinguishing them from individuals with 46,XX karyotype. Individuals with 17a-hydroxylase deficiency have primary amenorrhea, no secondary sexual characteristics, hypertension, and hypokalemia. The diminished levels of 17a-hydroxylase that characterize this disorder lead to a reduction in cortisol production, which in turn causes an increase in adrenocorticotropic hormone (ACTH). 17a-Hydroxylase is not required for production of mineralocorticoids; thus, excessive amounts of mineralocorticoid are produced, resulting in sodium retention, loss of potassium, and hypertension. Over 20 mutations, which alter the reading frame of the gene, have been identified even though fewer than 200 people in the world have the disorder.

**17,20-Desmolase Deficiency**

Complete block in the d-4 pathway of 17,20-desmolase leads to a female phenotype in individuals with an XY karyotype. The uterus is absent, and sexual development does not occur at puberty. Although cortisol levels respond normally to ACTH stimulation, testosterone levels are low and do not respond to human chorionic gonadotropin (hCG) stimulation.

**Aromatase Deficiency**

This rare autosomal recessive abnormality, which has been reported in only six cases, prevents the affected individual from aromatizing androgens to estrogens. This syndrome may be suspected even before birth because most mothers of affected children develop virilization during pregnancy. The placenta cannot convert the fetal androgens to estrogens, leading to androgen diffusion into the maternal circulation. The female child is born with clitoromegaly and posterior labioscrotal fusion. At puberty breasts do not develop, primary amenorrhea occurs, virilization worsens, growth spurt is absent, bone growth is delayed, and multicystic ovaries are present. The diagnostic hormonal pattern consists of an elevation of FSH, LH, testosterone, and dehydroepiandrosterone sulfate (DHEAS) levels and undetectable levels of estradiol.

Estrogen therapy has been shown to improve the ovarian and skeletal abnormalities, but it must be titrated to mimic normal estrogen levels. Therefore, only minimal amounts need to be given during childhood and then should be increased at puberty.

**Gonadotropin Receptor Mutations**

**Luteinizing Hormone Receptor Mutation**

LH receptor inactivation caused by a homzygous premature stop codon was identified in a Brazilian family with 3,XY pseudohermaphroditism with primary amenorrhea in the absence of development of secondary sexual characteristics. The Leydig cells are unable to respond to LH; as a result, Leydig cell hypoplasia occurs, leading to early testicular failure and preventing masculinization. An XX sibling with the same mutation developed normal secondary sexual characteristics but was amenorrheic with elevated LH levels, normal FSH levels, and cystic ovaries.

**Follicle-stimulating Receptor Mutation**

In six Finnish families, an autosomal recessive single amino acid substitution in the extracellular domain of the FSH receptor gene has been identified that prevents FSH binding. This leads to primary or early secondary amenorrhea, variable development of secondary sexual characteristics, and high levels of FSH and LH.

**Other Causes of Primary Ovarian Failure**

Amenorrhea and premature ovarian failure can occur in association with irradiation of the ovaries, chemotherapy with alkylating agents, or combinations of radiation and other chemotherapeutic agents. In girls, galactosemia is often associated with premature ovarian failure, but usually it is
detected by newborn screening programs. Gonadotropin resistance, autoimmune ovarian failure, and ovarian failure resulting from infectious and infiltrative processes also have been described.

### Hypogonadotropic Hypogonadism

Primary amenorrhea resulting from hypogonadotropic hypogonadism occurs when the hypothalamus fails to secrete adequate amounts of GnRH or when a pituitary disorder associated with inadequate production or release of pituitary gonadotropins is present.

#### Physiologic Delay

Physiologic or constitutional delay of puberty is the most common manifestation of hypogonadotropic hypogonadism. Amenorrhea may result from the delay of physical development caused by delayed reactivation of the GnRH pulse generator. Levels of GnRH are functionally deficient in relation to chronicologic age but normal in terms of physiologic development.

#### Kallmann's Syndrome

The second most common hypothalamic cause of primary amenorrhea associated with hypogonadotropic hypogonadism is insufficient pulsatile secretion of GnRH (Kallmann's syndrome), which has various modes of genetic transmission, as discussed in Chapter 23. Insufficient pulsatile secretion of GnRH leads to deficiencies in FSH and LH. Deficiencies in GnRH may also be caused by developmental or genetic defects, inflammatory processes, tumors, vascular lesions, or trauma. Patients with isolated deficiencies of LH and FSH usually are a normal height for their age, whereas patients with physiologic delay of puberty are usually short for their chronologic age but normal for their bone age (19).

#### Central Nervous System Tumors

Central nervous system tumors that lead to primary amenorrhea, the most common of which is craniopharyngioma, are usually extracerebral masses that interfere with synthesis and secretion of GnRH or stimulation of pituitary gonadotropins. Virtually all patients with these tumors have disorders in the production of other pituitary hormones as well as LH and FSH (19,20). Prolactin-secreting pituitary adenomas are rare in childhood and more commonly occur after development of secondary sexual characteristics.

### Genetic Disorders

#### 5α-Reductase Deficiency

5α-Reductase deficiency should also be considered as a cause of amenorrhea (21). Patients with this disorder are genotypically XY, frequently experience virilization at puberty, have testes (because of functioning Y chromosomes), and have no müllerian structures due to functioning müllerian-inhibiting factor (MIF). 5α-Reductase converts testosterone to its more potent form, dihydrotestosterone. Patients with 5α-reductase deficiency differ from patients with androgen insensitivity, because they do not develop breasts at puberty and have low gonadotropin levels as a result of testosterone levels sufficient to suppress breast development and to allow normal feedback mechanisms to remain intact. Normal male differentiation of the urogenital sinus and external genitalia do not occur, because dihydrotestosterone is required for this development. However, normal internal male genitalia derived from the Wolffian ducts are present because this development requires only testosterone.

#### Gonadotropin-releasing Hormone Receptor Mutations

In two families with hypogonadotropic hypogonadism, compound heterozygous mutations (autosomal recessive inheritance) have been identified in the GnRH receptor gene. The GnRH receptor is a G-protein–coupled receptor. Functional studies show that the mutations either cause marked decreased binding in kinase of GnRH to its receptor or prevent second-messenger signal transduction. Without a functional signal transduction, FSH and LH are not stimulated and are unable to promote follicular growth (22,23).

#### Follicle-stimulating Hormone Deficiency

These patients usually seek treatment for delayed puberty and primary amenorrhea due to hypoestrogenism. They are distinguished from other hypoestrogenic patients by having decreased FSH levels and increased LH levels. These patients have low serum androgen levels despite the abnormal LH-to-FSH ratio, indicating that FSH-stimulated follicular development is a prerequisite for thecal cell androgen production. In some of these patients autosomal recessive mutations in the FSH β subunit, which impair dimerization of α and β subunits and prevent binding to the FSH receptor, have been identified (24). Pregnancy was achieved in one patient after induction of ovulation with injectable gonadotropins (25).

### Other Hypothalamic and Pituitary Dysfunctions

Functional gonadotropin deficiency results from malnutrition, malabsorption, weight loss or anorexia nervosa, stress, excessive exercise, chronic disease, neoplasias, and marijuana use (26,27,28,29 and 30). Hypothyroidism, Cushings syndrome, hyperprolactinemia, and infiltrative disorders of the central nervous system are rare causes of primary amenorrhea (31,32).

### Diagnosis

A careful history and physical examination are necessary to appropriately diagnose and manage primary amenorrhea associated with hypogonadism. The physical examination is particularly helpful in patients with Turner's syndrome. A history of short stature but consistent growth rate, a family history of delayed puberty, and normal physical findings (including assessment of smell, optical discs, and visual fields) may suggest physiologic delay. Headaches, visual disturbances, short stature, symptoms of diabetes insipidus, and weakness of one or more limbs suggest central nervous system lesions (20). Galactorrhea may be seen with prolactinomas, and the history of galactorrhea is also helpful when diagnosing postinfectious, inflammatory, or vascular lesions of the central nervous system; trauma; anorexia nervosa; stress-related amenorrhea; or other systemic disease processes.

The diagnostic workup is summarized as follows:

1. Assessment of the serum FSH level should be performed as the initial laboratory test unless the history and physical examination suggest otherwise. The FSH level differentiates hypergonadotropic and hypogonadotropic forms of hypogonadism. If the FSH level is elevated, a karyotype is obtained. An elevated FSH level in combination with a 45,X karyotype confirms the diagnosis of Turner's syndrome. Partial deletion of the X chromosome, mosaicism, pure gonadal dysgenesis, and mixed gonadal dysgenesis are diagnosed by obtaining a karyotype. If the association of coarctation of the aorta and thyroid dysfunction, patients with Turner's syndrome should undergo echocardiography and thyroid function studies.

2. If the karyotype is normal and the FSH is elevated, it is important to consider the diagnosis of 17α-hydroxylase deficiency because it may be a life-threatening disease if untreated. This diagnosis is confirmed with an ACTH stimulation test. After ACTH bolus administration, affected individuals have markedly increased levels of serum progesterone levels (>3 ng/ml), a low 17α-hydroxyprogesterone level (<0.2 ng/ml), and an elevated serum deoxycorticosterone (DOS) level (33). The diagnosis is confirmed with an ACTH stimulation test. After ACTH bolus administration, affected individuals have markedly increased levels of serum progesterone compared with baseline levels and no change in serum 17α-hydroxyprogesterone levels.

3. If the screening FSH level is low, the diagnosis of hypogonadotropic hypogonadism is established.

4. If the history suggests the presence of a central nervous system lesion or galactorrhea, imaging of the head using computed tomography (CT) or magnetic resonance imaging (MRI) is helpful in the diagnosis. Suprasellar or intrasellar calcification in an abnormal sella is found in approximately 70% of patients with craniopharyngioma (23).

### Treatment of Amenorrhea

Individuals with primary amenorrhea associated with all forms of gonadal failure and hypergonadotropic hypogonadism need cyclic estrogen and progestin therapy to initiate, mature, and maintain secondary sexual characteristics. Prevention of osteoporosis is an additional benefit of estrogen therapy:

1. Therapy is usually initiated with 0.625 mg/day of conjugated estrogens or 1 mg/day of estradiol.

2. If the patient is short in stature, higher doses should not be used in an attempt to prevent premature closure of the epiphyses. Most of these patients are of

Phyological delay is a diagnosis of exclusion that is difficult to distinguish from insufficient GnRH secretion. The diagnosis can be supported by a history suggesting physiologic delay, a radiograph showing delayed bone age, and the absence of a central nervous system lesion on CT or MRI scanning. Gonadotropin-deficient patients can usually be distinguished from patients with physiologic delay by their response to GnRH stimulation. Patients with physiologic delay have a normal LH response to GnRH stimulation for their bone age, in contrast with gonadotropin-deficient patients, in whom the LH and FSH responses are low (34).
normal height, however, and higher estrogen doses may be used initially and then reduced to the maintenance doses after several months.

3. Estrogens can be given daily in combination with progestin (medroxyprogesterone acetate) or progesterone to prevent unopposed estrogen stimulation of the endometrium in patients with a uterus. Medroxyprogesterone acetate may be administered daily at a dose of 2.5 mg or for 12 to 14 days every 1 to 2 months at a dose of 5 to 10 mg. Oral micronized progesterone may be administered at a dose of 100 mg daily or 200 mg for 12 to 14 days every 1 to 2 months. Likewise, progesterone suppositories may be administered at a dose of 50 mg daily or 100 mg for 12 to 14 days every 1 to 2 months.

4. Occasionally, individuals with mosaicism and gonadal streaks may ovulate and be able to conceive either spontaneously or after the institution of estrogen replacement therapy (5).

5. If 17a-hydroxylase deficiency is confirmed, treatment is instituted with corticosteroid replacement as well as estrogen. Progestin is added if a uterus is present.

If possible, therapeutic measures are aimed at correcting the primary cause of amenorrhea:

1. Craniofornygomas may be resected with a transphenoidal approach or during craniotomy, depending on the size of the tumor. Some studies have shown improved prognosis with radiation therapy used in combination with limited tumor removal (20,35).

2. Germinomas are highly radiosensitive, and surgery is rarely indicated (36).

3. Prolactinomas and hyperprolactinemia often may respond to dopamine agonists (37).

4. Specific therapies are directed toward malnutrition, malabsorption, weight loss, anorexia nervosa, exercise amenorrhea, neoplasia, and chronic diseases.

5. Logically, it would appear that patients with hypogonadotropic hypogonadism of hypothalamic origin should be treated with long-term administration of pulsatile GnRH. This form of therapy is impractical, however, because of the necessity for the use of an indwelling catheter and a portable pump for prolonged periods. Therefore, these patients should be treated with cyclic estrogen and progestin therapy.

6. Patients with Kallmann's syndrome, as well as patients with exercise or stress amenorrhea and anorexia and weight loss, are treated with hormone replacement.

7. If the patient has physiologic delay of puberty, only management required is reassembly that the anticipated development will occur eventually (38).

 Individuals whose karyotypes contain a Y cell line (45,XY/46,XY mosaicism, or pure gonadal dysgenesis 46,XY) are predisposed to gonadal ridge tumors such as gonadoblastomas, dysgerminomas, and yolk sac tumors. The gonads of these individuals should be removed when the condition is diagnosed to prevent malignant transformation (13,33). There is some evidence that these individuals without Y chromosomes should also undergo gonad removal. One patient with hirsutism and the karyotype 45,X was noted to have a streak gonad, the contralateral gonad was dysgenetic and contained developing follicles, well-differentiated seminiferous tubules, and Leydig cells. This patient was found to be H-Y antigen-positive (39).

Clomiphene citrate is ineffective in inducing ovulation in patients with hypogonadism who desire pregnancy, because such patients are hypoestrogenic. In patients with hypogonadism, ovulation induction with injectable gonadotropins is generally successful, and pulsatile treatment with GnRH may be used in patients who have normal pituitary function. In patients without ovarian function, oocyte donation may be appropriate. Because most patients with hypogonadism and lack of sexual development are young, pregnancy is not desired.

### Amenorrhea with Secondary Sexual Characteristics and Anatomic Abnormalities

#### Causes

##### Anatomic Abnormalities

Amenorrhea occurs if there is blockage of the outflow tract or if the outflow tract is missing (Table 24.2). An intact outflow tract includes a patent vagina as well as a functioning cervix and uterus. Any transverse blockage of the müllerian system (Buttram and Gibbons classification I) will cause amenorrhea (40). Such outflow obstructions include imperforate hymen, transverse vaginal septum, and hypoplasia or absence of the uterus, cervix, and vagina (Mayer-Rokitansky-Küster-Hauser syndrome). Mayer-Rokitansky-Küster-Hauser syndrome has been associated with abnormal galactose metabolism (41). Of the patients with this syndrome 15% have an absent kidney, 40% have a double urinary collecting system (42), and 5% to 12% have skeletal abnormalities (43). Transverse blockage of the outflow tract with an intact endomterium frequently causes cyclic pain without menstrual bleeding in adolescents. The blockage of blood flow can cause hematocolpos, hematometra, or hemoperitoneum. Endometriosis may develop.

When the findings of the physical examination are normal, anatomic abnormalities may still be considered. A congenitally absent endometrium is a rare finding in patients with primary amenorrhea. Asherman's syndrome, which is more common with secondary amenorrhea or hypomenorrhea, may occur in patients with risk factors for endometrial or cervical scarring, such as a history of uterine or cervical surgery, infections related to use of an intrauterine device, and severe pelvic inflammatory disease. It is found in 39% of patients undergoing hysterosalpingography who have previously undergone postpartum curettage (44). Infections such as tuberculosis and schistosomiasis may cause Asherman's syndrome but are rare in the United States. Cervical stenosis resulting from surgical removal of dysplasia (cone biopsy, loop electroexcision procedure) may also lead to amenorrhea.

#### Androgen Insensitivity

Phenotypic females with complete congenital androgen insensitivity (previously called testicular feminization) develop secondary sexual characteristics but do not have menses. These patients are male pseudohermaphrodites. Genotypically, they are male (XY) but have a defect that prevents normal androgen receptor function, leading to the development of the female phenotype. Defects in the androgen receptor gene located on the X chromosome include absence of the gene that encodes for the androgen receptor and abnormalities in the androgen-binding domain of the receptor. Postreceptor defects also exist (45). Total serum testosterone concentration is in the range of normal males. Because anti–müllerian hormone is present and functions normally in these patients, internal female (müllerian) structures such as a uterus, vagina, and fallopian tubes are absent. Testes rather than ovaries are present in the abdomen or in inguinal hernias because of the presence of normally functioning genes on the Y chromosome. Patients have a blind vaginal pouch, and scant or absent axillary and pubic hair. These patients experience abundant breast development at puberty; however, the nipples are immature and the areolae are pale. Testosterone is not present during development to suppress the formation of breast tissues; at puberty, the conversion of testosterone to estrogen stimulates breast growth. Patients are unusually tall with eunuchoidal tendency (long arms with big hands and feet) (45,46).
An imperforate hymen is diagnosed by the presence of a bulging membrane that distends during Valsalva maneuver. Ultrasonography or MRI is useful to identify the membrane. The patient should also be assessed for skeletal malformations and intravenous pyelography to detect concomitant renal abnormalities.

It is difficult to differentiate a transverse septum or complete absence of the cervix and uterus in a female from a blind vaginal pouch in a male. Adhesions in the cervix and uterus (Asherman's syndrome) can be removed using hysteroscopic resection with scissors or electrocautery.

In patients with complete androgen insensitivity, the testes should be removed after pubertal development is complete to prevent malignant degeneration. Patients thus treated achieve pregnancy, but complications including miscarriage, premature labor, placenta previa, and placenta accreta are common. Bilateral laparoscopic gonadectomy is the preferred procedure for removal of intrabdominal testes.

If the vagina is absent or short, progressive dilation is usually successful in making it functional. Frank dilators should be used to distend the vagina until it is healed to prevent vaginal adhesions. If dilation fails or the patient is unable to perform dilation, the McIndoe split thickness graft technique may be performed. The initial use of vaginal dilators is required to maintain a functional vagina.

Amenorrhea with Secondary Sexual Characteristics and Nonanatomic Causes

Pregnancy must be considered in all women of reproductive age with amenorrhea. Thyroid dysfunction and hyperprolactinemia are also frequent causes of amenorrhea. The treatment of congenital anomalies can be summarized as follows:

1. An imperforate hymen involves making a cruciate incision to open the vaginal orifice. Most imperforate hymens are not diagnosed until after a hematocolpos forms. It is wise to use a needle to drain the hematocolpos without completely removing the obstruction because a pyocolpos may occur.

2. If a transverse septum is present, surgical removal is required. Forty-six percent of transverse septa occur in the upper one-third of the vagina, and 40% occur in the middle one-third of the vagina. Frank dilators should be used to distend the vagina until it is healed to prevent vaginal adhesions. Patients have a fully functional reproductive system after surgery; however, patients with repaired high transverse septa have lower pregnancy rates.

3. Hypoplasia or absence of the cervix in the presence of a functioning uterus is more difficult to treat than other outflow obstructions. Curettage of the cervix has not been successful, and hysterectomy is required. Endometriosis is a common finding, and it is questionable whether this condition should be treated with initial surgery or if it will resolve spontaneously after surgical repair of the obstruction. The ovaries should be retained to provide the benefits of estrogen and to allow for the possibility of future childbearing by removing mature oocytes for in vitro fertilization and using a surrogate mother for implantation.

4. If the vagina is absent or short, progressive dilation is usually successful in making it functional. If dilation fails or the patient is unable to perform dilation, the McIndoe split thickness graft technique may be performed. The initial use of vaginal dilators is required to maintain a functional vagina.

5. In patients with complete androgen insensitivity, the testes should be removed after pubertal development is complete to prevent malignant degeneration. In patients with testes, 52% develop a neoplasia, most often a gonadoblastoma. Almost one-half of the testicular neoplasms are malignant (dysgerminomas), but transformation usually occurs after puberty. In patients who develop virilization and have an XY karyotype, the testes should be removed immediately to preserve the female phenotype and to promote female gender identity. Bilateral laparoscopic gonadectomy is the preferred procedure for removal of intrabdominal testes.

6. Adhesions in the cervix and uterus (Asherman's syndrome) can be removed using hysteroscopic resection with scissors or electrocautery. A pediatric Foley catheter should be placed in the uterine cavity for 7 to 10 days postoperatively (along with systemic administration of broad-spectrum antibiotic therapy), and a 2-month course of high-dose estrogen therapy with monthly progesterone withdrawal is used to prevent reformation of adhesions. Eighty percent of patients thus treated achieve pregnancy, but complications including miscarriage, premature labor, placenta previa, and placenta accreta are common.

Cervical stenosis can be treated by cervical dilation.

True Hermaphroditism

True hermaphroditism is a rare condition that should be considered as a possible cause of amenorrhea. Both male and female gonadal tissue is present in these patients, in whom XX, XY, and mosaic genotypes have been found. Two-thirds of the patients menstruate, but menstruation has never been reported in XY genotypes. The external genitalia is usually ambiguous, and breast development frequently occurs in these individuals.

Diagnosis

Most congenital abnormalities can be diagnosed by physical examination:

1. An imperforate hymen is diagnosed by the presence of a bulging membrane that distends during Valsalva maneuver. Ultrasonography or MRI is useful to identify the membrane. The patient should also be assessed for skeletal malformations and intravenous pyelography to detect concomitant renal abnormalities.

2. It is difficult to differentiate a transverse septum or complete absence of the cervix and uterus in a female from a blind vaginal pouch in a male. Adhesions in the cervix and uterus (Asherman's syndrome) can be removed using hysteroscopic resection with scissors or electrocautery.

3. An absent endometrium is an outflow tract abnormality that cannot be diagnosed by physical examination in a patient with primary amenorrhea. This abnormality is so rare that, in a patient with normal physical findings, it may be advisable to proceed with evaluation of endocrine abnormalities. Absence of the endometrium should be suspected in patients with primary amenorrhea and normal secondary sexual characteristics when the results of hormonal studies are normal and the patients do not bleed after withdrawal of combined estrogen and progesterone replacement.

4. Asherman's syndrome also cannot be diagnosed by physical examination. It is diagnosed by performing hysterosalpingography, saline infusion, ultrasonography, or hysteroscopy. These tests will show either complete obliteration or multiple filling defects caused by synechiae. If tuberculosis or schistosomiasis is suspected, endometrial cultures should be performed.
amenorrhea and are discussed further in Chapter 25. The three major causes of amenorrhea with secondary sexual characteristics are ovarian failure, pituitary and hypothalamic lesions, and abnormal hypothalamic GnRH secretion.

### Causes

#### Ovarian Failure

Ovarian failure is a normal occurrence during menopause. The age of menopause is determined by genetic inheritance. Once a patient is exposed to estrogen, estrogen withdrawal causes hot flashing factors such as body weight that could accelerate the menopause (56). Cigarette smoking alters both gametogenesis and hormonogenesis, suggesting an effect on the follicle. Smoking has also been shown to increase the risk of diminished ovarian reserve (59).

**Sex Chromosome Disorders** Deletion of the X chromosome (Turner's Syndrome) is associated with premature ovarian failure despite normal development of the ovaries due to accelerated atresia of the follicles (61). Mosaicism of an XO or XY cell line may cause ovarian failure in patients younger than 30 years of age. A deletion of a portion of the X chromosome is present in patients with premature ovarian failure. The Xq26–28 region is critical (62). Individuals with a 47,XXX karyotype also may develop ovarian failure. Familial ovarian failure is inherited by dominant mendelian inheritance in some cases (63).

**Iatrogenic Causes** Radiation, chemotherapy (especially alkylating agents such as cyclophosphamide) (64), surgical interference with ovarian blood supply, and infections can cause ovarian failure from early loss of follicles. At a radiation dose of 800 cGy, all patients become sterile. Ovarian failure can be caused by as little as 150 cGy in some patients, especially if they are older than 40 years with limited follicle reserves. In six Finnish families an autosomal recessive single amino acid substitution has been identified in the FSH receptor, which prevents binding of FSH (65). However, only 20% of these patients exhibited signs of immunologic dysfunction, most frequently a thyroid disorder (65). Rarely, premature ovarian failure is associated with myasthenia gravis, idiopathic thrombocytopenic purpura, rheumatoid arthritis, vitiligo, autoimmune hemolytic anemia, diabetes mellitus, and other autoimmune disorders (66,67 and 68).

**Galactosmia** Galactosemia is caused by a lack of functional galactose-1-phosphate uridyl transferase. Galactose metabolites appear to have toxic effects on ovarian follicles, causing their premature destruction (69). There is also evidence that heterozygote carriers of this disorder may have suboptimal ovarian function (70). Early dietary modification may delay the ovarian failure.

**Savage Syndrome** In some patients follicles are present, but they do not mature in response to FSH because FSH receptors are absent or a postreceptor defect exists (67,71). In six Finnish families an autosomal recessive single amino acid substitution has been identified in the FSH receptor, which prevents binding of FSH (15). These patients experience ovarian resistance (Savage syndrome) as opposed to ovarian failure, in which no follicles are present. Except in the rare cases in which a genetic defect has been identified, ovarian biopsy is the only way to distinguish these disorders. Biopsy is not advised, however, because diagnosing resistant ovarian failure will not affect management. Although the use of GnRH agonists, estrogen therapy, and ovarian stimulation have been attempted in patients desiring pregnancy, studies have shown little success.

### Pituitary and Hypothalamic Lesions

#### Hypothalamic Tumors

In order for normal menstruation to occur, the hypothalamus must be able to secrete GnRH, and the pituitary must be able to respond with production and release of FSH and LH. Tumors of the hypothalamus or pituitary such as craniopharyngiomas, germinomas, tubercular or sarcoid granulomas, or dermoid cysts may prevent appropriate hormonal secretion. Patients with these disorders may exhibit neurologic abnormalities and abnormal secretion of other hypothalamic and pituitary hormones. Craniopharyngiomas are the most common tumors. They are located in the suprasellar region and frequently cause headaches and visual changes. The surgical and radiologic treatment of tumors may in itself cause further abnormalities in hormone secretion (Table 24.4).

### Pituitary Lesions

Hypopituitarism is rare because a large portion of the gland must be destroyed before decreased hormonal secretion affects the patient clinically. The pituitary gland may be destroyed by tumors (nonfunctioning or hormone secreting), infarction, infiltrating lesions such as lymphocytic hypophysitis, granulomatous
lesions, and surgical or radiologic ablations.

Sheehan's syndrome is associated with postpartum necrosis of the pituitary resulting from a hypotensive episode that, in its severe form (pituitary apoplexy), causes shock. The patient may develop a localized severe retroorbital headache or abnormalities in visual fields and visual acuity. Patients with a mild form of postpartum pituitary necrosis experience failure to lactate, loss of pubic and axillary hair, and failure to resume menses after delivery.

Diabetic vasculitis and sickle cell anemia rarely manifest as pituitary failure. Hypopituitarism is associated with hyposecretion of ACTH and thyroid-stimulating hormone (TSH) as well as gonadotropins; therefore, thyroid and adrenal function also must be evaluated. If hypopituitarism occurs prior to puberty, menses and secondary sexual characteristics will not develop.

Growth hormone (GH), TSH, ACTH, and prolactin also are secreted by the pituitary, and the excess production of each by pituitary tumors causes menstrual abnormalities. The menstrual abnormalities are caused by adverse effects of these hormones on the GnRH pulse generator and not by directly effecting the ovary. Prolactinomas are the most common hormone-secreting tumors in the pituitary (see Chapter 29).

### Altered Hypothalamic GnRH Secretion

The pulsatile secretion of GnRH is modulated by interactions with neurotransmitters and peripheral gonadal steroids. Endogenous opioids, corticotropin-releasing hormones (CRH), melatonin, and g-aminobutyric acid (GABA) inhibit the release of GnRH, whereas catecholamines, acetylcholine, and vasoactive intestinal peptide (VIP) stimulate GnRH pulses. Dopamine and serotonin have variable affects (72). Chronic disease, malnutrition, stress, psychiatric disorders, and exercise inhibit GnRH pulses, thus altering the menstrual cycle (Table 24.5). Other hormonal systems that produce excess or insufficient hormones can cause abnormal feedback and GnRH secretion. In hyperprolactinemia, Cushing's disease (excess ACTH), and acromegaly (excess GH) excess pituitary hormones are secreted that inhibit GnRH secretion. When the decrease in GnRH pulsatility is severe, amenorrhea results. With less severe alterations in GnRH pulsatility, anovulation can occur. Even slight defects in the pulsatility may result in luteal phase defect.

Table 24.5 Abnormalities Affecting Release of Gonadotropin-Releasing Hormone

#### Anorexia Nervosa

Anorexia nervosa is an eating disorder that affects 5% to 10% of adolescent women in the United States. The criteria for anorexia nervosa as stated in the psychiatric diagnostic manual (DSM-IV) are refusal to maintain body weight above 15% below normal, an intense fear of becoming fat, altered perception of one's body image (i.e., patients see themselves as fat despite being overweight), and amenorrhea. Patients attempt to maintain their low body weight by food restriction, induced vomiting, laxative abuse, and intense exercise. This is a life-threatening disorder with a mortality rate as high as 9%. Amenorrhea may precede, coincide with, or follow the weight loss. Multiple hormonal patterns are altered. The 24-hour patterns of FSH and LH may show constantly low levels as seen in childhood or increased LH pulsatility during sleep consistent with the pattern seen in early puberty. Hypercortisolism is present despite normal ACTH levels, and the ACTH response to CRH administration is blunted. Circulating triiodothyronine (T3) is low, yet circulating inactive reverse T3, concentrations are high (73). Patients may develop cold and heat intolerance, lanugo hair, hypotension, bradycardia, and diabetes insipidus. They may have yellowish discoloration of the skin resulting from elevated levels of serum carotene caused by altered vitamin A metabolism.

#### Exercise and Stress-induced Disorders

In patients with exercise-induced amenorrhea, there is a decrease in the frequency of GnRH pulses, which is assessed by measuring a decreased frequency of LH pulses. These patients are usually hypoestrogenic, but less severe alterations may cause minimal menstrual dysfunction (anovulation or luteal phase defect). The decrease in LH pulsatility can be caused by hormonal alterations such as elevations in endogenous opioids, ACTH, prolactin, adrenal androgens, cortisol, and melatonin (74). Rates of amenorrhea by sport have been attributed to differences in body fat content. Runners and ballet dancers are at higher risk for amenorrhea than swimmers (75). Frisch and McArthur suggest that a minimum of 17% body fat is required for the initiation of menses and 22% body fat for the maintenance of menses (76). DSM-IV newer studies suggest that inappropriately low caloric intake during strenuous exercise is more important than body fat content (77). Higher intensity training, poor nutrition, stress of competition, and associated eating disorders increase an athlete's risk for menstrual dysfunction (78).

Stress-related amenorrhea can be caused by abnormalities in neuromodulation in hypothalamic GnRH secretion, similar to those that occur with exercise and anorexia nervosa. Excess endogenous opioids and elevations in CRH secretion inhibit the secretion of GnRH (72). These mechanisms are not fully understood but appear to be the common link between amenorrhea and chronic diseases, pseudocyesis, and malnutrition.

#### Obesity

Most obese patients have normal menstrual cycles, but the percentage of women with menstrual disorders increases from 2.6% in normal-weight patients to more than 8.4% in women 75% above ideal body weight. The menstrual disorder is more often irregular uterine bleeding with anovulation than amenorrhea. Obese women have an excess number of fat cells in which extraglandular aromatization of androgens to estrogen occurs. They also have lower circulating levels of sex hormone–binding globulin, which allows a larger proportion of free androgens to be converted to estrone. Excess estrogen creates a higher risk for endometrial cancer for these women. The decrease in sex hormone–binding globulin also allows an increase in free androgen levels, which initially are removed by an increased rate of metabolic clearance. This compensatory mechanism diminishes over time, and hirsutism can develop. Frequently, these patients are classified as having polycystic ovary (PCO) syndrome. Alterations in the secretion of endorphins, cortisol, insulin, growth hormone, and insulin-like growth factor–1 (IGF-1) may interact with the abnormal estrogen and androgen feedback to the GnRH pulse generator to cause menstrual abnormalities.

#### Other Hormonal Dysfunctions

The secretion of hypothalamic neuropeptides can be altered by feedback from abnormal levels of peripheral hormones. Excesses or deficiencies of thyroid hormone, corticosteroids, androgens, and estrogens can cause menstrual dysfunction. PCO syndrome usually causes irregular bleeding but may cause amenorrhea. It is likely that PCO syndrome is the result of peripheral alteration in IGF-1, androgen, and estrogen levels, which leads to hypothalamic dysfunction. Elevations in androgens (e.g., Sertoli-Leydig, hilus, and lipid cell tumors) and estrogens (e.g., granulosa cell tumors) by ovarian tumors may lead to abnormal menstrual patterns, including amenorrhea. In patients who are hirsute and amenorrheic, androgen-secreting adrenal tumors and congenital adrenal hyperplasia should be considered.

Excess secretion of GH, TSH, ACTH, and prolactin from the pituitary gland can cause abnormal feedback inhibition of GnRH secretion, leading to amenorrhea. GH excess causes acromegaly, which may be accompanied by anovulation, hirsutism, and polycystic ovaries as a result of stimulation of the ovary by IGF-1. More commonly, GH excess is accompanied by amenorrhea, low gonadotropin levels, and elevated prolactin levels. Acromegaly is characterized by enlargement of facial features, hands, and feet, hyperhidrosis, visceral organ enlargement, and multiple skin tags. Cushing's disease is caused by an ACTH-secreting pituitary tumor.
Serum TSH level

Assessments of serum electrolytes, calcium, and phosphorus concentrations can be used to evaluate the possibility that parathyroid autoantibodies are active. After anatomic lesions have been excluded, the patient's history of weight changes, exercise, eating habits, body image, and career or school achievements are important factors in identifying anorexia nervosa, malnutrition, obesity, or exercise-induced or stress-induced menstrual disorders. In patients less than 30 years of age with hypergonadotropic amenorrhea, a karyotype is required to rule out the presence of a Y cell line. In situ hybridization studies may prove the existence of Y chromosomal material with a Y-specific probe when the karyotype is normal (79). It is important to identify Y chromosomal material so it may be removed to prevent malignant degeneration.

There is much debate regarding the extent of an autoimmune workup required for a patient with ovarian failure. In a patient with hypergonadotropic amenorrhea, it is not advisable to perform ovarian biopsy to determine whether follicles are present. Even if oocytes are found, no good method exists to stimulate those oocytes to ovulate. Some patients with negative biopsy results later ovulated spontaneously. This phenomenon can be explained by considering that the biopsy samples only a small portion of the ovary (57).

Assessment of Estrogen Status

Traditionally, estrogen status has been determined by giving medroxyprogesterone acetate, either 5 or 10 mg for 10 days, to determine whether the patient bleeds after withdrawal of the medication (usually 2 to 10 days after the last dose). There is a debate as to how much bleeding constitutes withdrawal bleeding. If vaginal bleeding does not occur after oral administration of progesterone, frequently 100 to 200 mg progesterone in oil is given intramuscularly. Other ways of testing for estrogen status may be quicker and easier. The development of vaginal dryness and hot flashes increase the likelihood of a diagnosis of hypoestrogenism. A sample of vaginal secretions can be obtained during the physical examination, and mucosal estrogen response can be demonstrated by the presence of superficial cells. A serum estradiol level higher than 40 pg/ml is considered adequate, but interassay discrepancies often exist.

The finding of vaginal bleeding after progesterone challenge is important when Asherman's syndrome is suspected. In a patient with primary amenorrhea and an apparently normal estrogen status, a progesterone challenge will diagnose the rare finding of congenitally absent endometrium. If estrogen status is questioned, 2.5 mg conjugated estrogen or 2 mg micronized estradiol can be given for 25 days with 5 to 10 mg of medroxyprogesterone acetate added for the last 10 days of therapy. Congenital absence of the endometrium is confirmed if no bleeding occurs with this regimen in a patient with primary amenorrhea and no physical abnormalities. Transvaginal ultrasonography to assess endometrial thickness may also be helpful. If similar findings occur in patients with secondary amenorrhea, Asherman's syndrome is diagnosed. Asherman's syndrome must be confirmed by showing filling defects on hysterosalpingography or by visualizing adhesions with hysteroscopy.

Assessment of the Pituitary and Hypothalamus

If the patient is hypoestrogenic and the FSH level is not high, pituitary and hypothalamic lesions should be excluded. A complete neurologic examination, including electroencephalography (EEG), may help localize a lesion. Either CT or MRI scanning should be performed to confirm the presence of a tumor. MRI can identify smaller lesions than can CT; if a lesion is too small for identification by MRI, it may be clinically insignificant. After anatomic lesions have been excluded, the patient's history of weight changes, exercise, eating habits, body image, and career or school achievements are important factors in identifying anorexia nervosa, malnutrition, obesity, or exercise-induced or stress-induced menstrual disorders.

Amenorrheic patients who have hypothalamic dysfunction and are hypoestrogenic may have disorders similar to those who are well estrogenized. The hypothalamic dysfunction caused by chronic disease, anorexia nervosa, stress, and malnutrition may be more severe or may exist for a more prolonged time in hypoestrogenic patients than in eustrogenic patients.

Patients with appropriate clinical findings should undergo screening for other hormonal alterations as follows:

1. Androgen levels should be assessed in any hirsute patient to ensure that adrenal and ovarian tumors are not present as well as to diagnose PCO syndrome (Chapter 25).
2. Acromegaly is suggested by coarse facial features, large doughy hands, and hyperhidrosis and may be confirmed by measuring IGF-1 levels.
3. Cushing's syndrome should be ruled out by assessing 24-hour urinary cortisol levels or a 1-mg overnight dexmethasone suppression test in patients with truncal obesity, hirsutism, hypertension, and erythematous striae.
Treatment

The treatment of nonanatomic causes of amenorrhea associated with secondary sexual characteristics varies widely according to the cause. The underlying disorder should be treated whenever possible. Patients who are pregnant may be counseled regarding the options for continued care. When thyroid abnormalities are discovered, thyroid hormone, radioactive iodine, or antithyroid drugs may be administered as appropriate. When hyperprolactinemia is discovered, treatment may include discontinuation of contributing medications, treatment with dopamine agonists such as bromocriptine or cabergoline and, rarely, surgery for particularly large pituitary tumors. When ovarian failure causes amenorrhea, hormone replacement is prescribed for prevention of osteoporosis and to diminish menopausal symptoms. Gonadectomy is required when a Y cell line is present.

Surgical removal, radiation therapy, or a combination of both is generally advocated for treatment of central nervous system tumors other than prolactinomas. It may be necessary to treat individuals who have panhypopituitarism with various replacement regimens once all the deficits have been elucidated. These regimens include estrogen replacement for lack of gonadotropins, corticosteroid replacement for lack of ACTH, thyroid hormone for lack of TSH, and desmopressin acetate (t-desamino-D-8-APV [DDAVP]) to replace vasopressin.

The treatment of amenorrhea associated with hypothalamic dysfunction also depends on the underlying cause:

1. Hormonally active ovarian tumors are surgically removed.
2. Obesity, malnutrition or chronic disease, Cushing's syndrome, and acromegaly should be specifically treated.
3. Pseudocyesis and stress-induced amenorrhea may respond to psychotherapy.
4. Exercise-induced amenorrhea may improve with moderation of activity and weight gain when appropriate.
5. Cushing's syndrome may require hydrocortisone or dexamethasone in cases requiring hospitalization.

6. Chronic anovulation or PCO syndrome may be treated after identifying the desires of the patient. Patients often are concerned about their lack of menstruation but not about hirsutism or infertility. The endometrium of these individuals should be protected from the environment of unopposed estrogen that accompanies the anovulatory state. An oral contraceptive is a good alternative for those patients who also require contraception. For those patients who are not candidates for oral contraceptives, cyclic administration of progestin is advised. This treatment option preserves an adequate estrogenic environment to induce proliferation of the endometrium and is not sufficient to cause withdrawal bleeding in patients who are hypoestrogenic (i.e., anorexia nervosa). In these individuals, estrogen replacement must be added to the progestin regimen for success. The most common progestin used to induce withdrawal bleeding and thus protect the endometrium from hyperplastic transformation is medroxyprogesterone acetate (10 mg for 10 days per month).

Occasionally, ovulation may occur; therefore, patients should be made aware that pregnancy is possible and appropriate contraceptive measures should be used. There is concern that medroxyprogesterone acetate used in early pregnancy may increase the incidence of pseudohermaphroditism (89). Alternatively, progesterone suppositories (50 to 100 mg or more) or progesterone (200 mg) could be gynecostereone (progestosterone) for 10 days to induce withdrawal bleeding. No increased incidence of birth defects has been associated with the use of these natural progestin (81).

7. When chronic anovulation is caused by attenuated congenital adrenal hyperplasia, glucocorticoid administration (i.e., deoxamethasone 0.5 mg at bedtime) is sometimes successful in restoring the normal feedback mechanisms, thereby permitting regular menstruation and ovulation.

Hirsutism

Patients who have oligomenorrhea or amenorrhea resulting from chronic anovulation may have hirsutism (Chapter 25). After ruling out androgen-secreting tumors and congenital adrenal hyperplasia, treatment may be aimed at decreasing coarse hair growth.

Oral Contraceptives Oral contraceptives may be effective by decreasing ovarian androgen production as well as increasing circulating levels of sex hormone-binding globulin, leading to decreased free androgen circulation.

Antiandrogens Spironolactone has also been used because of its ability to decrease androgen production as well as compete with androgens at the androgen receptor level. Side effects include limited diuresis and dysfunctional uterine bleeding.

Flutamide is approved by the U.S. Food and Drug Administration for adjuvant therapy in prostate cancer, and in the treatment of hirsutism it has similar to spironolactone with fewer side effects (82). Liver function should be monitored because of the rare complication of hepatotoxicity.

Cyproterone acetate, a strong progestin and antiandrogen, is used widely abroad but is not currently available in the United States. It is usually administered in combination with ethinyl estradiol in an oral contraceptive. By decreasing circulating androgen and LH levels, and by inducing antagonism of androgen effects at the peripheral level, cyproterone acetate is effective in treating hirsutism (83).

 GnRH Agonist GnRH agonist administration with add-back therapy is increasingly being used in the United States. Administration of GnRH agonist agents virtually eliminates ovarian steroid production, and estrogen-progestin add-back therapy allows long-term administration and protection against osteoporosis.

5α-Reductase Inhibitors Finasteride, a 5α-reductase inhibitor, is approved by the U.S. Food and Drug Administration for the treatment of benign prostatic hypertrophy and male pattern baldness. It is effective in treating hirsutism, although perhaps no more effective than other available agents (84,85). Finasteride has significant teratogenic potential, which precludes its use in any woman who may become pregnant. Its major advantage is that it is exceptionally well tolerated and may be used when side effects preclude the use of other therapeutic options for hirsutism. Finasteride is indicated primarily in patients with adequate levels of estrogen and normal levels of FSH and prolactin. It is generally ineffective in hypogonadotropic patients who already have a poor estrogen supply (93). Patients with inappropriate gonadotropin release (an increased LH-to-FSH ratio), such as that which occurs in PCO syndrome, are also candidates for therapy with clomiphene citrate. Up to 80% of certain patients can be expected to ovulate after 5α-reductase therapy, and pregnancy rates approach 40% (86). Contraindications to the use of clomiphene citrate include pregnancy, liver disease, and preexisting ovarian cysts. Side effects include hot flashes (>11% of patients) and poorly understood visual symptoms, which generally have been viewed as an indication to discontinue subsequent clomiphene citrate use. The incidence of multiple gestation ranges from 6.25% to 12.3% (86). The most commonly recommended treatment regimen is 50 mg daily for 5 days, beginning on the third to fifth day of menstruation (3). Larger courses of clomiphene citrate therapy, as well as adjunctive therapy with glucocorticoids and hCG, have been recommended (93). Patients

Ovulation Induction

A large subset of patients with amenorrhea or oligomenorrhea and chronic anovulation seek care because they are unable to conceive (Chapter 27). Ovulation induction therapy is generally the treatment of choice for such patients, but pretreatment counseling should be provided in sufficient detail to ensure realistic expectations. The patient should be provided with information regarding the chances of a successful pregnancy (considering age of the patient and treatment modality), potential complications (hyperstimulation and multiple gestation), expense, time, and psychological impact involved in completing the course of therapy (88). Patients may be advised that there is no increase in congenital anomalies in children born following ovulation induction (87).

Recent studies have raised the possibility of a relationship between ovulation induction and the risk of ovarian cancer (88,89). Ongoing studies are attempting to address this issue conclusively, but data support an increase of approximately 2.5-fold in ovarian cancer in patients treated for infertility, which appears unrelated to the use of ovulation-inducing drugs (90,91). No change in ovulation induction practices seems warranted at the present time. Pregnancy and treatment with oral contraceptives before or after chlordihydro may protect against ovarian cancer.

Clomiphene citrate is the usual first choice for ovulation induction in most patients because of its relative safety, efficacy, route of administration (oral), and relatively low cost (92). Clomiphene citrate is indicated primarily in patients with adequate levels of estrogen and normal levels of FSH and prolactin. It is generally ineffective in hypogonadotropic patients who already have a poor estrogen supply (93). Patients with inappropriate gonadotropin release (an increased LH-to-FSH ratio), such as that which occurs in PCO syndrome, are also candidates for therapy with clomiphene citrate. Up to 80% of certain patients can be expected to ovulate after 5α-reductase therapy, and pregnancy rates approach 40% (86). Contraindications to the use of clomiphene citrate include pregnancy, liver disease, and preexisting ovarian cysts. Side effects include hot flashes (>11% of patients) and poorly understood visual symptoms, which generally have been viewed as an indication to discontinue subsequent clomiphene citrate use. The incidence of multiple gestation ranges from 6.25% to 12.3% (86). The most commonly recommended treatment regimen is 50 mg daily for 5 days, beginning on the third to fifth day of menstruation (3). Larger courses of clomiphene citrate are not currently used, and more than 70% of conceptions occur at doses no higher than 100 mg/day for 5 days (88). Doses higher than 150 mg/day for 5 days are usually ineffective, and patients who remain anovulatory with this dosage should undergo further evaluation accompanied by changes in the therapeutic plan. Longer courses of clomiphene citrate therapy, as well as adjunctive therapy with glucocorticoids and hCG, have been recommended (93). Patients
with PCO syndrome, especially those with insulin resistance, may benefit from the use of insulin-sensitizing agents either as initial or adjunctive therapy (95). These include the biguanide metformin and thiazolidinediones (rosiglitazone and pioglitazone).

Women who do not ovulate or become pregnant with clomiphene citrate, as well as women with hypergonadotropic hypogonadism, may be candidates for therapy with injectable gonadotropins. Much higher pregnancy rates (up to 90%) occur in the latter category. Available preparations include recombinant FSH or products purified from the urine of menopausal women (FSH or FSH-LH combinations). Oral gonadotropin therapy is currently in research and development. Administration protocols and dosages vary widely and should be adjusted to individual needs. Safe administration requires careful monitoring of ovarian response with ultrasonography and serial estradiol measurements. In general, gonadotropins are administered at a dose of 75 to 150 IU/day by subcutaneous injection to as few as 1 to 5 days for 3 cycles, and then to as many as 7 cycles in mild cases. In cases of gonadotropin administration lasts from 7 to 12 days. Ovulation is triggered by subcutaneous or intramuscular injection of 5,000 to 10,000 IU HCG once the follicle reaches 16 to 20 mm in diameter based on ultrasonographic assessments. Ovulation generally occurs approximately 36 hours after HCG administration. Luteal phase support is sometimes given with additional injections of HCG or progesterone supplementation.

The two major complications associated with induction of ovulation with gonadotropins are multiple pregnancy (10% to 30%) and ovarian hyperstimulation syndrome. The incidence of both of these complications can be lowered by careful monitoring. Cycles complicated by the recruitment of numerous follicles or by estradiol levels exceeding 4000 pg/ml may be cancelled or the dosage of the HCG dose. Select patients may be treated safely by in vitro fertilization. Because severe ovarian hyperstimulation syndrome is life-threatening and may prolong hospitalization, ovulation induction with gonadotropins is generally performed by experienced practitioners who devote a significant portion of their practice to the treatment of infertility.

Ovulation induction with GnRH may be effective in patients with chronic anovulation associated with low levels of estradiol and gonadotropins. In order for therapy to be successful, a functional ovarian and uterine gland must be present. Therefore, patients with ovarian or pituitary failure do not respond to GnRH therapy. To be effective, GnRH must be administered in a pulsatile fashion either intravenously or subcutaneously by a programmable pump. Ovulation induction with GnRH, as compared with gonadotropins, is associated with a relatively low incidence of ovarian hyperstimulation and multiple births. In addition, the need for appropriate timing of the ovulatory dose of HCG is avoided because patients treated with pulsatile GnRH have an appropriately timed endogenous LH surge. Disadvantages are mainly related to maintaining the programmable pump and injection site. After ovulation, luteal phase support is necessary and may be provided with HCG, progesterone, or continuation of the GnRH therapy.

Patients who lack ovulation (ovarian failure) and desire pregnancy may be candidates for oocyte donation. Oocytes may be harvested after ovulation induction from appropriate donors, fertilized with sperm from the recipient's husband, and transferred to the recipient's uterus after the endometrium has been prepared with hormonal regimens. Estrus and progesterone are used to prepare the endometrium for implantation of the transferred embryo(s).

References

The endocrine disorders encountered most frequently in gynecologic patients are those related to androgen excess, including what is arguably the most common endocrinopathy in women—polycystic ovary syndrome (PCOS). Rare causes of virilization in women include tumors of the ovary and the adrenal gland. These conditions, as well as some disorders of the pituitary and thyroid glands, are reviewed in this chapter.

**Hyperandrogenism**

Diseases that reflect a state of hyperandrogenism result from either excess production of androgen such as from an adrenal or ovarian tumor, from metabolic derangements such as PCOS, or from increased end-organ sensitivity.

**Hirsutism**

Hirsutism, which is the most frequent manifestation of androgen excess in women, is defined as excessive growth of terminal hair in a malelike pattern. This refers particularly to midline hair, side burns, moustache, beard, chest or intermammary hair, and inner thigh and midline lower back hair entering the intergluteal area. The response of the pilosebaceous unit to androgens causes vellus hair to transform into terminal hair in androgen-dependent areas. The resulting terminal hair is coarse, stiff, pigmented, and long.

Androgens affect various types of hair differently. Hair that shows no androgen dependence includes lanugo, eyebrows, and eyelashes. Hair that is more dependent on adrenal androgens includes axillary and pubic hair. Hair that depends significantly on gonadal androgens includes midline, facial, and intermammary hair. Scalp hair is inhibited by gonadal androgens, resulting in the common temporal balding seen in males and in virilized females. Hirsutism results from both increased androgen production and skin sensitivity to androgens. Skin sensitivity depends on the local activity of 5a-reductase, the enzyme that converts testosterone to dihydrotestosterone (DHT), the active androgen in hair follicles.

Hair demonstrates cyclic activity between growth (anagen), involution (catagen), and resting (telogen) phases. Both the growth and resting phases vary in length for different areas of hair growth. Much of the influence of androgens or pharmaceutical agents depends on the phase of hair growth. Synchronization in the hair growth phase may lead to dramatic consequences, such as the hair loss occasionally encountered during pregnancy.

Social and clinical reactions to hirsutism may vary significantly. Androgen-dependent hair (excluding pubic and axillary hair) occurs in only 5% of premenopausal Caucasian women and is considered abnormal in white women of North America. The presence of sexual hair in other locations is viewed as normal, however, and is socially acceptable in some ethnic groups, such as Eskimos and women of Mediterranean origin.

Two conditions should be distinguished from hirsutism. **Hypertrichosis** is the term reserved for androgen-independent growth of hair that is prominent in nonsexual areas, such as the trunk and extremities. This may be either an autosomal-dominant congenital disorder or may be caused by metabolic disorders (such as anorexia nervosa, hyperthyroidism, porphyria cutanea tarda) or medications (phenytoin, minoxidil, cyclopentol, diazoxide). Virilization is characterized by male-pattern baldness ( crown routinely and temples occasionally), coarsening of the voice, decrease in breast size, increase in muscle mass, loss of female body contour (obesity, particularly of the upper segment, and alteration of the waist-to-hip ratio), and enlargement of the clitoris (the mean transverse diameter of the glans is 3.4 ± 1 mm and the longitudinal diameter is 5.1 ± 1.4 mm) (1).

The history should focus on the age of onset and rate of progression of hirsutism or virilization. A fast rate of progression is associated with a more severe degree of hyperandrogenism and should raise suspicion of ovarian and adrenal neoplasms or Cushing’s syndrome. The same is true of rapid progression or onset of symptoms before or after adolescence. Anovulation, manifesting as amenorrhea or oligomenorrhea, increases the probability of hyperandrogenism. Hirsutism in women with regular cycles may be associated with normal androgen levels and is considered **idiopathic hirsutism**.

A sensitive and tactful approach by the physician is mandatory and should include questioning of the patient regarding whether she shaves or removes hair chemically or mechanically and, if so, how frequently. A family history should be obtained to disclose evidence of idiopathic hirsutism, PCOS, congenital adrenal hyperplasia (CAH), diabetes mellitus, and cardiovascular disease. A history of drug use should also be obtained. In addition to drugs that commonly cause hypertrichosis, anabolic steroids and testosterone derivatives may cause virilization. During the physical examination, attention should be directed to obesity, hypertension, galactorrhea, male-pattern baldness, acne (face and back), and hyperpigmentation. The presence of an androgen-producing ovarian neoplasm or Cushing's syndrome should be considered. In many cases of Cushing's syndrome, the patient's initial symptom is hirsutism. The physician should search for the physical signs of the syndrome such as “moon face,” plethora, purple striae, dorsocervical and supraclavicular fat pads, and proximal muscle weakness. The type,
pattern, and extent of hair growth are next evaluated.

Typically, clinical evaluation of the degree of hirsutism is subjective. Most physicians arbitrarily classify the degree of hirsutism as mild, moderate, or severe. Objective assessment is helpful, however, especially in establishing a baseline from which therapy can be evaluated. A hirsutism scoring scale of androgen-sensitive hair in nine body areas rated on a scale of 0 to 4 has been used (2). A score higher than 8 is defined as hirsutism.

Role of Androgens

Androgens and their precursors are produced by both the adrenal glands and the ovaries in response to their respective trophic hormones, luteinizing hormone (LH) and adrenocorticotropic hormone (ACTH) (Fig. 25.1). Biosynthesis begins with the rate-limiting conversion of cholesterol to pregnenolone by side-chain cleavage enzyme. Thereafter, pregnenolone undergoes a two-step conversion to the 17-ketosteroid dehydroepiandrosterone (DHEA) along the D-5 steroid pathway. This conversion is accomplished by CYP17, an enzyme with both 17α-hydroxylase and 17,20-lyase activities. In a parallel fashion, progesterone undergoes transformation to androstenedione in the D-4 steroid pathway. The metabolism of D-5 to D-4 intermediate is accomplished via a D-5-isomerase, 3b-hydroxysteroid dehydrogenase (3b-HSD).

Adrenal 17-Ketosteroids

Secretion of adrenal 17-ketosteroids begins prepubertally (adrenarche) with a dramatic change in the response of the adrenal cortex to ACTH and with preferential secretion of D-5 steroids, including 17α-hydroxypregnenolone, DHEA, and dehydroepiandrosterone sulfate (DHEAS). The basis for this action is related to the increase in the zona reticularis and in the increased activity of the 17α-hydroxylase and the 17,20-lyase enzymes.

Testosterone

Approximately one-half of a woman's serum testosterone is derived from peripheral conversion of secreted androstenedione, and the other one-half is derived from direct glandular secretion. The ovaries and adrenal glands contribute about equally to the direct glandular testosterone production in women.

Approximately 85% to 78% of circulating testosterone is bound to sex hormone–binding globulin (SHBG) and is considered biologically inactive. Most of the proportion of serum testosterone that is not bound to SHBG is associated with albumin (20% to 32%). Finally, a small percentage (1% to 2%) of testosterone is entirely unbound or free.

The concentration of free testosterone has an inverse relationship with the SHBG concentration. Increased SHBG levels are noted in conditions associated with high estrogen levels. Thus, pregnancy and the luteal phase, use of estrogen (including oral contraceptives), and conditions causing elevated thyroid hormone levels and cirrhosis of the liver are associated with reduced free testosterone levels caused by elevated SHBG levels. Conversely, levels of SHBG decrease and result in elevated free testosterone levels in response to androgens, androgenic medications (progestational agents with androgenic biologic activities, danazol), androgenic disorders (PCOS, CAH, Cushings syndrome), glucocorticoids, growth hormone, prolactin, insulin, and obesity.

Because nearly all practitioners measure some form of testosterone level, a basic understanding of the methods and accuracy of various techniques is critical. Testosterone nonspecifically bound to albumin (AT) is linearly related to free testosterone (FT) by the equation AT = Kₐ [A] × FT, where AT is the albumin-bound testosterone, Kₐ is the association constant of albumin for testosterone, and [A] is the albumin concentration. In most cases of hirsutism, albumin levels are within a tight physiologic range and thus do not significantly affect the free testosterone concentration. Therefore, in most cases of hirsutism, the free testosterone level can be calculated by measuring the total testosterone as well as the SHBG concentration. A physiologic albumin level is assumed, and the free testosterone level is calculated with good reliability when compared with equilibrium dialysis. This method provides a rapid, simple, and accurate determination of the total and calculated free testosterone level as well as the concentration of SHBG.

The bioavailable testosterone level is also based on the relationship of albumin and free testosterone but incorporates the actual measurement of albumin levels with the total testosterone and SHBG. The assessment of free testosterone by methods other than the direct immunoassay of total testosterone, SHBG, and albumin in the case of bioavailable testosterone is unreliable (3).

A notable exception to the accuracy of the aforementioned measurements is pregnancy. During pregnancy estradiol occupies a large proportion of SHBG binding sites, resulting in an overestimation of the actual binding capacity of SHBG. Testosterone is unable to bind all the SHBG sites because they are occupied by estradiol; thus, an underestimation of free testosterone level occurs. Therefore, during pregnancy a total testosterone level is the only clinically reliable measurement and can be used to help rule out a testosterone-secreting tumor.

For testosterone to exert its biologic effects on many target tissues, it must be converted into its active metabolite, DHT, by 5α-reductase (a cytosolic enzyme that reduces testosterone and androstenedione levels). Two isozymes of 5α-reductase exist: type 1, which predominates in the skin, and type 2, or acidic 5α-reductase, which is found in the liver, prostate, seminal vesicles, and genital skin. The type 2 isozyme has a 20-fold higher affinity for testosterone than type 1. Both type 1 and 2 deficiencies in males result in ambiguous genitalia, and both isozymes may play a role in androgen effects on hair growth. Dihydrotestosterone is more potent than testosterone, primarily because of its higher affinity and slower dissociation from the androgen receptor. The relative androgenicity of androgens is as follows: DHT = 300, testosterone = 100, androstenedione = 10, and DHEAS = 5.

Until adrenarche, androgen levels remain low. Around 8 years of age, adrenarche is heralded by a marked increase in DHEA and DHEAS. The half-life of free DHEA is extremely short (about 30 minutes) but extends to several hours if DHEA is sulfated. Although no clear role is identified for DHEAS, it is associated with stress and level is inversely related to aging.

With age, the adrenal glands produce less DHEA and DHEAS. Once the ovaries cease production of estrogen during menopause, the production of testosterone and androstenedione increases. The diurnal variation is maintained by the adrenal contribution. These androgens are ultimately converted to estrone (E₁) and estradiol (E₂) via extraglandular aromatization.

Laboratory Evaluation

Critical laboratory testing for the assessment of hirsutism should include total testosterone, SHBG, calculated free or bioavailable testosterone (includes actual albumin concentration measurement), DHEAS, and 17-hydroxyprogesterone (17-OHP) measurements (Table 25.1). If a patient is oligomenorrheic, LH,
Insulin resistance increased risk of diabetes mellitus and cardiovascular disease (Obesity PCOS). In hyperandrogenic women with regular menstrual cycles, the rate of anovulation is 21% (Menstrual dysfunction). A likely explanation for this discrepancy is the genetically determined differences in skin 5α-reductase activity (Hirsutism). Onset of hirsutism and obesity, elevated LH-to-FSH ratio, ultrasonographic evidence of PCOS, and oligoovulation. All other frequently encountered manifestations are less consistent findings and therefore qualify only as minor criteria. They include insulin resistance, perimenarchal amenorrhea, and obesity.

Some hirsute women manifest testosterone levels above normal (20 to 80 ng/dl [0.723 nmol/L]). However, there is no direct correlation between the level of hirsutism and the total testosterone concentration because hirsutism is caused by the action of the testosterone metabolite DHT, which in turn is related to the concentration of SHBG. Low SHBG levels, which frequently occur in the presence of elevated androgen and insulin levels, increase free testosterone levels. The result is hirsutism in the absence of an increase in total testosterone. Therefore, the total serum testosterone concentration is subject to wide variation in the concentration of binding proteins, and therefore is not a reliable index of bioavailable testosterone. It does, however, serve as a marker for androgen-producing neoplasms. Total testosterone levels >200 ng/dl should prompt a workup for ovarian or adrenal tumors.

In the past, testing for androgen conjugates (e.g., 3α-androstenediol G [3α-diol G] and androsterone G [AOG] as markers for 5α-reductase activity in the skin) has been advocated. However, routine determination of androgen conjugates to assess hirsute patients is not recommended, because hirsutism itself is an excellent bioassay of free testosterone action on the hair follicle and because these androgen conjugates arise from adrenal precursors and are likely markers of only adrenal and not ovarian steroid production (4).

In most laboratories, the upper limit of a DHEAS level is 350 µg/dl (9.5 nmol/L). A random sample is sufficient because the level of variation is minimized as a result of the long half-life of the sulfated form. A normal level essentially rules out adrenal disease, and moderate elevations are a common finding in the presence of PCOS. As a rule, a DHEAS level of over 700 µg/dl (20 nmol/L) indicates the need to rule out an adrenal tumor or Cushing's syndrome. Occasionally, ovarian tumors are associated with high DHEAS levels.

Because the 17-OHP level varies significantly in the cycle, standardized testing requires evaluation in the morning during the follicular phase. A baseline follicular phase 17-OHP level should be less than 200 ng/dl (6 nmol/L). When levels are greater than 200 ng/dl but less than 800 ng/dl (24 nmol/L), ACTH testing should be performed. Levels greater than 800 ng/dl (24 nmol/L) also warrant ACTH testing but are virtually diagnostic of 21-hydroxylase deficiency.

**Polycystic Ovary Syndrome**

The most common cause of hyperandrogenism and hirsutism is PCOS. The association of amenorrhea with bilateral polycystic ovaries was first described in 1935 by Stein and Leventhal (5) and was known for decades as the Stein-Leventhal syndrome. In the past the clinical diagnosis rested on the triad of hirsutism, amenorrhea, and obesity. Subsequently it has been recognized that PCOS has an extremely heterogeneous clinical picture and is multifactorial in etiology (6). Following are diagnostic criteria based on the modified consensus of the National Institutes of Health and Child Health and Human Development:

- **Major**
  - Chronic anovulation
  - Hyperandrogenemia
  - Clinical signs of hyperandrogenism
  - Other etiologies excluded
- **Minor**
  - Insulin resistance
  - Perimenarchal onset of hirsutism and obesity
  - Elevated LH-to-FSH ratio

Intermittent anovulation associated with hyperandrogenemia (free testosterone, DHEAS) in the absence of other pathologies such as ovarian and adrenal neoplasms, pituitary disease, or CAH.

All other frequently encountered manifestations are less consistent findings and therefore qualify only as minor criteria. They include insulin resistance, perimenarchal onset of hirsutism and obesity, elevated LH-to-FSH ratio, ultrasonographic evidence of PCOS, and oligoovulation.

Hirsutism occurs in approximately 70% of patients in the United States with PCOS (7) and in only 10% to 20% of Japanese patients with PCOS (8). A likely explanation for this discrepancy is the genetically determined differences in skin 5α-reductase activity (9). Menstrual dysfunction typically occurs in PCOS, ranging from oligomenorrhea to amenorrhea. As a rule, patients with PCOS exhibit anovulation. Even in hyperandrogenic women with regular menstrual cycles, the rate of anovulation is 21% (11). Severe acne in the teenage years appears to be an accurate predictor of PCOS (12).

Obesity is found in over 50% of patients with PCOS. The body fat is usually deposited centrally (android obesity), and a higher waist-to-hip ratio indicates an increased risk of diabetes mellitus and cardiovascular disease (13). Insulin resistance and hyperinsulinemia are commonly exhibited in PCOS. Insulin resistance is now recognized as a major risk factor for the development of type 2 diabetes mellitus (14). About one-third of obese PCOS patients have impaired glucose tolerance (IGT), and 7.5% to 10% have type 2 diabetes mellitus (15,16). These
rates are mildly increased even in nonobese women who have PCOS (10% IGT; 1.5% diabetes, respectively) (16), compared with the general population of the United States (7.8% IGT; 1% diabetes, respectively) (17).

Abnormal lipoproteins are common in PCOS and include elevated total cholesterol, triglycerides, and low-density lipoproteins (LDL), and low levels of high-density lipoproteins (HDL) and apoprotein A-I (19,20). According to one report, the most characteristic lipid alteration is decreased levels of HDL → (19).

Other observations in women with PCOS include impaired fibrinolysis as shown by elevated circulating levels of plasminogen activator inhibitor (20), an increased incidence of hypertension over the years that reaches a 40% incidence by perimenopause (18), a greater prevalence of atherosclerosis and cardiovascular disease (21-23), and an estimated sevenfold increased risk for myocardial infarction (23).

Pathophysiology and Laboratory Findings

The hyperandrogenism and anovulation that accompany PCOS may be caused by abnormalities in four endocrinologically active compartments, (a) the ovaries, (b) the adrenal glands, (c) the periphery (fat), and (d) the hypothalamus-pituitary compartment.

In patients with PCOS, the ovarian compartment is the most consistent contributor of androgens. Dysregulation of CYP17, the androgen-forming enzyme in both the adrenals and the ovaries, may be one of the central pathogenetic mechanisms underlying hyperandrogenism in PCOS (25). The ovarian stroma, theca, and granulosa contribute to ovarian hyperandrogenism and are stimulated by LH (26). This hormone relates to ovarian androgenic activity in PCOS in a number of ways.

1. Total and free testosterone levels correlate directly with LH levels (27).
2. The ovaries are more sensitive to gonadotropic stimulation, possibly as a result of CYP17 dysregulation (25).
3. Treatment with a gonadotropin-releasing hormone (GnRH) agonist effectively suppresses serum testosterone and androstenedione levels (28).
4. Larger doses of a GnRH agonist are required for androgen suppression than for estrogen suppression (29).

The increased testosterone levels in patients with PCOS are considered ovarian in origin. The serum total testosterone levels are usually no more than twice the upper normal range (20 to 80 ng/dl). However, in ovarian hyperthecosis, values may reach 200 ng/dl or more (30). High intraovarian androgen concentrations inhibit follicular maturation. Although ovarian theca cells are hyperactive, the retarded follicular maturation results in inactive granulosa cells with minimal aromatase activity for conversion to estrogens.

The adrenal compartment also plays a role in the development of PCOS. Although the hyperfunctioning CYP17 androgen-forming enzyme coexists in both the ovaries and the adrenal glands (30), DHEAS is increased in only about 50% of patients with PCOS (31,32). The hyperresponsiveness of DHEAS to stimulation with ACTH (30), the onset of symptoms around puberty, and the observation that 17,20-lyase activation (one of the two CYP17 enzymes) is a key event in adrenarche have led to the concept of PCOS as an exaggerated adrenarche.

The peripheral compartment, defined as the skin and the adipose tissue, manifests its contribution to the development of PCOS in several ways.

1. The presence and activity of 5a-reductase in the skin largely determines the presence or absence of hirsutism (9,10).
2. Aromatase and 17b-hydroxysteroid dehydrogenase activities are increased in fat cells (33), and peripheral aromatization of androstenedione is increased with body weight (34).
3. The metabolism of estrogens, by way of reduced 2-hydroxylation and 17a-oxidation, is decreased (2).
4. Large doses of a GnRH agonist are required for estrogen suppression (29).
5. A chronic hyperandrogenic state results with reversal of the E_{1}-to-E_{2} ratio.

The hypothalamic-pituitary compartment also participates in aspects critical to the development of PCOS.

1. An increase in LH pulse frequency is the result of increased GnRH pulse frequency (37).
2. This increase in LH pulse frequency typically results in elevated LH and LH-to-FSH ratio.
3. FSH is not increased with LH, probably because of the synergistic negative feedback of chronically elevated estrogen levels and normal follicular inhibit.
4. About 25% of patients with PCOS exhibit elevated prolactin levels. The hyperprolactinemia may result from abnormal estrogen feedback to the pituitary gland. In some patients with PCOS, bromocriptine has reduced LH levels and restored ovulatory function (39).

Genetic association and linkage analysis studies presently under way suggest an oligogenic origin for PCOS.

Insulin Resistance

Patients with PCOS are at risk for hyperinsulinemia and insulin resistance. The most common cause of insulin resistance and compensatory hyperinsulinemia is obesity. The insulin resistance seen in PCOS seems to be independent of the expected insulin resistance that occurs with obesity alone (38). The following observations provide evidence that the insulin resistance associated with PCOS is not the result of hyperandrogenism:

1. Hyperinsulinemia is not a characteristic of hyperandrogenism in general but is uniquely associated with PCOS (39).
2. In women with PCOS, 30% to 45% have glucose intolerance or frank diabetes mellitus, whereas ovulatory hyperandrogenic women have normal insulin levels and glucose tolerance (39). It seems that the negative effects of PCOS and obesity on the action of insulin are synergistic.
3. Treatment with long-acting GnRH analogs does not change insulin levels or insulin resistance (40).
4. Oophorectomy in patients with hyperthecosis accompanied by hyperinsulinemia and hyperandrogenemia does not change insulin resistance, despite a decrease in androgen levels (41).

Acanthosis nigricans is considered a marker for insulin resistance in hirsute women. This thickened, pigmented, velvety skin lesion is most often found in the vulva and may be present on the axilla, over the nape of the neck, below the breast, and on the inner thigh (42). Women with severe insulin resistance sometimes develop HAIR-AN syndrome (43), consisting of hyperandrogenism (HA), insulin resistance (IR), and acanthosis nigricans (AN). These patients usually have high testosterone levels (>150 ng/d), fasting insulin levels of greater than 25 µU/ml (normal <20 to 24 µU/ml), and maximal serum insulin responses to glucose load exceeding 300 µU/ml (normal is <160 µU/ml at 2 hours post–glucose load).

Insulin alters ovarian steroidogenesis independent of gonadotropin secretion in PCOS. Insulin and insulin-like growth factor I (IGF-I) receptors are present in the ovarian stromal cells. A specific defect in the early steps of insulin receptor–mediated signaling (diminished autophosphorylation) has been identified in 50% of women with PCOS (44).

Clinically, it is important to realize that patients with PCOS are at increased risk for glucose intolerance or frank diabetes mellitus early in life. Therefore, it is appropriate to screen obese women with PCOS for glucose intolerance on a regular basis, once or twice a year. Abnormal glucose metabolism may be significantly improved with weight reduction, which may also reduce hyperandrogenism and restore ovulatory function (45). In obese, insulin-resistant women, caloric restriction that results in weight reduction will reduce the severity of insulin resistance (a 40% decrease in insulin level with a 10-kg weight loss) (46). This decrease in insulin levels should result in a marked decrease in androgen production (a 35% decrease in testosterone levels with a 10-kg weight loss) (46).

Radiologic Studies
Estrogens decrease conversion of testosterone to DHT in the skin by inhibition of 5α-reductase.

The progestin component suppresses LH, resulting in diminished ovarian androgen production. Circulating androgen levels are reduced, which to some extent is independent of the effects of both LH and SHBG. Adrenal androgen secretion is reduced (norgestrel, norethindrone).

Side effects that resemble Cushing's syndrome.

Glucocorticoids

Dexamethasone may be used to treat patients with PCOS who have either adrenal or mixed adrenal and ovarian hyperandrogenism. Doses of dexamethasone as low as 0.25 mg nightly or every other night are used initially to suppress DHEAS concentrations to less than 400 µg/dl. Because dexamethasone has 40 times the glucocorticoid effect of cortisol, daily doses greater than 0.5 mg every evening should be avoided to prevent the risk of adrenal suppression and severe side effects that resemble Cushing's syndrome. To avoid oversuppression of the pituitary-adrenal axis, morning serum cortisol levels should be monitored intermittently (maintain at >2 µg/dl). Reduction in hair growth rate has been reported.

Medroxyprogesterone Acetate

Oral or intramuscular administration of medroxyprogesterone acetate has been used successfully for treatment of hirsutism. It directly affects the hypothalamic-pituitary axis by decreasing GnRH production and the release of gonadotrophins, thereby reducing testosterone and estrogen levels. Despite a decrease in SHBG, total and free androgen levels are decreased significantly. The recommended oral dosage is 20 to 40 mg daily in divided doses or 150 mg given intramuscularly every 8 days decreases hirsutism.

Weight Reduction

When an OC is used to treat hirsutism, a balance must be maintained between the decrease in free testosterone levels and the intrinsic androgenicity of the progestin. Three progestin compounds that are present in OCs (norgestrel, norethindrone, and norethindrone acetate) are believed to be androgen dominant. The androgenic bioactivity of these steroids may be a factor of their shared structural similarity with 19-nortestosterone steroids. Oral contraceptives containing the so-called new progestins (desogestrel, gestodene, norgestimate, and drospirenone) have minimized androgenic activity.

The use of OCs alone may be relatively ineffective (<10% success rate) in the treatment of hirsutism in women with PCOS. Insulin resistance may also be enhanced by OCs in these patients.

Gonadotropin-releasing Hormone Agonists

Administration of GnRH agonists may allow the differentiation of androgen produced by adrenal sources from that of ovarian sources. It has been shown to suppress ovarian steroids to castration levels in patients with PCOS. Treatment with leuprolide acetate given intramuscularly every 8 days decreases hirsutism and hair diameter in both idiopathic hirsutism and hirsutism secondary to PCOS. Ovarian androgen levels are significantly and selectively suppressed. The addition of OC or estrogen replacement therapy to GnRH agonist treatment (add-back therapy) prevents bone loss and other side effects of menopause, such as hot flushes and genitai atrophy. The hirsutism-reducing effect is retained.

Glucocorticoids

Dexamethasone may be used to treat patients with PCOS who have either adrenal or mixed adrenal and ovarian hyperandrogenism. Doses of dexamethasone as low as 0.25 mg nightly or every other night are used initially to suppress DHEAS concentrations to less than 400 µg/dl. Because dexamethasone has 40 times the glucocorticoid effect of cortisol, daily doses greater than 0.5 mg every evening should be avoided to prevent the risk of adrenal suppression and severe side effects that resemble Cushing's syndrome. To avoid oversuppression of the pituitary-adrenal axis, morning serum cortisol levels should be monitored intermittently (maintain at >2 µg/dl). Reduction in hair growth rate has been reported, as well as significant improvement in acne associated with adrenal hyperandrogenism.
Ketoconazole

Ketoconazole inhibits the key steriodogenic cytochromes. Administered at a low dose (200 mg/day), it can significantly reduce the levels of androstenedione, testosterone, and calculated free testosterone (73).

Spironolactone

Spironolactone is a specific antagonist of aldosterone, which competitively binds to the aldosterone receptors in the distal tubular region of the kidney. It is, therefore, an effective potassium-sparing diuretic, which was originally used for treatment of hypertension. The effectiveness of spironolactone in the treatment of hirsutism is based on the following mechanisms:

1. Competitive inhibition at the intracellular receptor level for DHT (74).
2. Suppression of testosterone biosynthesis by a decrease in the CYP enzymes (75).
3. Increase in androgen catabolism (with increased peripheral conversion of testosterone to estrone).
4. Inhibition of skin 5α-reductase activity (75).

Although total and free testosterone levels are significantly reduced in patients with both PCOS and idiopathic hirsutism (hyperandrogenism with regular menses) after treatment with spironolactone, total and free testosterone levels in patients with PCOS remain higher than those with idiopathic hirsutism (hyperandrogenism with regular menses) (76). In both groups, SHBG levels are unaltered. The reduction in circulating androgen levels observed within a few days of spironolactone treatment partially accounts for the progressive regression of hirsutism.

At least a modest improvement in hirsutism can be anticipated in 70% to 80% of women using at least 100 mg of spironolactone per day for 6 months (77). Spironolactone reduces the daily linear growth rate of sexual hair, hair shaft diameters, and daily hair volume production (78). The most common dosages is 25 to 100 mg twice daily. Women treated with 200 mg/day show a greater reduction in hair shaft diameter than women receiving 100 mg/day (79). Maximal effect on hair growth is noted between 3 and 6 months but continues for 12 months. Electrolysis can be recommended 9 to 12 months after the initiation of spironolactone for permanent hair removal.

The most common side effect of spironolactone is menstrual irregularity (usually metrorrhagia), which may occur in over 50% of patients with a dosage of 200 mg/day (73). Normal menses may resume with reduction of the dosage. Infrequently, other side effects such as urticaria, mastodynia, or scalp hair loss occur (73). Nausea and fatigue can occur with high doses (77). Because spironolactone can increase serum potassium levels, its use is not recommended in patients with renal insufficiency or hyperkalaemia. Periodic monitoring of potassium and creatinine levels is suggested.

Return of normal menses in amenorrheic patients is reported in up to 60% of cases (76). Patients must be counseled to use contraception while taking spironolactone because it theoretically can feminize a male fetus.

Cyproterone Acetate

Cyproterone acetate is a synthetic progestin derived from 17-OHP that has potent antiandrogenic properties. The primary mechanism of cyproterone acetate is competitive inhibition of testosterone and DHT at the level of androgen receptors (80). This agent also induces hepatic enzymes and may increase the metabolic clearance rate of plasma androgens (81).

The combination of ethinyl estradiol with cyproterone acetate, which was commonly used in Europe for many years, significantly reduces plasma testosterone and androstenedione levels, suppresses gonadotropins, and increases SHBG levels (82). Cyproterone acetate also shows mild glucocorticoid activity (83) and may reduce DHEAS levels (84). Administered in a reverse sequential regimen (cyproterone acetate 100 mg/day on days 5 to 15, and ethinyl estradiol 30 to 50 mg/day on cycle days 5 to 25), a cyclic schedule allows regular menstrual bleeding, provides excellent contraception, and is effective in the treatment of even severe hirsutism and acne (85). When a desired clinical response is achieved, the dose of cyproterone acetate may be tapered gradually at 3- to 6-month intervals.

Side effects of cyproterone acetate include fatigue, weight gain, decreased libido, irregular bleeding, nausea, and headaches. These symptoms occur less often when ethinyl estradiol is added. Cyproterone acetate administration has been associated with liver tumors in beagles and is not approved by the U.S. Food and Drug Administration for use in the United States.

Flutamide

Flutamide, a pure nonsteroidal antiandrogen, is approved for treatment of advanced prostate cancer. Its mechanism of action is inhibition of nuclear binding of androgens in target tissues. Although it has a weaker affinity to the androgen receptor than spironolactone or cyproterone acetate, larger doses (250 mg given 2 or 3 times daily) may compensate for the reduced potency. Flutamide is also a weak inhibitor of testosterone biosynthesis.

In a single, 3-month study of flutamide alone, most patients demonstrated significant improvement in hirsutism with no change in androgen levels (86). Significant improvement in hirsutism with a significant drop in androstenedione, DHT, LH, and FSH levels was observed in an 8-month follow-up of flutamide and low-dose OCs in women who did not respond to OCs alone (87). The side effects of flutamide treatment combined with a low-dose OC included dry skin, hot flashes, increased appetite, headaches, fatigue, nausea, dizziness, decreased libido, liver toxicity, and breast tenderness (88). Many patients taking flutamide (50% to 75%) report dry skin or a blue-green discoloration of urine. The risk of liver toxicity precludes flutamide as a routine option for the treatment of hirsutism.

Cimetidine

Cimetidine is a histamine H2 receptor antagonist that has demonstrated a weak antiandrogenic effect as a result of its ability to occupy androgen receptors and inhibit DHT binding at the level of the hair follicles. Although cimetidine has been reported to reduce hair growth in women with hirsutism (89), two later studies show no beneficial effect (90,91).

Flutamide

Finasteride

Finasteride is a specific inhibitor of type 2 5α-reductase enzyme activity that has been approved in the United States at a 5-mg dose for the treatment of benign prostatic hyperplasia and at a 1-mg dose to treat male-pattern baldness. In a study in which finasteride (5 mg daily) was compared with spironolactone (100 mg daily) (92), both drugs resulted in similar significant improvement in hirsutism despite differing effects on androgen levels. Most of the improvement in hirsutism occurred after 6 months of therapy with 7.5 mg of finasteride daily (93). The improvement in hirsutism in the presence of rising testosterone levels serves as convincing evidence that it is the binding of DHT and not testosterone to the androgen receptor that is responsible for hair growth. Finasteride does not prevent ovulation or cause menstrual irregularity. The increase in SHBG caused by OCs further decreases free testosterone levels; OCs in combination with finasteride are more effective in reducing hirsutism than finasteride alone. As with spironolactone, finasteride could theoretically feminize a male fetus; therefore, both of these agents are used only with additional contraception.

Ovarian Wedge Resection

Bilateral ovarian wedge resection is associated with only transient reduction in androstenedione levels and a prolonged minimal decrease in plasma testosterone (94,95). In patients with hirsutism and PCOS who have had wedge resection, hair growth was reduced by approximately 16% (96,97). Although Stein's original report cited a pregnancy rate of 85% following wedge resection and maintenance of ovulatory cycles, subsequent reports show lower pregnancy rates and a concerning incidence of periovulatory adhesions (98).
Laparoscopic ovarian electrocautery is used as an alternative to wedge resection in patients with severe PCOS whose condition is resistant to clomiphene citrate. In a recent series (99), ovarian drilling was achieved laparoscopically with an insulated electrocautery needle, using 100-W cutting current to aid in entry and 40-W coagulating current to treat each microcrypt over 2 seconds (8-mm needle in ovary). In each ovary, 10 to 15 punctures were created. This led to spontaneous ovulation in 73% of patients, with 72% conceiving within 2 years. Of those who had undergone a follow-up laparoscopy, 11 of 15 were adhesion free. To reduce adhesion formation, a technique that cauterized the ovary only in four points led to a similar pregnancy rate (100), with a miscarriage rate of 14% (much lower than the usual miscarriage rate of 30% to 40% for patients with PCOS). Most series report a decrease in both androgen and LH concentrations and an increase in FSH concentrations (101,102). Unilateral diathermy has been shown to result in bilateral ovarian activity (103). Further studies are anticipated to define candidates who may benefit most from such a procedure. The risk of adhesion formation should be discussed with the patient.

### Physical Methods of Hair Removal

Depilatory creams remove hair only temporarily. They break down and dissolve hair by hydrolyzing disulfide bonds. Although depilatories can have a dramatic effect, many women cannot tolerate these irritative chemicals. The topical use of corticosteroid cream may prevent contact dermatitis. Ellfornithine hydrochloride cream also known as diflauramethyleneornithine (DMFO), irreversibly blocks ornithine decarboxylase (ODC), the enzyme in hair follicles that is important in regulating hair growth. It also has proved effective in the treatment of unwanted facial hair (104).

Shaving is effective. Contrary to common belief, it does not change the quality, quantity, or texture of hair (105). However, plucking, if done unevenly and repeatedly, may cause inflammation and damage to hair follicles and render them less amenable to electrolysis. Waxing is a grouped method of plucking in which hairs are plucked out from under the skin surface. The results of waxing last longer (up to 6 weeks) than shaving or depilatory creams (105).

Bleaching removes the hair pigment through the use of hydrogen peroxide (usually 6% strength), which is sometimes combined with ammonia. Although hair lightens and softens during oxidation, this method is frequently associated with hair discoloration, or skin irritation, and is not always effective (104).

Electrolysis and laser hair removal are the only permanent means recommended for hair removal. Under magnification, a trained technician destroys each hair follicle individually. When a needle is inserted into a hair follicle, galvanic current, electrocautery, or both used in combination (blend) destroy the hair follicle. After the needle is removed, a forceps is used to remove the hair. Hair regrowth ranges from 15% to 50%. Problems with electrolysis include pain, scarring, and pigmentation. Cost can also be an obstacle (106). Laser hair removal destroys the hair follicle through photoablation.

### Insulin Sensitizers

Because hyperinsulinemia appears to play a role in PCOS-associated anovulation, treatment with insulin sensitizers may shift the endocrine balance toward ovulation and pregnancy, either alone or in combination with other treatment modalities.

Metformin (Glucophage) is an oral biguanide antihyperglycemic drug used extensively in Europe for non–insulin-dependent diabetes. Given its category B status, there has been limited use of the drug in pregnant women with diabetes. Preliminary studies evaluating metformin use in pregnancy suggest no teratogenicity and a reduced miscarriage rate but a potential increased risk of preeclampsia and perinatal mortality (107,108).

Metformin lowers blood glucose mainly by inhibiting hepatic glucose production and by enhancing peripheral glucose uptake. Metformin enhances insulin sensitivity at the postreceptor level and stimulates insulin-mediated glucose disposal (109).

The hyperandrogenism of PCOS is substantially relieved with metformin therapy, which leads to a drop in insulin levels and improved reproductive function (110,111 and 112). Metformin (500 mg 3 times daily) increases ovulation rates both spontaneously and when used in combination with clomiphene citrate in obese patients with PCOS. In this group, a 90% ovulation rate has been achieved (113).

The most common side effects are gastrointestinal, including nausea, vomiting, diarrhea, bloating, and flatulence. Because the drug has caused fatal lactic acidosis in men with diabetes who have renal insufficiency, baseline renal function testing is suggested. The drug should not be given to women with elevated serum creatinine levels (114).

Troglitazone, another insulin sensitizer, has been reported to enhance the number of ovulatory cycles when used alone or with clomiphene citrate (114). The drug has been withdrawn from the market because of liver toxicity and other adverse effects.

A step-by-step approach to ovulation induction in women with PCOS has been suggested (109). This algorithm offers a practical way to integrate insulin sensitizers and ovulation induction in the treatment of PCOS. This regimen may need to be modified as knowledge of the disorder and its treatment continues to evolve. The step approach is: If body-mass index is elevated, loss of at least 5% of current body weight, ovulation induction with clomiphene (with or without glucocorticoid if DHEAS is elevated), Insulin sensitizer as a single agent, Insulin sensitizer in combination with gonadotropin therapy, Ovarian surgery, and in vitro fertilization (IVF).

Current concepts regarding the role of obesity and insulin resistance/hyperinsulinemia in PCOS suggest that the primary intervention should be to recommend and assist with weight loss (5–10% of body weight). In those with an elevated BMI, orlistat has proven to be helpful in initiating and maintaining weight loss. A percentage of PCOS patients will respond to weight loss with spontaneous ovulation. In those who do not respond to weight loss alone or who are unable to lose weight, the sequential addition of clomiphene citrate followed by an insulin sensitizer alone, followed by the combination of these agents may promote ovulation without the need to proceed to injectable gonadotropins.

A prevailing concern over the increased incidence of spontaneous abortions in women with PCOS and the potential reduction afforded by insulin sensitizers suggest that insulin sensitizers may be beneficial in combination with gonadotropin therapy for ovulation induction or in vitro fertilization (115).

### Cushing's Syndrome

The adrenal cortex produces three classes of steroid hormones—glucocorticoids, mineralocorticoids, and sex steroids (androgen and estrogen precursors). Hyperfunction of the adrenal gland can produce clinical signs of increased activity of any or all of these hormones. Increased glucocorticoid action results in nitrogen wasting and a catabolic state. This causes muscle weakness, osteoporosis, atrophy of the skin with striae, nonhealing ulcerations and ecchymoses, reduced immune function, and softens during oxidation, this method is frequently associated with hair discoloration, or skin irritation, and is not always effective (104).

### Causes

The six recognized noniatrogenic causes of Cushing's syndrome can be either ACTH dependent or ACTH independent (Table 25.3). The ACTH-dependent causes can result from ACTH secreted by pituitary adenomas or from an ectopic source. The hallmark of ACTH-dependent forms of Cushing's syndrome is...
the presence of normal or high plasma ACTH concentrations with increased cortisol levels. The adrenal glands are hyperplastic bilaterally. Pituitary ACTH-secreting adenoma, or Cushing's disease, is the most common cause of Cushing's syndrome. These pituitary adenomas are usually microadenomas (<10 mm in diameter) that may be as small as 1 mm. They behave as if they are resistant, to a variable degree, to the feedback effect of cortisol. Like the normal gland, these tumors secrete ACTH in a pulsatile fashion; unlike the normal gland, the diurnal pattern of cortisol secretion is lost. **Ectopic ACTH syndrome most often is caused by malignant tumors.** About one-half of these tumors are small-cell carcinomas of the lung (116). Other tumors include bronchial and thymic carcinomas, carcinoid tumors of the pancreas, and medullary carcinoma of the thyroid.

Table 25.3 Causes of Cushing's Syndrome

Ectopic corticotropin-releasing hormone (CRH) tumors are rare and include such tumors as bronchial carcinoids, medullary thyroid carcinoma, and metastatic prostatic carcinoma (118). The presence of an ectopic CRH-secreting tumor should be suspected in patients who react biochemically similar to those with pituitary ACTH-dependent disease but who have rapid disease progression and very high plasma ACTH levels.

The most common cause of ACTH-independent Cushing's syndrome is exogenous or iatrogenic (i.e., superphysiologic therapy with corticosteroids) or factitious (self-induced). Corticosteroids are used in pharmacologic quantities to treat a variety of diseases with an inflammatory component. Over time, this practice will result in Cushing's syndrome. When corticosteroids are taken by the patient but not prescribed by a physician, the diagnosis may be especially challenging. The diagnostic workup for Cushing's syndrome is summarized in **Fig. 25.2**, Table 25.4, and Table 25.5 (117,118, and 119).

Figure 25.2 The workup of Cushing's syndrome.

Table 25.4 Diagnostic Workup for Cushing's Syndrome

Table 25.5 Laboratory Diagnosis of Cushing's Syndrome

**Treatment of ACTH-independent Forms of Cushing's Syndrome**

Excluding cases that are of iatrogenic or factitious etiology, ACTH-independent forms of Cushing's syndrome are adrenal in origin. Adrenal cancers are usually very large by the time Cushing's syndrome is manifest. This is because the tumors are relatively inefficient in the synthesis of steroid hormones. In general, tumors are larger than 6 cm in diameter and are easily detectable by computed tomography (CT) scanning or magnetic resonance imaging (MRI). Adrenal cancers often produce steroids other than cortisol. Thus, when Cushing's syndrome is accompanied by hirsutism or virilization in women or feminization in men, adrenal cancer should be suspected.

An adrenal tumor that appears large and irregular on radiologic imaging is suggestive of carcinoma. In these cases, a unilateral adrenalectomy through an abdominal exploratory approach is preferable. In most malignant tumors, complete resection is virtually impossible. However, a partial response to postoperative chemotherapy...
or radiation may be achieved. Most patients with malignancy die within 1 year. When administered immediately after surgery, mitotane (O.P-DDD, adrenocortico-lytic drug) may be of benefit in preventing or delaying recurrent disease (124). Manifestations of Cushing’s syndrome in these patients are controlled by adrenal enzyme inhibitors.

Adrenal adenomas are smaller than carcinomas and average 3 cm in diameter. These tumors are usually unilateral and infrequently are associated with other steroid-mediated syndromes. Micronodular adrenal disease is a disorder of children, adolescents, and young adults. The adrenal glands contain numerous small (>3 mm) nodules, which often are pigmented and secrete sufficient cortisol to suppress pituitary ACTH. This condition can be sporadic or familial.

Surgical removal of a neoplasm is the treatment of choice (127,128). If a unilateral, well-circumscribed adenoma is identified by MRI or CT scanning, the flank approach may be the most convenient. The cure rate following surgical removal of adrenal adenomas approaches 100%. Several months of corticosteroid replacement therapy usually is required.

### Treatment of Cushing’s Disease

**The treatment of choice for Cushing’s disease is transphenoidal resection.** The cure rate is approximately 80% in patients with microadenomas who undergo surgery by an experienced surgeon (120) and is less than 50% in patients with macroadenomas (121). Transient diabetes insipidus is common (122).

### Radiation Therapy

High-voltage external pituitary radiation (4,200 to 4,500 cGy) is given at a rate not exceeding 200 cGy/day. Although only 15% to 25% of adults show total improvement (123), approximately 80% of children respond (123).

### Medical Therapy

Mitotane cannot be used to induce medical adrenalectomy during or after pituitary radiation (124). The role of medical therapy is to prepare the severely ill patient for surgery and to maintain normal cortisol levels while a patient awaits the full effect of radiation. Occasionally, medical therapy is used for patients who respond to therapy with only partial remission. Adrenal enzyme inhibitors include aminoglutethimide, metyrapone, triostane, and etomidade.

A combination of aminoglutethimide and metyrapone may cause a total adrenal enzyme block requiring corticosteroid-replacement therapy. Ketoconazole, an FDA-approved antifungal agent, also inhibits adrenal steroid biosynthesis at the side arm cleavage and 11β-hydroxylation steps. The dose of ketoconazole for adrenal suppression is 600 to 800 mg/day for 3 months to 1 year (125). Ketoconazole is effective for long-term control of hypercortisolism of either pituitary or adrenal origin.

 Nelson’s syndrome is an ACTH-secreting pituitary adenoma that develops after bilateral adrenalectomy for Cushing’s disease (126). This syndrome reportedly complicates 10% to 50% of bilateral adrenalectomy cases. Nelson’s syndrome is less common today because bilateral adrenalectomy is less frequently used as initial treatment. Present medical management produces such an effective block to steroid overproduction that it is used primarily as well as after the failure of surgical and radiation therapy. This syndrome is usually caused by a macroadenoma that produces sellar pressure symptoms of headaches, visual field disturbances, and ophthalmoplegia. Extremely high ACTH levels are associated with severe hyperpigmentation (melanocyte-stimulating hormone activity). The treatment is surgical removal or radiation.

### Congenital Adrenal Hyperplasia

CAH is transmitted as an autosomal recessive disorder. Several adrenocortical enzymes necessary for cortisol biosynthesis may be affected. Failure to synthesize the fully functional enzyme has the following effects:

1. A relative decrease in cortisol production
2. A compensatory increase in ACTH levels
3. Hyperplasia of the zona reticularis of the adrenal cortex
4. An accumulation of the precursors of the affected enzyme in the bloodstream.

### 21-Hydroxylase Deficiency

Deficiency of 21-hydroxylase is responsible for over 90% of all cases of CAH. The disorder produces a spectrum of conditions. Salt-wasting CAH, which is the most severe form, affects 75% of patients in whom, during the first 2 weeks of life, a hypovolemic salt-wasting crisis is manifest, accompanied by hypotension, hyperkalemia, and acidosis. The salt-wasting crisis results from ineffective aldosterone synthesis. The condition is usually diagnosed earlier in affected women than in men because it causes genital virilization (e.g., clitoromegaly, labioscrotal fusion, and abnormal urethral course).

In simple virilizing CAH, affected patients are diagnosed as virilized newborn females or as rapidly growing masculinized boys at 3 to 7 years of age.

1. Basal follicular phase 17-OHP <200 ng/dl virtually excludes the disorder; no further testing is required.
2. Basal 17-OHP >500 ng/dl establishes the diagnosis; there is no need for further testing (125).
3. Basal 17-OHP >200 ng/dl and <500 ng/dl requires ACTH stimulation testing.
4. In the ACTH stimulation test, plasma levels of 17-OHP are checked 1 hour following intravenous administration of a bolus of 0.25 mg ACTH 1-24 (cosyntropin [Cortrosyn]) (Fig. 25.3). 17-OHP levels after ACTH stimulation in adult-onset adrenal hyperplasia are generally >1,000 ng/dl (129) (Fig. 25.3).

![Figure 25.3 Basal and stimulated 17-hydroxyprogesterone concentration.](image)

5. Individuals who are heterozygous (carriers) for both adult-onset adrenal hyperplasia and CAH reveal stimulated 17-OHP values <1,000 ng/dl. In many cases, an overlap with the values seen in the normal population is observed (130) (Fig. 25.3).

### Nonclassic Congenital Adrenal Hyperplasia

The nonclassic type 21-hydroxylase deficiency represents partial deficiency in 21-hydroxylatation, which produces a late-onset, milder hyperandrogenemia. Some women with a mild gene defect demonstrate elevated circulating 17-OHP concentrations but no clinical symptoms or signs.
The 21-hydroxylase gene is located on the short arm of chromosome 6, in the midst of the HLA region. The 21-hydroxylase gene is now termed the abdomen and pelvis after injection with NP-59 ((131-iodine) 6-beta-iodomethyl-19-norcholesterol), preceded by adrenal and thyroid suppression, may facilitate CT scanning can reveal tumors larger than 10 mm (1 cm) in the adrenal gland but may not help to distinguish among different types of solid tumors. A vaginal and abdominal ultrasonographic examination is the first step in the evaluation of an ovarian neoplasm. Duplex Doppler scanning may increase the accuracy especially testosterone suppression and stimulation, are unreliable (level greater than 800 µg/dl is typical of an adrenal tumor. An adrenal tumor is unlikely when serum DHEAS and urinary 17-ketosteroid excretion measurements are in androgen-secreting neoplasm. In prepubertal girls, virilizing tumors may cause signs of heterosexual precocious puberty in addition to hirsutism, acne, and virilization.

3b-Hydroxysteroid Dehydrogenase Deficiency

In the mild, nonclassic form, children are found to have virilization or precocious puberty but not hypertension. Adult women will seek treatment for postpubertal onset of hirsutism, acne, and amenorrhea.

3-Dehydroisoandrosterone Synthase Deficiency

Deficiency of 3β-hydroxysteroid dehydrogenase occurs with varying frequency in hirsute patients (142,143). The enzyme is found in both the adrenal glands and ovaries (unlike 21- and 11-hydroxylase) and is responsible for transforming D-5 steroids into the corresponding D-4 compounds. The diagnosis of this disorder relies on the relationship of D-5 and D-4 steroids. A marked elevation of DHEA and DHEAS in the presence of normal or mildly elevated testosterone or androstenedione may be a signal to initiate a screening protocol for 3β-hydroxysteroid dehydrogenase deficiency using exogenous ACTH stimulation (142). Following intravenous administration of a 25-mg ACTH 1-24 bolus, 17-hydroxyprogrenolone levels rise significantly within 60 minutes in women with 3β-hydroxysteroid dehydrogenase deficiency compared with normal women (2.726 ng/ml compared with normal of 1.050 ng/dl). The mean poststimulation ratio between 17-hydroxyprogrenolone and 17-OHP was markedly elevated (mean ratio of 11 compared with 3.4 in normal controls and 0.4 in 21-hydroxylase deficiency). Because of the rarity of this disorder, routine screening of hyperandrogenic patients is not justified (142,143).

Treatment of Adult-onset Congenital Adrenal Hyperplasia

In adults with CAH, dexamethasone has been shown to suppress the hypothalamic–pituitary axis better than cortisone acetate or hydrocortisone administered in equivalent doses and to possibly induce less fluid retention than other corticosteroids. Evening administration with a dosage of 0.25 to 0.5 mg is more effective. Blood pressure is lowered in the mild, nonclassic form, and is associated with a decrease in aldosterone. In some patients, alternate-day therapy using the same dosage is sufficient. Periodic evaluation of serum cortisol is recommended. If morning serum cortisol concentrations are maintained at greater than 2 µg/dl, oversuppression is unlikely.

Androgen-secreting Ovarian and Adrenal Tumor

Patients with severe hirsutism, virilization, or recent and rapidly progressing signs of androgen excess require careful investigation for the presence of an androgen-secreting neoplasm. In prepubertal girls, virilizing tumors may cause signs of heterosexual precocious puberty in addition to hirsutism, acne, and virilization. A markedly elevated total testosterone level (2.5 times the upper normal range or over 200 ng/dl) is typical of an ovarian androgen-secreting tumor, and a DHEAS level greater than 800 µg/dl is typical of an adrenal tumor. An adrenal tumor is unlikely when serum DHEAS and urinary 17-ketosteroid excretion measurements are in the normal basal range and the serum cortisol concentration is greater than 3.3 µg/dl after dexamethasone administration. The results of other dynamic tests, especially testosterone suppression and stimulation, are unreliable.

A vaginal and abdominal ultrasonographic examination is the first step in the evaluation of an ovarian neoplasm. Duplex Doppler scanning may increase the accuracy of tumor localization.

CT scanning can reveal tumors larger than 10 mm (1 cm) in the adrenal gland but may not help to distinguish among different types of solid tumors. In the ovaries, CT scanning cannot help differentiate hormonally active from functional tumors. MRI is comparable, if not superior, to CT scanning in detecting ovarian neoplasms. When CT and selective venous catheterization fail, nuclear medicine scanning of the abdomen and pelvis after injection with NP-59 ([131-iodine] 6-beta-iodomethyl-19-norcortisol), preceded by adrenal and thyroid suppression, may facilitate
If all four vessels are catheterized transversely, selective venous catheterization allows direct localization of the tumor. Samples are obtained for hormonal analysis, with positive localization defined as a 5:1 testosterone gradient compared with lower vena cava values (151). Under such circumstances specificity approaches 80%, but this rate should be weighed against the 5% rate of significant complications such as adrenal hemorrhage and infarction, venous thrombosis, hematoma, and radiation exposure (152).

**Androgen-producing Ovarian Neoplasms**

Ovarian neoplasms are the most frequent androgen-producing tumors. Granulosa cell tumors constitute 1% to 2% of all ovarian tumors and occur mostly in adult women (in postmenopausal more frequently than in premenopausal women) (see Chapter 32). Usually associated with estrogen production, they are the most common functioning tumors in children and lead to isosexual precocious puberty (153). Total abdominal hysterecomy and bilateral salpingo-oophorectomy are the treatments of choice. If fertility is desired, in the absence of contralateral or pelvic involvement, unilateral salpingo-oophorectomy is justifiable. The 10-year survival rates vary from 60% to 90%, depending on the stage, tumor size, and histologic atypia (153).

Thecomas are rare and occur in older patients (153). In one study only 11% were found to be androgenic, even in the presence of steroid-type cells (luteinized thecomas) (154). The tumor is rarely malignant and rarely bilateral, and a simple oophorectomy is sufficient treatment.

Sclerosing stromal tumors are benign neoplasms that usually occur in patients younger than 30 years (153). A few cases with estrogenic or androgenic manifestations have been reported.

Sertoli-Leydig cell tumors, previously classified as androblastoma or arhenoblastoma, account for 11% of solid ovarian tumors. They contain various proportions of Sertoli cells, Leydig cells, and fibroblasts (153). Sertoli-Leydig cell tumors are the most common virilizing tumors in women of reproductive age; however, masculinization occurs in only one-third of patients. The tumor is bilateral in 1.5%. In 80% of cases, it is diagnosed at stage IA (153). Treatment with unilateral salpingo-oophorectomy is justified in patients with stage IA disease who desire fertility. Total abdominal hysterectomy, bilateral salpingo-oophorectomy, and adjuvant therapy are recommended for postmenopausal women who have advanced-stage disease.

Pure Sertoli cell tumors are usually unilateral. For a premenopausal woman with stage I disease, a unilateral salpingo-oophorectomy is the treatment of choice. Malignant tumors are rapidly fatal (156).

Gynandroblastomas are benign tumors with well-differentiated ovarian and testicular elements. A unilateral oophorectomy or salpingo-oophorectomy is sufficient treatment.

Sex cord tumors with annular tubules (SCTAT) are frequently associated with Peutz-Jeghers syndrome (gastrointestinal polyposis and mucocutaneous melanin pigmentation) (156). Their morphologic features range between those of the granulosa cell and Sertoli cell tumors.

Whereas SCTAT with Peutz-Jeghers syndrome tend to be bilateral and benign, SCTAT without Peutz-Jeghers syndrome are almost always unilateral and are malignant in one-fifth of cases (153).

**Steroid Cell Tumors**

According to Young and Scully, steroid cell tumors are composed entirely of steroid-secreting cells subclassified into stromal luteoma, Leydig cell tumors (hilar and nonhilar), and steroid cell tumors that are not otherwise specific (153). Virilization or hirsutism is encountered with three-fourths of Leydig cell tumors, with one-half of steroid cell tumors that are not otherwise specific, and with 12% of stromal luteomas.

**Nonfunctioning Ovarian Tumors**

Ovarian neoplasms, which are usually non-steroid-producing, are occasionally associated with androgen excess and include serous and mucinous cystadenomas, Brenner tumors, Krukenberg tumors, benign cystic teratomas, and dysgerminomas (157). Gonadoblastomas arising in the dysgenetic gonads of patients with a Y chromosome are associated with androgen and estrogen secretion (158,159).

**Stromal Hyperplasia and Stromal Hyperthecosis**

*Stromal hyperplasia is a nonneoplastic proliferation of ovarian stromal cells. Stromal hyperthecosis is defined as the presence of luteinized stromal cells at a distance from the follicles (159). Stromal hyperplasia, which is typically seen in patients between 60 and 80 years of age, may be associated with hyperandrogenism, endometrial carcinoma, obesity, hypertension, and glucose intolerance (160). Hyperthecosis also is seen in a mild form in older patients. In patients of reproductive age, hyperthecosis may demonstrate clinically manifestations of virilization, obesity, and hypertension. Hyperinsulinemia and glucose intolerance may occur in up to 90% of patients with hyperthecosis and probably play a role in the etiology of stromal luteinization and hyperandrogenism (161). Hyperthecosis is found in many patients with hyperandrogenemia, insulin resistance, and acanthosis nigricans (HAIR-AN syndrome).*

In patients with hyperthecosis, levels of ovarian androgens, including testosterone, DHT, and androstenedione are increased, usually in the male range. The predominant estrogen, as in PCOS, is estrone, which is derived from peripheral aromatization. The E₂-to-E₁ ratio is increased. Unlike in PCOS, gonadotropin levels are normal (162).

Wedge resection for the treatment of mild hyperthecosis has been successful and has resulted in resumption of ovulation and even in a pregnancy (163). However, in cases of more severe hyperthecosis and high free testosterone levels (1 to 3 ng/dl), the ovulatory response to wedge resection is only transient (162). In a study in which bilateral oophorectomy was used to control severe virilization, hypertension and glucose intolerance sometimes disappeared (164). Moreover, when a GnRH agonist was used to treat patients with severe hyperthecosis, ovarian androgen production was dramatically suppressed (165).

**Virilization During Pregnancy**

Luteomas of pregnancy are frequently associated with maternal and fetal masculinization. This is not a true neoplasm but rather a reversible hyperplasia, which usually regresses postpartum. A review of the literature reveals a 30% incidence of maternal virilization and a 65% incidence of virilized females in the presence of a pregnancy luteoma and maternal masculinization (166).

Other tumors causing virilization in pregnancy include (in descending order of frequency) Krukenberg tumors, mucinous cystic tumors, Brenner tumors, serous cystadenomas, endometrial sinus tumors, and dermoid cysts. Five cases of virilization of a female child have been reported (153).

**Virilizing Adrenal Neoplasms**

High testosterone levels (in the tumor range), accompanied by normal or only moderately elevated DHEAS levels, should not divert attention from the adrenal gland to the ovary. In fact, patients with these adenomas manifest increased testosterone production following stimulation with human chorionic gonadotropin (hCG) or LH and decreased testosterone secretion following LH suppression.

Of the fewer than 100 reported cases of pure virilizing adrenal neoplasms, 90% were benign. Although the peak age for the diagnosis of adenomas was 20 to 40 years, most of the pure testosterone-producing tumors occurred in menopausal women. With one exception, all cases of adenomas and carcinomas were unilateral.
Fifty percent were palpable abdominally in children; in adults, none was detected solely by physical examination (167).

### Prolactin Disorders

Prolactin was first identified as a product of the anterior pituitary in 1933 (168). Since that time, it has been found in nearly every vertebrate species. The specific activities of human prolactin (hPRL) have been further defined by the separation of its activity from growth hormone (169) and subsequently by the development of radioimmunossays (170,171 and 172). Although the initiation and maintenance of lactation is the primary function of prolactin, many studies have documented a significant role for prolactin activity both within and beyond the reproductive system.

#### Prolactin Secretion

There are 199 amino acids within human prolactin, with a molecular weight (MW) of 23,000 daltons (Fig. 25.4). Although human growth hormone and placental lactogen have significant lactogenic activity, they have only a 16% and 15% amino acid sequence homology with prolactin, respectively.

![Figure 25.4 Amino acid sequence of prolactin. Three cysteine disulfide bands are located within the molecule. (From Bondy PK. Rosenberg leukocyte esterase: metabolic control and disease, 6th ed. Philadelphia: WB Saunders, 1980, with permission.)](image)

In the basal state three forms are released, a monomer, a dimer, and a multimeric species, called little, big, and big-big prolactin, respectively (173,174 and 175). The two larger species can be degraded to the monomeric form by reducing disulfide bonds (176). The proportions of each of these prolactin species vary with physiologic, pathologic, and hormonal stimulation (176,177,178 and 179). The heterogeneity of sequestred forms remains an active area of research. Overall, studies thus far indicate that little prolactin (MW 23,000 daltons) constitutes more than 50% of all combined prolactin production and is most responsive to extrapituitary stimulation or suppression (175,178,179). The bioactivity and immunoreactivity of little prolactin is influenced by glycosylation (180,181,182 and 183). It appears that the glycosylated form is the predominant species secreted, but the most potent biologic form appears to be the 23,000-dalton nonglycosylated form of prolactin (182).

To some degree, the physical heterogeneity of prolactin may explain the biologic heterogeneity of this hormone, but it further complicates the physiologic evaluation of prolactin's myriad effects.

In contrast to other anterior pituitary hormones, which are controlled by hypothalamic-releasing factors, prolactin secretion is primarily under inhibitory control mediated by dopamine. Multiple lines of evidence suggest that dopamine, which is secreted by the tuberoinfundibular dopaminergic neurons into the portal hypophyseal vessels, is the primary prolactin-inhibiting factor. Dopamine receptors have been found on pituitary lactotrophs (184), and treatment with dopamine or dopamine agonists suppresses prolactin secretion (185,186,187,188,189 and 190). The dopamine antagonist metoclopramide abolishes the pulsatility of prolactin release and increases serum prolactin levels (196,197,198). Interference with dopamine release from the hypothalamus to the pituitary routinely increases serum prolactin levels. g-Aminobutyric acid (GABA) and other neuropeptides also may function as prolactin-inhibiting factors (Table 25.6) (192,193,194 and 195). Several hypothalamic polypeptides that increase prolactin-releasing activity are listed in Table 25.6.

![Table 25.6 Chemical Factors Modulating Prolactin Release and Conditions That Result in Hyperprolactinemia](image)

#### Hyperprolactinemia

Physiologic alterations or conditions may result in transient as well as persistent elevations in prolactin levels. Drug-related and physiologic conditions resulting in hyperprolactinemia do not always require intervention.

### Evaluation

Plasma levels of immunoreactive prolactin are 5 to 27 ng/ml throughout the normal menstrual cycle. Samples should not be drawn soon after the patient awakes or after procedures. Prolactin is secreted in a pulsatile fashion with a pulse frequency ranging from about 14 pulses per 24 hours in the late follicular phase to about nine pulses per 24 hours in the late luteal phase. There also is a diurnal variation, with the lowest levels occurring in midmorning. Levels rise 1 hour after the onset of sleep and continue to rise until peak values are reached between 5:00 and 7:00 AM (196,197). The pulse amplitude of prolactin appears to increase from early to late follicular and luteal phases (198,199 and 200). Because of the variability of secretion and inherent limitations of radioimmunoassay, an elevated level should always be rechecked. This sample preferably is drawn midmorning and not after stress, previous venipuncture, breast stimulation, or physical examination, which increase prolactin levels.

Prolactin and TSH determinations are basic evaluations in infertile women. Infertile men with hypogonadism also should be tested. Likewise, prolactin levels should be measured in the evaluation of amenorrhea, galactorrhea, amenorrhea with galactorrhea, hirsutism, with amenorrhea, anovulatory bleeding, and delayed puberty (Fig. 25.5).
Physical Signs

Amenorrhea without galactorrhea is associated with hyperprolactinemia in approximately 15% of women (201,202 and 203). The cessation of normal ovulatory processes attributed to elevated prolactin levels may be related to the following gonadal and hypothalamic-pituitary effects: reduction in granulosa cell number and FSH binding (204), inhibition of granulosa cell 17β-estradiol production by interfering with FSH action (204,205 and 206), inadequate luteinization and reduced progesterone (207,208 and 209), and the suppressive effects of prolactin on GnRH pulsatile release, which may mediate most of the anovulatory effects (210,211,212,213,214,215,216,217,218,219,220,221 and 222).

Although isolated galactorrhea commonly is considered indicative of hyperprolactinemia, prolactin levels are within the normal range in nearly 50% of such patients (223,224 and 225) (Fig. 25.5). In these cases, an earlier transient episode of hyperprolactinemia may have existed, that triggered galactorrhea. This situation is very similar to nursing mothers in whom milk secretion, once established, continues despite normal prolactin levels. Repeat testing is occasionally helpful in detecting hyperprolactinemia. Approximately one-third of women with galactorrhea have normal menses. Conversely, hyperprolactinemia commonly occurs in the absence of galactorrhea (66%), which may result from inadequate estrogenic or progesterational priming of the breast.

In patients with both galactorrhea and amenorrhea (including the syndromes described and named by Forbes, Henneman, Griswold, and Albright in 1951, Argonz and del Castillo in 1953, and Chiari and Frommel in 1985), approximately two-thirds will have hyperprolactinemia; in that group, approximately one-third will have a pituitary adenoma (226). In anovulatory women, 3% to 10% of women diagnosed with polycystic ovary disease have hyperprolactinemia (227,228) (Fig. 25.6).

In all cases of delayed puberty, pupillary abnormalities, including craniopharyngiomas and adenomas, must be considered. Additionally, the multiple endocrine neoplasia type 1 syndrome should be considered, particularly in patients with a family history of multiple adenomas (229). Prolactinomas are noted in approximately 20% of patients with multiple endocrine neoplasia type 1 (MEN-1). The MEN-1 gene is localized to chromosome 11q13 and appears to act as a constitutive tumor suppressor gene. An inactivating mutation results in development of the tumor. It is thought that prolactinomas that occur in patients with MEN-1 may be more aggressive than sporadic prolactinomas (230). Prolactin and TSH levels should be measured in all patients with delayed puberty.

Once an elevated prolactin level is documented, knowledge of neuroanatomy as well as imaging techniques and their interpretation is essential to further management (see Chapter 7). Patients can be reassured that hyperprolactinemia usually is associated with a relatively benign condition (pituitary microadenoma or release of pituitary stem cell growth inhibition through activation or loss of function mutations in the pituitary lactotroph) that requires only periodic monitoring. However, it is critical for the physician to exercise vigilance and to consider other potential etiologies, particularly sellar and suprasellar tumors. Levels of TSH should be measured in all cases of hyperprolactinemia (Fig. 25.5).

Imaging Techniques

In patients with larger microadenomas and macroadenomas prolactin levels usually are higher than 100 ng/ml. However, levels lower than 100 ng/ml may be associated with smaller microadenomas and other suprasellar tumors that may be easily missed on a “coned-down” view of the sella turcica. In patients with a clearly identifiable drug-induced or physiologic hyperprolactinemia, scanning may not be necessary. MRI imaging of the sella and pituitary gland with gadolinium enhancement appears to provide the best anatomic detail (231) (Fig. 25.7). The cumulative radiation dose from multiple CT scans may cause cataracts, and the “coned-down” views or tomograms of the sella are very insensitive and likewise expose the patient to radiation. Even modest elevations of prolactin can be associated with microadenomas or macroadenomas, nonlactotroph pituitary tumors, and other central nervous system abnormalities; thus, imaging of the pituitary gland must be considered (Table 25.7). For patients with hyperprolactinemia who desire future fertility, MRI is indicated to differentiate a pituitary microadenoma from a macroadenoma as well as to identify other potential sellar-suprasellar masses. Although rare, when pregnancy-related complications of a pituitary adenoma occur, they occur more frequently in the presence of macroadenomas (Table 25.7).

Figure 25.5 Workup for hyperprolactinemia.

Figure 25.6 Prolactin levels in 235 patients with galactorrhea.

Figure 25.7 Anatomy of the intrasellar region and cavernous sinus by: (A) anatomic diagram, (B) coronal cytomicrosection, (C) coronal postcontrast.
Although bromocriptine. Very rarely, patients experience nausea and vomiting with cabergoline; they may be treated with intravaginal cabergoline just as with bromocriptine. Although cabergoline appears to be safe to use during pregnancy, more extensive data regarding the use of cabergoline in pregnancy is available; therefore a microadenoma from growing is false. Whereas prolactin levels correlate with tumor size, both elevations and reductions in prolactin levels may occur without any change in tumor size. If during follow-up a prolactin level rises significantly or central nervous system symptoms (headache, visual changes) are noted, repeat scanning may be indicated.

### Hypothalamic Disorders

Dopamine was the first of many substances demonstrated to be produced in the arcuate nucleus. Dopamine-releasing neurons innervate the external zone of the median eminence. When released into the hypophyseal portal system, dopamine inhibits prolactin release in the anterior pituitary. Lesions that disrupt dopamine release can result in hyperprolactinemia. Such lesions may arise from the suprasellar area, pituitary gland, and infundibular stalk, as well as from adjacent bone, brain, cranial nerves, dura, leptomeninges, nasopharynx, and vessels. Numerous pathologic entities and physiologic conditions in the hypothalamic-pituitary region can disrupt dopamine release and cause hyperprolactinemia (Table 25.7).

### Pituitary Disorders

#### Microadenoma

In over one-third of women with hyperprolactinemia, a radiologic abnormality consistent with a microadenoma is found. Release of pituitary stem cell growth inhibition via activation or loss-of-function mutations results in cell cycle dysregulation and is critical to the development of pituitary microadenomas and macroadenomas. Microadenomas (<1 cm) are monoclonal in origin. Genetic mutations are thought to release stem cell growth inhibition and result in autonomous anterior pituitary hormone production, secretion, and cell proliferation. Additional anatomic factors that may contribute to adenoma formation include reduced dopamine concentrations in the hypophyseal portal system and vascular isolation of the tumor or both. Recently, the heparin-binding secretory transforming (HST) gene has been noted in a variety of cancers as well as in prolactinomas (232). Patients with microadenomas (<1 cm) can generally be reassured of a benign course (233,234).

Both microadenomas and macroadenomas (>1 cm) are monoclonal in origin. Pituitary prolactinomas or lactotrope adenomas are sparsely or densely granulated histologically. The sparsely granulated lactotrope adenomas have trabecular, papillary, or solid patterns. Calcification of these tumors may take the form of a psammoma body or a pituitary stone. Densely granulated lactotrope adenomas are strongly acidophilic tumors and appear to be more aggressive than sparsely granulated lactotrope adenomas. Unusual acidophil stem cell adenomas can be associated with hyperprolactinemia with some clinical or biochemical evidence of growth hormone excess.

Microadenomas rarely progress to macroadenomas. Six large series of patients with microadenomas reveal that, with no treatment, the risk of progression for microadenoma to a macroadenoma is only approximately 7% (235). Treatments include expectant, medical or, rarely, surgical therapy. All affected women should be advised to notify their physicians of chronic headaches, visual disturbances (particularly tunnel vision consistent with bitemporal hemianopsia), and extracocular muscle palsies. Formal visual field testing is rarely necessary.

### Expectant Management

In women who do not desire fertility, expectant management can be used for both microadenomas and hyperprolactinemia without an adenoma if menstrual function remains intact. Hyperprolactinemia-induced estrogen deficiency, rather than prolactin itself, is the major factor in the development of osteoporosis. In the absence of symptoms, imaging may be repeated in 12 months to assess further growth of the microadenoma.

### Medical Treatment

Ergot alkaloids are the mainstay of therapy. In 1985, bromocriptine was approved for use in the United States to treat hyperprolactinemia caused by a pituitary adenoma. Ergot alkaloids increase dopamine levels, thus decreasing prolactin levels. Bromocriptine decreases prolactin synthesis, DNA synthesis, cell multiplication, and tumor growth. Bromocriptine treatment results in normal prolactinemia or return of ovulatory menses in 80% to 90% of patients.

Because ergot alkaloids, like bromocriptine, are excreted via the biliary tree, caution is required using it in the presence of liver disease. The major adverse effects include nausea, headaches, hypotension, dizziness, fatigue and drowsiness, vomiting, headaches, nasal congestion, and constipation. Many patients tolerate the drug on the following regimen: one-half tablet every evening (1.25 mg) for 1 week, one-half tablet morning and evening (1.25 mg) during the second week, one-half tablet in the morning (1.25 mg) and a full tablet every evening (2.5 mg) during the third week, and one tablet every morning and early evening during the fourth week and thereafter (2.5 mg twice a day). The lowest dose that maintains the prolactin level in the normal range is continued. Pharmacokinetic studies show peak serum levels occur 3 hours after an oral dose with a nadir at 7 hours. There is little detectable bromocriptine in the serum by 11 to 14 hours. Therefore, twice-a-day administration is required. Prolactin levels can be checked soon (6 to 24 hours) after the last dose.

One rare, but notable, adverse effect of bromocriptine is a psychotic reaction. Symptoms include auditory hallucinations, delusional ideas, and changes in mood that quickly resolve after discontinuation of the drug (237).

Many investigators report no difference in fibrosis, calcification, prolactin immunoreactivity, or the surgical success in patients pretreated with bromocriptine compared to those not receiving bromocriptine (238).

An alternative to oral administration is the vaginal administration of bromocriptine tablets, which is well tolerated (239). Cabergoline, another ergot alkaloid, has a very long half-life and can be given orally once per week. Its long duration of action is attributable to slow elimination by pituitary tumor tissue, high affinity binding to pituitary dopamine receptors, and extensive enterohepatic recirculation.

Cabergoline, which appears to be as effective as bromocriptine in lowering prolactin levels and in reducing tumor size, has substantially fewer adverse effects than bromocriptine. Very rarely, patients experience nausea and vomiting with cabergoline; they may be treated with intravaginal cabergoline just as with bromocriptine. Although cabergoline appears to be safe to use during pregnancy, more extensive data regarding the use of cabergoline in pregnancy is available; therefore.
Thyroid-stimulating hormone regulates thyroidal iodine metabolism by activation of adenylate cyclase. This facilitates endocytosis, digestion of heme-containing oligomer TPO is localized in the rough endoplasmic reticulum, Golgi vesicles, lateral and apical vesicles, and the follicular cell surface. The thyroid provides a storage capacity capable of maintaining a euthyroid state for nearly 2 months without the formation of new thyroid hormones. The membrane-bound, MIT and DIT, are also catalyzed by TPO. Thyroglobulin, the major protein formed in the thyroid gland, has an iodine content of 0.1% to 1.1% by weight. About 33% of molecule, which results in the formation of monoiodotyrosine (MIT) and diiodotyrosine (DIT). Triiodothyronine (T₃) and thyroxine (T₄) are formed by secondary coupling of MIT and DIT, are also catalyzed by TPO. Thyroglobulin, the major protein formed in the thyroid gland, has an iodine content of 0.1% to 1.1% by weight. About 33% of the iodine is present in thyroglobulin in the form of T₃ and T₄ and the remainder is present in the iodotyrosines (MIT and DIT) and unbound iodine. Thyroglobulin provides a storage capacity of maintaining a euthyroid state for nearly 2 months without the formation of new thyroid hormones. The membrane-bound, heme-containing oligomer TPO is localized in the rough endoplasmic reticulum, Golgi vesicles, lateral and apical vesicles, and the follicular cell surface. The thyroid antimicrobial antibodies found in patients with autoimmune thyroid disorders are directed against the TPO enzyme.

Discontinuation of bromocriptine therapy after 2 to 3 years may be attempted because some adenomas undergo hemorrhagic necrosis and cease to function.

**Macroadenomas**

Macroadenomas are pituitary tumors that are larger than 1 cm in size. Bromocriptine is the best initial and potentially long-term treatment option, but transsphenoidal surgery may be required. Evaluation for pituitary hormone deficiencies may be indicated. Symptoms of macroadenoma enlargement include severe headaches, visual field changes and, rarely, diabetes insipidus and blindness. After prolactin has reached normal levels following ergot alkaloid treatment, a repeat MRI is indicated within 6 months to document shrinkage or stabilization of the size of the macroadenoma. This examination may be performed earlier if new symptoms develop or if there is no improvement in previously noted symptoms. Normalized prolactin levels or resumption of menses should not be taken as absolute proof of tumor response to treatment.

**Medical Treatment**

Macroadenomas treated with bromocriptine routinely show a decrease in prolactin levels and size; nearly one-half show a 50% reduction in size, and another one-fourth show a 33% reduction after 6 months of therapy. Because tumor regrowth occurs in over 60% of cases after discontinuation of bromocriptine therapy, long-term therapy is required.

After stabilization of tumor size is documented, the MRI scan is repeated 6 months later and, if stable, yearly for several years. Serum prolactin levels are measured every 6 months. Because tumors may enlarge despite normalized prolactin values, a reevaluation of symptoms at regular intervals (6 months) is required.

**Surgical Intervention**

Tumors that are unresponsive to bromocriptine or that cause persistent visual field loss require surgical intervention. Some neurosurgeons have noted that a short (2- to 6-week) preoperative course of bromocriptine increases the efficacy of surgery in patients with larger adenomas (239). Unfortunately, despite surgical resection, recurrence of hyperprolactinemia and tumor growth is common. Complications of surgery include cerebral carotid artery injury, diabetes insipidus, meningitis, nasal septal perforation, partial or panhypopituitarism, spinal fluid rhinorrhea, and third nerve palsy. Periodic MRI scanning after surgery is indicated, particularly in patients with recurrent hyperprolactinemia.

**HR color=#000000 nuShade SIZE=1**

**Metabolic Dysfunction**

Occasionally, patients with hypothyroidism exhibit hyperprolactinemia with remarkable pituitary enlargement caused by thyrotroph hyperplasia. These patients present to thyroid replacement with reduction in pituitary enlargement and normalization of prolactin levels (240).

Hyperprolactinemia occurs in 20% to 75% of women with chronic renal failure. Prolactin levels are not normalized through hemodialysis but are normalized after transplantation (241,242,243) and (244). Occasionally, women with hyperandrogenemia also have hyperprolactinemia. Elevated prolactin levels may alter adrenal function by enhancing the release of adrenal androgens such as DHEAS (245).

**Drug-induced Hyperprolactinemia**

Numerous drugs interfere with dopamine secretion (Table 25.6). The same principles used in the management of pituitary microadenomas or hyperplasia can be applied in these situations. If medication can be discontinued, resolution of hyperprolactinemia is uniformly prompt.

**Use of Estrogen in Hyperprolactinemia**

In rodents, rapid pituitary prolactin-secreting adenoma (prolactinoma) occurs with high-dose estrogen administration (246). However, even conditions associated with high estrogen levels, such as pregnancy, do not cause prolactinomas in humans. Indeed, pregnancy may have a favorable influence on preexisting prolactinomas (247,248). Studies (249,250 and 251) and autopsy surveys (229) indicate that estrogen administration is not associated with clinical, biochemical, or radiologic evidence of growth of pituitary microadenomas or the progression of idiopathic hyperprolactinemia to an adenoma status. For these reasons, estrogen replacement or OC use is appropriate for hypogonadotropic patients with hyperprolactinemia secondary to microadenoma or hyperplasia.

**Monitoring Pituitary Adenomas During Pregnancy**

Prolactin-secreting microadenomas rarely create complications during pregnancy. However, monitoring of patients with serial gross visual field examinations and fundoscopic examination is recommended. If persistent headaches, visual field deficits, or visual or fundoscopic changes occur, MRI scanning is advisable. Because serum prolactin levels are elevated throughout pregnancy, prolactin measurements are of no value.

Although not recommended, bromocriptine use during pregnancy in women with symptomatic (visual field defects, headaches) microadenoma enlargement has resulted in resolution of deficits and symptoms (253,254,255 and 256).

Pregnant women with previous transsphenoidal surgery for microadenomas or macroadenomas may be monitored additionally with monthly Goldman perimetry visual field testing. Periodic MRI scanning may be necessary in women with symptoms or visual changes. Bromocriptine has been used on a temporary basis to resolve symptoms and visual field deficits in symptomatic patients with macroadenomas to allow completion of pregnancy before initiation of definitive therapy. Breast feeding is not contraindicated in the presence of microadenomas or macroadenomas (253,254,255 and 256).

**Thyroid Disorders**

Thyroid disorders are 10 times more common in women than men (233). Approximately 1% of the female population of the United States will develop overt hypothyroidism. Even prior to the discovery of the long-acting thyroid stimulator (LATS) in women with Graves’ disease in 1956, numerous investigations demonstrated a link between these autoimmune thyroid disorders and reproductive physiology and pathology (259).

**Thyroid Hormones**

Iodide is actively transported into the thyroid follicular cell. Sodium-iodide symporter (NIS) is a key molecule in thyroid function. It allows the accumulation of iodide into the thyroid follicle. Sodium-iodide symporter (NIS) then oxidizes iodide near the cell-colloid surface and incorporates it into tyrosyl residues within the thyroglobulin molecule, which results in the formation of monooiodotyrosine (MIT) and diiodotyrosine (DIT). Triiodothyronine (T₃) and thyroxine (T₄), formed by secondary coupling of MIT and DIT, are also catalyzed by TPO. Thyroglobulin, the major protein formed in the thyroid gland, has an iodine content of 0.1% to 1.1% by weight. About 33% of the iodine is present in thyroglobulin in the form of T₃ and T₄ and the remainder is present in the iodotyrosines (MIT and DIT) and unbound iodine. Thyroglobulin provides a storage capacity of maintaining a euthyroid state for nearly 2 months without the formation of new thyroid hormones. The membrane-bound, heme-containing oligomer TPO is localized in the rough endoplasmic reticulum, Golgi vesicles, lateral and apical vesicles, and the follicular cell surface. The thyroid antimicrobial antibodies found in patients with autoimmune thyroid disease are directed against the TPO enzyme.

Thyroid-stimulating hormone regulates thyroidal iodine metabolism by activation of adenylyl cyclase. This facilitates endocytosis, digestion of thyroglobulin-containing colloid, and the release of thyroid hormones T₃ and T₄. The reverse T₃, T₃, and T₄ is released from the thyroid at 40 to 100 times the concentration of T₄. The reverse T₃ concentration, a histologically inactive metabolite, is 30% to 50% of T₃ secretion and 1% of T₄ concentration. Of thyroid hormones released, 70% are
bound. Although \( T_4 \) is present in the circulating storage pool and has a slow turnover rate (about 7 days), \( T_3 \) concentration is lower and has a higher turnover rate. Approximately 30% of \( T_4 \) is converted to \( T_3 \) in the periphery. Reverse \( T_3 \) levels may help regulate the conversion of \( T_4 \) to \( T_3 \). \( T_3 \) is the primary physiologically functional thyroid hormone, which binds the nuclear receptor at 10 times the affinity of \( T_4 \). Thyroid hormone effects on cells include increased oxygen consumption, heat production, and metabolism of fats, proteins, and carbohydrates. Systemically, thyroid hormone activity is responsible for the basal metabolic rate and balances fuel efficiency, much as a carburetor functions in an engine. Hyperthyroid states result in excessive fuel consumption with marginal performance.

**Iodide Metabolism**

Normal function of the thyroid gland is dependent on iodine. The present recommended daily allowance by the U.S. National Research Council is 150 to 300 mg/day. Present daily consumption in the United States averages 200 to 600 mg/day. Iodine is usually ingested in the form of iodized salt (100 mg of potassium iodide/kg of salt) (261).

Although the thyroid gland depends on iodine, sufficiency of iodine also appears to be associated with the development of autoimmune thyroid disorders (262,263) and reduced remission rates in patients treated for Graves’ disease (264). Animal studies suggest that iodine stimulates immunoglobulin production by B lymphocytes, activates macrophages, and increases the immunogenic potential of thyroglobulin because of the higher iodide content (265,266,267, and 268).

**Factors Affecting Thyroid Function**

Other potential causes of autoimmune thyroid diseases include pollutants (plasticizers, polychlorinated biphenyls, and coal-processing pollutants) (269,270) and antibodies to *Yersinia enterocolitica* (271). The female hormonal milieu and its potential effects on immune surveillance undoubtedly play a role in the increased risk (10-fold) of women to develop autoimmune thyroid disease. The immunoglobulins produced against the thyroid are polyclonal, and the multiple combinations of various antibodies present (stimulating versus blocking, complement fixing, and noncytotoxic) combine to create the clinical spectrum of autoimmune thyroid diseases that affect successful reproductive function.

**Evaluation**

**Thyroid Function**

Total serum \( T_4 \) is measured by radioimmunoassay. Conditions that elevate the levels of thyroid-binding globulin (TBG) (pregnancy, OC use, estrogen replacement, hepatitis, and genetic abnormalities of TBG) necessitate measuring \( T_3 \) resin uptake for clarification.

The \( T_3 \) resin uptake determines the concentration of radiolabeled \( T_3 \) bound to serum TBG and an artificial resin. The number of binding sites available in TBG is inversely proportional to the amount of labeled \( T_3 \) bound to the artificial resin. Therefore, high TBG \( T_3 \) receptor site availability results in a low \( T_3 \) resin uptake.

The free \( T_4 \) index (FTI) is obtained by multiplying the serum \( T_4 \) concentration by the \( T_3 \) resin uptake percentage, yielding an indirect measurement of free \( T_4 \).

\[
\% \text{ free } T_4 \times T_3 \text{ total } = \text{ free } T_4
\]

Equilibrium dialysis may be used to determine the percentage of free \( T_4 \). Free \( T_4 \) and \( T_3 \) may also be determined by radioimmunoassay.

TSH receptor antibodies (TSHR-Ab or TRAb) are pathogenic and capable of activating or blocking TSH receptor functions. TSHR-Ab are detected using two approaches—competitive and functional assays. The competition between antibody and TSH for binding to the TSH receptor is the basis for the measurement of TSH-binding inhibitory immunoglobulin (TSII). The functional assay approach is based on the status of the receptor induced by the antibody-receptor interaction. This functional assay measures the production and accumulation of cyclic (AMP), thyroid hormone or thyroglobulin secretion, or iodide uptake in thyroid epithelial cells or Chinese hamster ovary cells transfected with the human TSH receptor. Whereas the competitive assay does not indicate any functional activity of the antibody, the functional assay identifies whether the antibody is agonistic (thyroid-stimulating antibody [TSAb] or antagonistic TSH stimulation–blocking antibody [TSHBAb]). Both types of antibodies may be present in the same patient, and the effect is the algebraic sum of the two levels of activity (agonistic and antagonistic) (Fig. 25.5).

**Figure 25.5 Types of autoimmune injury found in Hashimoto’s thyroiditis.** A: Complement-mediated cytotoxicity, which can be abolished by inactivating the complement system. B: Antibody-dependent cell-mediated cytotoxicity (ADCC) function through killer T cells, monocytes, and natural killer cells that have immunoglobulin G fragment receptors. C: Stimulation of blockade of hormone receptors leading to hyperfunction or hypofunction or growth, depending on the types of immunoglobulins acting on the target cell. (TBII, TSH-binding inhibitor immunoglobulin; TGI, thyroid growth–promoting immunoglobulin; TSAb, thyroid-stimulating antibodies; TSH, thyroid-stimulating hormone.) (From Coulam CB, Faulk WP, McIntyre JA. Immunologic obstetrics. New York: Norton Medical Books, 1992:658, with permission.)

The present TSH sandwich immunoassays are extremely sensitive and are capable of differentiating low-normal from pathologic or iatrogenically subnormal values and elevations. Thus, TSH measurements provide the best single screen for thyroid dysfunction (272) and accurately predict thyroid hormone dysfunction in about 80% of cases.

**Immunologic Abnormalities**

Many antigen-antibody reactions affecting the thyroid gland can be detected. A number of recognized thyroid autoantigens are listed in Table 25.8. Antibody production to thyroglobulin obviously depends on a breach in normal immune surveillance (273,274). The incidence of thyroid autoantibodies in various autoimmune thyroid disorders is shown in Table 25.9.
Table 25.8 Thyroid Autoantigens

Table 25.9 Prevalence of Thyroid Autoantibodies and Their Role in Immunopathology

Antibodies to thyroglobulin are restricted to one minor and two major epitopes. Antibodies are mainly noncomplement-fixing immunoglobulin G (IgG) polyclonal antibodies (275). Antithyroglobulin antibodies are found in patients with Hashimoto's thyroiditis, Graves' disease, acute thyroiditis, nontoxic goiter, and thyroid cancer. They also appear in normal women.

Antimicrosomal antibodies directed against TPO are found in Hashimoto's thyroiditis, Graves' disease, and postpartum thyroiditis. The antibodies produced are characteristically cytotoxic, complement-fixing IgG antibodies. Antimicrosomal antibodies correlate with the histologic appearance of lymphocytic thyroiditis (259,260).

Antibodies to T₃ and T₄ are present in some patients with Hashimoto's thyroiditis and Graves' disease who have antithyroglobulin antibodies (276). These antibodies can cause artifacts in the measurement of thyroid hormone levels.

Another group of antibodies important in autoimmune thyroid disease binds the TSH receptor. These antibodies often create the signs and symptoms that lead to an evaluation. TSAb or thyroid-stimulating immunoglobulin (TSI) activates the TSH receptor (Table 25.10). Long-acting thyroid stimulators are monoclonal or limited polyclonal TSAb, which mimic TSH action. They are quantified by their ability to stimulate human thyroid cell cultures to produce cyclic adenosine monophosphate or to release T₃.

Table 25.10 Nomenclature of Anti-TSH Receptor Antibodies

TBII is detectable in two varieties, those that block TSH binding and those that block both pre- and postreceptor processes. Several investigators have detected such blocking antibodies in patients with primary hypothyroidism who have atrophic thyroid glands (277,278 and 279). The nomenclature and detection assay of TSH receptor antibodies are listed in Table 25.10.

Thyroid growth-promoting immunoglobulins (TGI) stimulate growth but not hormone release (250,251,252,253,254,255,256,257,258 and 259). Their immunologic antagonists are the TGI-blocking antibodies that are capable of inhibiting TSH-mediated growth responses in patients who may have had thyroid damage by immune destruction (277,278,279 and 280).

Antibodies to the NIS are prevalent in a number of thyroid conditions. Increased expression of NIS protein and NIS mRNA is found in patients with autonomous thyroid adenomas and in Graves' disease. They are decreased in Hashimoto's thyroiditis, cold nodules, and thyroid carcinoma.

Autoimmune Thyroid Disease

The most common thyroid abnormalities in women, autoimmune thyroid disorders, represent the combined effects of the multiple antibodies produced (281). The various antigen-antibody reactions result in the wide clinical spectrum of these disorders. The transmission of these immunoglobulins transplacentally potentially complicates thyroid function in the fetus. The presence of autoimmune thyroid disorders, particularly Graves' disease, is associated with other autoimmune conditions. Other autoimmune conditions associated with Graves' disease are Hashimoto's thyroiditis, Addison's disease, ovarian failure, rheumatoid arthritis, Sjögren's syndrome, diabetes mellitus (type I), vitiligo, pernicious anemia, myasthenia gravis, and idiopathic thrombocytopenic purpura.

Certain groups of individuals require assessment of thyroid function at least once. Such individuals include women with atrial fibrillation, hyperemesis gravidarum, and hyperlipidemia. Periodic assessment of thyroid function is indicated in patients who receive amiodarone and lithium. Epidemiologists recommend that all women with diabetes be annually screened for thyroid dysfunction. Women with type 1 diabetes are 3 times more likely to experience postpartum thyroid dysfunction, and it is recommended that all women with diabetes be screened in their first trimester with TSH. Any woman with a history of postpartum thyroiditis should also be offered annual surveillance of thyroid function. Because there is a high prevalence of hypothyroidism in women with Turner's and Down's syndrome, an annual check of thyroid function is recommended. Periodic TSH screening in mature women is advisable.
Hashimoto's Thyroiditis

Hashimoto’s thyroiditis or chronic lymphocytic thyroiditis, which was first described in 1912, can manifest as hyperthyroidism, hypothyroidism, euthyroid goiter, or diffuse goiter. High levels of antithyroglobulin and antithyroidglobulin antibody are usually present. Typically, glandular hypertrophy is found, but atrophic forms are also present. The composition of various antibodies (i.e., TBI, causing the atrophic form and congenital hypothyroidism in some neonates, and TGI, causing the goitrous variety) results in varied physical findings.

Three classic types of autoimmune injury are found in Hashimoto’s thyroiditis, (a) complement-mediated cytotoxicity, (b) antibody-dependent cell-mediated cytotoxicity, and (c) stimulation or blockade of hormone receptors, which results in hyper- or hypofunction or growth (Fig. 25.3).

The histologic picture of Hashimoto’s thyroiditis includes cellular hyperplasia, disruption of follicular cells, and infiltration of the gland by lymphocytes, monocytes, and plasma cells. Occasionally, adjacent lymphadenopathy may be noted. Some epithelial cells are enlarged and demonstrate oxyphilic changes in the cytoplasm (Askanazy cells or Hürthle cells, which are not specific to this disorder). The interstitial cells show fibrosis and lymphocytic infiltration. Graves’ disease and Hashimoto’s thyroiditis may cause very similar histologic findings manifested by a similar mechanism of action. Nearly all patients with Hashimoto's thyroiditis and about two-thirds of patients with Graves’ disease have sera demonstrating antibody-dependent cell-mediated cytotoxicity.

Clinical Characteristics and Diagnosis of Hashimoto’s Thyroiditis

Most patients with Hashimoto’s thyroiditis are relatively asymptomatic with painless goiter and hypothyroidism. The goiter can also involve the pyramidal lobe. At later stages of the disease, hypothyroidism can be found without a goiter. Notable manifestations of hypothyroidism include cold intolerance, constipation, carotene deposition in the periorbital region, carpal tunnel syndrome, dry skin, fatigue, hair loss, lethargy, and weight gain. Hashitoxicosis, the hyperthyroid manifestation of autoimmune thyroid disease, may represent a variant of Graves’ disease. This form is estimated to occur in 4% to 8% of patients with Hashimoto’s thyroiditis. These patients often become hypothyroid during the course of treatment.

In many cases, an elevated serum level of TSH is noted during routine screening. Elevated serum antithyroglobulin and antithyroidglobulin antibody elevation confirm the diagnosis. The sedimentation rate may be elevated, depending on the course of the disease at the time of recognition. Other causes of hypothyroidism should be considered as listed in Table 25.11.

Table 25.11 Potential Causes of Hypothyroidism

Most clinicians treat women who have elevated serum TSH concentrations and positive thyroid antibody tests, even in the absence of symptoms, in view of the annual risk for hypothyroidism of approximately 5% (283). If the serum TSH alone is elevated, without positive thyroid antibody titers, the annual risk for hypothyroidism drops to approximately 3% per year.

Treatment

Thyroxine replacement is initiated in patients with symptomatic hypothyroidism, patients who have a goiter that is cosmetically or physically bothersome and are subclinically hypothyroid, and patients who are undergoing fertility therapy and are subclinically hypothyroid. Regression of gland size usually does not occur, but treatment prevents further growth. Pregnant patients with an elevated TSH level should be treated with levothyroxine. Treatment does not slow progression of the disease. Replacement therapy is monitored by TSH determinations at least 6 weeks after a change in dose. Aluminum hydroxide (antacids), cholestyramine, iron, and sucralfate may interfere with absorption. The half-life of levothyroxine is nearly 7 days; therefore, nearly 6 weeks of treatment are necessary before the effects of a dose change can be evaluated.

Hypothyroidism appears to be associated with decreased fertility resulting from ovulatory difficulties and not with spontaneous abortion (283,284,285 and 286). Studies also suggest that early subclinical hypothyroidism may be associated with menorrhagia (287).

Severe primary hypothyroidism is associated with amenorrhea or anovulation (283,288,289 and 290). Enhanced sensitivity of the prolactin-secreting cells to thyrotropin-releasing hormone (TRH) and defective dopamine turnover resulting in hyperprolactinemia associated with a deficiency of thyroid hormone are the apparent explanations for the hyperprolactinemia (291,292,293 and 294). Hyperprolactinemia-induced luteal phase defects also are associated with less severe forms of hypothyroidism (273,274 and 275). Replacement therapy appears to reverse the hyperprolactinemia and correct ovulatory defects (295,296 and 297).

Graves’ Disease

Graves’ disease is characterized by exophthalmos, goiter, and hypothyroidism. A heritable specific defect in immunosurveillance by suppressor T lymphocytes is believed to result in the development of a helper T-cell population that reacts to thyroid antigens and induces a B-cell-mediated response (301), resulting in the clinical features of Graves’ disease. TSAb are detected in the serum of 90% of patients with Graves’ disease. Human leukocyte antigen (HLA) class II antigens DR, DP, DQ, and DS can present antigens to T cells and are expressed on thyroid epithelial cells. Antibodies to the TSH receptor are produced when this immunogen (TSH receptor) is presented to helper T lymphocytes with the D locus antigens (302). The class II antigens are upregulated by chronic stimulation of the TSH receptor, reduction in the iodinating capacity of thyroid tissue, viral transformation, and interferon-a (302,303). The clinical use of interferon-a has been associated with autoimmune thyroid disease. Graves’ disease is a complex autoimmune disorder in which several genetic susceptibility loci and environmental factors are likely to play a role in the development of the disease. HLA and the CTLA-4 gene region have been established as susceptibility loci; however, the magnitude of their contributions seems to vary among patient populations and study groups. Additional loci are likely to be identified by a combination of genome-wide linkage analyses and allelic association analyses of candidate genes.

Clinical Characteristics and Diagnosis

The classic triad of exophthalmos, goiter, and hyperthyroidism may be associated with frequent bowel movements, heat intolerance, irritability, nervousness, palpitations or tachycardia, tremor, weight loss, and lower extremity swelling. Physical findings include lid lag, non tender thyroid enlargement (2- to 4-times normal), ophthalmoplegia, follicular conjunctivitis, pretibial myxedema, and vision loss.

Approximately 40% of patients with new onset of Graves’ disease and many of those who have received treatment have elevated T3 and normal T4 levels. Therefore, assessment of T3, T4, and TSH values is indicated. The TSH value may remain undetectable for some time even after the initiation of treatment. In most patients,
 antimicrosomal antibodies are present. Measurement of TSHR-Ab is useful in evaluating medical treatment, prognosis, and potential fetal complications such as neonatal thyrotoxicosis. Autonomously functioning, benign thyroid neoplasias that exhibit a similar clinical picture include toxic adenomas and toxic multinodular goiter. Very rare conditions causing thyrotoxicosis include HCG-secreting choriocarcinoma, TSH-secreting pituitary adenomas, and struma ovarii. Factitious ingestion of thyroxine or desiccated thyroid must be considered in patients with eating disorders. Other potential causes of hyperthyroidism are listed in Table 25.12.

<tr>
<td><strong>Treatment</strong></td>
</tr>
<tr>
<td><strong>Iodine-131 Ablation</strong></td>
</tr>
<tr>
<td>Treatment of women with hyperthyroidism of an autoimmune origin presents unique challenges to the physician who must consider the patient's needs and her reproductive plans. Because the drugs used to treat this disorder have potentially harmful effects on the fetus, special attention must be given to the use of contraception and the potential for pregnancy. A single dose of radioactive iodine-131 (131I) is an effective cure in about 80% of cases and is the most commonly used definitive treatment in nonpregnant women. Any woman of childbearing age should be tested for pregnancy before undergoing diagnostic or therapeutic administration of 131I. Ablation of a second-trimester fetal thyroid gland and congenital hypothyroidism from treatment during the first trimester have been reported (304, 305). Nuclear medicine professionals provide expertise in the administration of the radioactive isotope, and the endocrinologist continues to provide suppressive medical treatment for 6 to 12 weeks after administration of 131I. Therefore, medical therapy is the backbone of therapy even when radioactive 131I or surgery is eventually planned. Postablative hypothyroidism develops in 50% of patients within the first year after 131I therapy and in more than 2% of patients per year thereafter.</td>
</tr>
<tr>
<td><strong>Thyroid-stimulating Receptor Antibody in Graves’ Disease</strong> The level of TSHR-Ab (TBII) grossly parallels the degree of hyperthyroidism as assessed by the serum levels of thyroid hormones and total thyroid volume. Recent studies suggest that the combination of a small goiter volume (&lt;40 ml) and a low TBII level (&lt;30 units/L) results in a 45% chance of remission during the 5 years after completion of a 12- to 24-month course of antithyroid drug therapy (306). In contrast, the overall rate of relapse exceeded 70% in patients with a large goiter volume (&gt;70 ml) and a higher TBII level (&gt;30 units/L). Thus, the subgroup of patients with larger goiters and higher TBII levels had less than a 10% chance to remain in remission in the 5 years after treatment. Therefore, although it is not necessary for the diagnosis of Graves’ disease, except in some cases of multinodular goiter, a TSHR-Ab measurement may be a useful marker of disease severity and, in combination with other clinical factors, may contribute to the initial decisions regarding treatment. See Table 25.10 to review the nomenclature and assay methods for TSHR-Ab. TSHR-Ab measurements (TBII) during treatment with antithyroid drugs also are predictive of subsequent outcome. In one series, 73% of TBII-negative patients had remission compared with only 28% of TBII-positive patients who had achieved remission after 12 months of antithyroid drug therapy (307). Furthermore, the duration of a course of antithyroid drug therapy can be modified according to the TSHR-Ab status. In patients whose TSHR-Ab (TBII) status became negative and antithyroid drug therapy was discontinued, the relapse rate was 41% compared with a rate of 92% for those patients who remained TSHR-Ab-positive (308). Regardless of the rapidity of the disappearance of TSAb, it does seem that antithyroid drug therapy should be maintained for 9 to 12 months to minimize the risk of relapse. TSHR-Ab status also appears to determine in an inverse relationship the reduction in thyroid volume after radioactive iodine therapy.</td>
</tr>
<tr>
<td><strong>Antithyroid Drugs</strong> Antithyroid drugs of the thioamide class include propylthiouracil (PTU) and methimazole. Low doses of these agents block the secondary coupling reactions that form T3 and T4 from MIT and DIT. At higher doses, they also block iodination of tyrosyl residues in thyroglobulin. Approximately one-third of patients treated by this modality alone go into remission and become euthyroid (309). PTU causes a reduction of hyperthyroid symptoms at a dose of 100 mg taken every 8 hours over 1 to 7 days. It blocks the intrathyroid synthesis of T3 and the peripheral conversion of T4 to T3, but does not cross the placenta as easily as methimazole, and therefore is the drug of choice during pregnancy. Drug efficacy is monitored weekly by evaluation of appetite, emotional lability, insomnia, and tremor. A general rule is to lower the dosage by 50% when thyroid function returns to normal, which frequently correlates with the return to a normal heart rate and, subsequently, normalization of TSH levels. Thyroxine is usually the first value to become normal. Pruritus affects 3% to 5% of treated patients. Serious adverse reactions include agranulocytosis (occurring 1 to 2 months after therapy in 0.02%) and a generalized drug eruption accompanied by arthralgia, fever, and sore throat. A complete blood count determination is performed if the patient develops an upper respiratory tract infection. If adverse reactions occur, methimazole may be used. Methimazole (10 mg) is given every 8 to 24 hours. Its dosage is reduced, as with PTU. It is not the drug of choice in pregnant women because it does not block peripheral conversion and crosses the placenta more readily than PTU. It does, however, have fewer adverse reactions, a longer dosing interval, and a lower cost than PTU; therefore, it is most often prescribed in nonpregnant women. Other medical therapies include iodide and lithium, both of which reduce thyroid hormone release and inhibit the organification of iodine. Iodide also leads to the secondary coupling of T4 and T3. These medications are rarely used in women of reproductive age because of their risks to the fetal thyroid and to fetal development (iodine causes congenital goiter; lithium causes Ebstain’s anomaly).</td>
</tr>
<tr>
<td><strong>Surgery</strong> A subtotal thyroidectomy is less commonly used primarily but is used routinely if medical treatment fails or if a patient is hypersensitive to medical therapy. Surgery is the most rapid and consistent method of achieving an euthyroid state in Graves’ disease that avoids the possible long-term risks of radioactive iodine. Children, young women, pregnant women, and patients with coexistent thyroid nodules are potential candidates for thyroidectomy. It is felt to be the treatment of choice for a patient with significant Graves’ ophthalmopathy. Patients should be rendered euthyroid before a thyroidectomy. The risks of surgery include postoperative hypoparathyroidism, recurrent laryngeal nerve paralysis, routine anesthetic and surgical risks, hypothyroidism, and failure to relieve thyrotoxicosis.</td>
</tr>
<tr>
<td><strong>b-Blockers</strong> Propranolol is occasionally used prior to surgery in patients who prove to be hypersensitive to other medical therapy and to provide symptomatic relief while awaiting a reduction in T4 caused by PTU or methimazole.</td>
</tr>
<tr>
<td><strong>Reproductive Effects of Hyperthyroidism</strong> High levels of TSAb in women with Graves’ disease have been associated with fetal-neonatal hyperthyroidism (310, 311). Despite both the inhibition and elevation of gonadotropins seen in thyrotoxicosis (312), most women remain ovulatory and fertile (313). Severe thyrotoxicosis can result in weight loss, menstrual cycle irregularities, and amenorrhea. An increased risk of spontaneous abortion is noted in women with thyrotoxicosis (313). In those who deliver, an increased incidence of congenital anomalies (6%) is noted in their offspring (287). Effective treatment appears to reduce this risk. Autoimmune hyperthyroid Graves’ disease may improve spontaneously, in which case antithyroid drug therapy may be reduced or stopped. Nevertheless, TSHR-Ab production may persist for several years after radical radioactive iodine therapy or surgical treatment for hyperthyroid Graves’ disease. In this circumstance there is a risk of exposing a fetus to TSHR-Ab. Fetal-neonatal hyperthyroidism is observed in 2% to 10% of pregnancies occurring in mothers with a current or previous pregnancy.</td>
</tr>
</tbody>
</table>
diagnosis of Graves’ disease, secondary to the transplacental passage of maternal TSHR-Ab. This is a serious condition with a 16% neonatal mortality rate as well as a risk of intrauterine fetal death, stillbirth, and skeletal developmental abnormalities such as craniosynostosis. Guidelines for TSHR-Ab testing during pregnancy in women with previously treated Graves’ disease are found in Table 25.13.

Table 25.13 Guidelines for TSHR-Ab Testing During Pregnancy With Previously Treated Graves’ Disease

Postpartum Thyroid Dysfunction

This clinical entity is often difficult to diagnose, because its symptoms appear 1 to 6 months postpartum and are often attributed to postpartum depression and difficulties adjusting to the demands of the neonate and infant. Following are criteria for the diagnosis of postpartum thyroiditis: (a) no history of thyroid hormonal abnormalities either before or during pregnancy, (b) documented abnormal TSH level (either depressed or elevated) during the first year postpartum, and (c) absence of a positive TSH-receptor antibody titer (Graves’ disease) or a toxic nodule. Amino and others, who alerted clinicians to this condition, documented an incidence of approximately 5% in their population (316). A number of studies now describe clinical and biochemical evidence of postpartum thyroid dysfunction in 5% to 10% (317). These women have a 25% chance of becoming permanently hypothyroid.

Histologically, lymphocytic infiltration and inflammation are found. Antimicrosomal antibodies are also found in this disorder (318,319). Women who are at greatest risk of developing this disorder are those with a personal or family history of the disorder, those with an autoimmune thyroid disorder, or those with an autoimmune disease.

Clinical Characteristics and Diagnosis

Postpartum thyroiditis usually begins with a transient hyperthyroid phase between 6 weeks and 6 months postpartum followed by a hypothyroid phase. However, only one-fourth of the cases follow this classic clinical picture, whereas over one-third have either hyperthyroidism or hypothyroidism alone. Individuals with type 1 diabetes are 3 times more likely to develop postpartum thyroiditis, and women with a history of postpartum thyroiditis in a previous pregnancy have nearly a 70% chance of recurrence in a subsequent pregnancy. Numerous case reports demonstrate a possible association between postpartum thyroiditis and other autoimmune disorders. Postpartum thyroiditis appears to be caused by the combination of a rebounding immune system in the postpartum state with the presence of thyroid autoantibodies. Although psychic episodes are rare, postpartum thyroid dysfunction should be considered in all women with postpartum psychosis. The thyrotoxic phase may be subclinical and overlooked, particularly in areas where iodine intake is low (320). In contrast to patients with Graves’ disease, those with the hyperthyroid form have a low level of radioactive isotope uptake.

The absence of thyroid tenderness, pain, fever, elevated sedimentation rate, and leukocytosis helps to rule out subacute thyroiditis (de Quervain thyroiditis). Evaluation of TSH, T4, T3, T4 resin uptake, and antimicrosomal antibody titer confirm the diagnosis.

Treatment

Most patients are diagnosed during the hypothyroid phase and require 6 to 12 months of T4 replacement if they are symptomatic. Because approximately 10% to 30% of women develop permanent hypothyroidism, TSH should be evaluated following discontinuation of replacement therapy.

Rarely, patients are diagnosed during the hyperthyroid phase (321). Antithyroid medications are not routinely used for these women. Propranolol may be used for symptomatic relief. Approximately two-thirds of these patients return to a euthyroid state, and one-third return to a hypothyroid state.

Positive Antithyroid Antibody Status

Women who have thyroid autoantibodies before and after conception appear to be at an increased risk for spontaneous abortion (322,323). Non–organ-specific antibody production and pregnancy loss are documented in cases of antiphospholipid antibodies (324). The concurrent presence of organ-specific thyroid antibodies and non–organ-specific autoantibody production is not uncommon (325,326). In cases of recurrent pregnancy loss, thyroid autoantibodies may serve as peripheral markers of abnormal T-cell function and further implicate an immune component as the cause of reproductive failure (327).

Thyroid Nodules

Thyroid nodules are a common finding on physical examination and are demonstrated by ultrasonography in more than 50% of patients (328). Fine-needle biopsy and aspiration are required to rule out malignancy. In the case of indeterminate aspirates, 2% to 20% are malignant; therefore, surgical biopsy is often indicated (329).

Turner’s Syndrome and Down’s Syndrome

Patients with Turner’s syndrome, characterized by a 45,XO karyotype (or other alterations in the X chromosome), have a short stature, primary amenorrhea, and other abnormalities. In this syndrome a high prevalence of autoimmune thyroid disorders is noted. Approximately 50% of adult patients with Turner’s syndrome have antithyroid peroxidase (anti-TPO) and antithyroglobulin (anti-TG) autoantibodies. Of these patients, approximately 30% will develop subclinical or clinical hypothyroidism. The disorder is indistinguishable from Hashimoto’s thyroiditis. A susceptibility locus for Graves’ disease is noted on chromosome X (330).

Down’s syndrome, caused by an extra chromosome 21, is characterized by an atypical body habitus, mental retardation, cardiac malformations, an increased risk for leukemia, and a reduced life expectancy. The extra chromosome is almost always of maternal origin. Autoimmune thyroid disorders are more common in patients with Down’s syndrome than in the general population. The gene for autoimmune polyglandular syndrome I (APECED) has been mapped to chromosome 21 and is thought to be a transcription factor involved in immune regulation (AIRE) and may play a role in the development of autoimmune thyroid disease in these patients (331). Hashimoto’s thyroiditis is the most common abnormality associated with Down’s syndrome. Hypothyroidism develops in as many as 50% of patients over age 40 with Down’s syndrome. These clinical syndromes and other evidence suggest that the genetic susceptibility to Hashimoto’s thyroiditis may reside on chromosomes X and 21.

References

Endometriosis is defined as the presence of endometrial tissue (glands and stroma) outside the uterus. The most frequent sites of implantation are the pelvic viscera and the peritoneum. Endometriosis varies in appearance from a few minimal lesions on otherwise intact pelvic organs to massive ovarian endometriotic cysts that distort tuboovarian anatomy and extensive adhesions often involving bowel, bladder, and ureter. It is estimated to occur in 7% of reproductive age women in the United States and often is associated with pelvic pain and infertility. Considerable progress has been made in understanding the pathogenesis, spontaneous evolution, diagnosis, and treatment of endometriosis.

**Etiology**

Although signs and symptoms of endometriosis have been described since the 1800s, its widespread occurrence was acknowledged only during this century. Endometriosis is an estrogen-dependent disease. Three theories have been proposed to explain the histogenesis of endometriosis:

1. **Transplantation Theory** The transplantation theory, originally proposed by Sampson in the mid-1920s, is based on the assumption that endometriosis is caused by the seeding or implantation of endometrial cells by transtubal regurgitation during menstruation (1). Substantial clinical and experimental data support this hypothesis (2-3). Retrograde menstruation occurs in 70% to 90% of women (4,5), and it may be more common in women with endometriosis than in those without the disease (5). The presence of endometrial cells in the peritoneal fluid, indicating retrograde menstruation, has been reported in 59% to 79% of women during menses or in the early follicular phase (6,7), and these cells can be cultured in vitro (7). Evidence supporting retrograde menstruation is the presence of endometrial cells in the dialysate of women undergoing peritoneal dialysis during menses (8). Also, endometriosis is most often found in dependent portions of the pelvis—the ovaries, the anterior and posterior cul-de-sac, the uterosacral ligaments, the posterior uterus, and the posterior broad ligaments (9).

Ovarian endometriosis may be caused by either retrograde menstruation or by lymphatic flow from the uterus to the ovary (10). Endometriosis has been found in 50% of Rhesus monkeys after surgical transposition of the cervix to allow intraabdominal menstruation (11). Increased retrograde menstruation by obstruction of the outflow of menstrual fluid from the uterus is associated with a higher incidence of endometriosis in women (12,13) and in baboons (14). Women with shorter intervals between menstruation and longer duration of menses are more likely to have retrograde menstruation and are at higher risk for endometriosis (15). Endometriosis obtained during menses can grow when injected beneath abdominal skin or into the pelvic cavity of animals (16,17). Endometriosis has been found in 50% of Rhesus monkeys after surgical transposition of the cervix to allow intraabdominal menstruation (18). Increased retrograde menstruation by obstruction of the outflow of menstrual fluid from the uterus is associated with a higher incidence of endometriosis in women (13,14) and in baboons (15). Women with shorter intervals between menstruation and longer duration of menses are more likely to have retrograde menstruation and are at higher risk for endometriosis (16).

2. **Coelomic Metaplasia** The transformation (metaplasia) of coelomic epithelium into endometrial tissue has been proposed as a mechanism for the origin of endometriosis. This mechanism is supported by experimental evidence but not by clinical data, however. In contrast, recent studies evaluating structural and cell surface antigen expression in the rete ovarii and epoophoron reported little commonality between endometriosis and ovarian surface epithelium, suggesting that serosal metaplasia is unlikely to occur (19).

3. **Induction Theory** The induction theory is, in principle, an extension of the coelomic metaplasia theory. It proposes that an endogenous (undefined) biochemical factor can induce undifferentiated peritoneal cells to develop into endometrial tissue. This theory has been supported by experiments in rabbits (20,21) but has not been substantiated in women and primates.
The risk of endometriosis is 7 times greater if a first-degree relative has been affected by endometriosis (22). Because no specific mendelian inheritance pattern has been identified, multifactorial inheritance has been postulated. A relative risk for endometriosis of 7.2 has been found in mothers and sisters, and a 75% (6 of 8) incidence has been noted in homozygotic twins of patients with endometriosis (23). In another twin study, 51% of the variance of the latent liability to endometriosis may be attributable to additive genetic influences (24). Other investigators reported that 14 monozygotic twin pairs were concordant for endometriosis, and 2 pairs were discordant (25). Of these twin pairs, 9 had moderate to severe endometriosis.

A relationship has been shown between endometriosis and systemic lupus erythematosus (26), dysplastic nevi, and a history of melanoma in women of reproductive age (27). Endometriosis also is linked to the presence of individual human leukocyte antigens (28,29 and 30).

Mutations
In women with endometriosis, no mutations were found in the TP53 and RASk genes (31). No significant differences were observed in N317D (galactose-1-phosphate uridyl transferase) mutation frequency between women with endometriosis (18%) and controls (17%) (32).

Steroid Receptor Genetics
An association of estrogen receptor gene polymorphisms (two-allele and multiallele polymorphism) with endometriosis has been reported (33). Furthermore, various exon-deleted progesterone-receptor messenger RNAs (mRNAs) have been documented in human endometrium and ovarian endometriosis (35).

Aneuploidy
Epithelial cells of endometriotic cysts are monoclonal on the basis of phosphoglycerate kinase gene methylation, but normal endometrial glands are monoclonal (35,36). In a comparison of endometriotic tissue with normal tissue from the endometrium flow, cytometric DNA analysis failed to show aneuploidy (37). However, more recent studies using comparative genomic hybridization (38) or multicolor in situ hybridization (39) showed aneuploidy for chromosomes 11, 16, and 17 (39), increased heterogeneity of chromosome 17 aneuploidy (40), and losses of 1p and 22q (50%), 5p (33%), 6q (27%), 70 (22%), 9q (22%), and 16 (22%) of 18 selected endometriotic tissues (39).

Loss of Heterozygosity
Microsatellite DNA assays reveal an allelic imbalance (loss of heterozygosity) in p16 (ink4), GALT, p53, and APA2 loci in patients with endometriosis, even in stage II of endometriosis (41). Another report (39) found in 28% of endometriotic lesions a loss of heterozygosity at one or more sites: chromosomes 9p (18%), 1q (18%), and 22q (15%).

Immunologic Factors and Inflammation
Although retrograde menstruation appears to be a common event in women, not all women who have retrograde menstruation develop endometriosis. The immune system may be altered in women with endometriosis, and it has been hypothesized that the disease may develop as a result of reduced immunologic clearance of viable endometrial cysts from the pelvic cavity (42,43). Endometriosis can be caused by decreased clearance of peritoneal fluid endometrial cells due to reduced natural killer (NK) cell activity, or decreased macrophage activity (45). Decreased cell-mediated cytotoxicity toward autologous endometrial cells has been associated with endometriosis (44,45,46,47 and 48). However, these studies used techniques that have considerable variability in target cells and methods (49,50). Whether NK cell activity is lower in patients who have endometriosis than in those without endometriosis is controversial. Some reports demonstrate reduced NK activity (51,52,53 and 54,57), whereas others have found no increase in NK activity, even in women with moderate to severe disease (46,47 and 48,55). There also is great variability in NK cell activity among normal individuals that may be related to variables such as smoking, drug use, and exercise (49).

In contrast, endometriosis can also be considered a condition of immunologic tolerance, as opposed to ectopic endometrium, which essentially is self-tissue (42). It can be questioned why viable endometrial cells in the peritoneal fluid would be a target for NK cells or macrophages. Autotransplantation of blood vessels, muscles, skin grafts, and other tissues is known to be extremely successful in (45,46 and 47). Furthermore, there is no in vitro evidence that peritoneal fluid macrophages actually attack and perform phagocytosis of viable peritoneal fluid endometrial cells. High-dose immunosuppression can slightly increase the progression of spontaneous endometriosis in baboons (50). There is no clinical evidence, however, that the prevalence of endometriosis is increased in immunosuppressed patients. The fact that women with kidney transplants, who undergo chronic immunosuppression, are not known to have increased infertility problems can be considered indirect evidence that these patients do not develop extensive endometriosis.

Substantial evidence suggests that endometriosis is associated with a state of subclinical peritoneal inflammation, marked by an increased peritoneal fluid volume, increased peritoneal fluid white blood cell count, increased cytokine production, increased inflammatory cytokines, growth factors, and angiogenesis-promoting substances. It has been reported in baboons that subclinical peritoneal inflammation occurs both during menstruation and after intraperitoneal injection of endometrium (57). A higher basal activation status of peritoneal macrophages in women with endometriosis may impair fertility by reducing sperm motility, increasing sperm phagocytosis, or interfering with fertilization (35,39), possibly by increased secretion of cytokines such as tumor necrosis factor-a (TNF-a) (60,61 and 62). TNF-a may also facilitate the pelvic implantation of ectopic endometrium (63,64). The adherence of human endometrial stromal cells to mesothelial cells in vitro has been increased by the pretreatment of mesothelial cells with physiologic doses of TNF-a (63). Macrophages or other cells may promote the growth of endometrial cells (65,66) by secretion of growth and angiogenic factors such as epidermal growth factor (EGF) (63), macrophage-derived growth factor (MDGF) (67), fibronectin (68), and adhesion molecules such as integrins (69). After attachment of endometrial cells to the peritoneum, subsequent invasion and growth appears to be regulated by matrix metalloproteinases (MMPs) and their tissue inhibitors (70,71).

There is increasing evidence that local inflammation and secretion of prostaglandins (PG) is related to differences in endometriatal activity between women with and without endometriosis. Expression of aromatase cytochrome P450 protein and mRNA was observed in human endometriotic implants but not in normal endometrium, suggesting that ectopic endometrium produces estrogens, which may be involved in the tissue growth interacting with the estrogen receptor (72). Inactivation of 17b-estradiol has been reported to be impaired in endometriotic tissues because of deficient expression of 17b-hydroxysteroid dehydrogenase type 2, which is normally expressed in eutopic endometrium in response to progesterone (73). Finally, the inappropriate aromatase expression in endometriosis lesions can be stimulated by progesterin E2 (PGE2). This also leads to local production of E2, which also stimulates PGE2 production, resulting in a positive-feedback system between local inflammation and estrogen-driven local growth of ectopic endometrium (74).

Environmental Factors and Dioxin
There is an increasing awareness of potential links between reproductive health, infertility, and environmental pollution. Attention has been directed to the potential role of dioxins in the pathogenesis of endometriosis, but the issue remains controversial.

A 1976 explosion of a factory in Seveso (Italy) resulted in the highest levels of dioxin exposure recorded in humans (75), but so far no data have been published. The Seveso Women's Health Study will correlate prospective individual data on exposure to dioxin with reproductive endpoints such as the incidence of endometriosis, infertility, and decreased sperm quality. Thus far, one case-control study has failed to show an association between endometriosis and dioxin exposure (76). Another report (77) found in 28% of endometriotic lesions a loss of heterozygosity at one or more sites: chromosomes 9p (18%), 1q (18%), and 22q (15%).

Mechanisms may play a role in dioxin exposure and the development of endometriosis. Transcripts of the CYP1A1 gene, a dioxin-induced gene, have been reported to be significantly higher (9 times higher) in endometriotic tissues than in eutopic endometrium (77). Other investigators have reported a similar expression of arylhydrocarbon receptor and dioxin-related genes (using semiquantitative reverse transcriptase polymerase chain reaction) in the endometrium from women with and without endometriosis (78). In Japanese subjects, no association was found between endometriosis prevalence or severity and polymorphisms for arylhydrocarbon receptor repressor, arylhydrocarbon (x2) receptor, and arylhydrocarbon nuclear translocator or CYP1A1 genes (79). Based on these data, there is insufficient
the onset of menstrual bleeding and continues throughout the menstrual period. In adolescents, the pain may be present after menarche without an interval of pain.

In adult women, dysmenorrhea may be especially suggestive of endometriosis if it begins after years of pain-free menses. Pain should, therefore, be addressed and studied using reliable and valid questionnaires (88). Therefore, there is a need to look at endometriosis, at least in a subset of highly symptomatic women, as a chronic disease. Quality-of-life issues associated with dysmenorrhea can be successfully induced by the intrapelvic injection of menstrual endometrium (90). In recent years, the baboon has been established in about 30 peer reviewed articles as an excellent model for endometriosis research (98).

Prevalence

Endometriosis is predominantly found in women of reproductive age but has been reported in adolescents and in postmenopausal women receiving hormonal replacement (99). It is found in women of all ethnic and social groups. In women with pelvic pain or infertility, a high prevalence of endometriosis (from a low of 20% to a high of 90%) has been reported (2,100). In asymptomatic women having tubal ligation (women of proven fertility), the prevalence of endometriosis ranges from 3% to 43% (101,102,103,104 and 105). This great variation in the reported prevalence may be explained by several factors. First, it may vary with the diagnostic method used. Second, the operation of choice for diagnosis is generally accepted to be laparoscopy for diagnosing minimal to mild endometriosis. Second, minimal or mild endometriosis may be more thoroughly noted in a symptomatic patient being given general anesthesia than in an asymptomatic patient undergoing minimal or mild endometriosis. Third, the experience of the surgeon is important because there is a wide variation in the appearance of subtle endometriosis implants, cysts, and adhesions. Most studies that evaluate the prevalence of endometriosis in women of reproductive age lack histologic confirmation (105-107,108,109 and 110).

Diagnosis

Clinical Presentation

Endometriosis should be suspected in women with subfertility, dysmenorrhea, dyspareunia, or chronic pelvic pain. However, endometriosis may be asymptomatic.

Risk factors for endometriosis include short cycle length (111), heavier menstruation, and longer flow duration (15,112), probably related to a higher incidence of retrograde menstruation. Patient height and weight are positively and negatively, respectively, associated with the risk for endometriosis (113).

Endometriosis can be associated with significant gastrointestinal symptoms (pain, nausea, vomiting, early satiety, bloating and distention, altered bowel habits). A characteristic motility change (ampulla of Vater–duodenal spasm, a seizure equivalent of the enteric nervous system), along with bacterial overgrowth, has been documented in most women with the disease (114). Women of reproductive age with endometriosis are not osteopenic (115).

The average delay between onset of pain symptoms and surgically confirmed endometriosis is quite long: 8 years in the United Kingdom and 19 to 12 years in the United States (116). A delay in diagnosis of endometriosis of 6 and 3 years in women with pain and women with infertility, respectively, has been reported. Over the past two decades, there has been a steady decrease in the delay in diagnosis and a decline in the prevalence of advanced endometriosis at first diagnosis (117). At the same time, patient awareness of endometriosis has increased. For many patients, endometriosis becomes a chronic disease, affecting quality of life resulting from pain, infertility, anger about disease recurrence, and uncertainty about the future regarding repeated surgeries or long-term medical therapy and its side effects. Therefore, there is a need to look at endometriosis, at least in a subset of highly symptomatic women, as a chronic disease. Quality-of-life issues should, therefore, be addressed and studied using reliable and valid questionnaires (118).

Pain

In adult women, dysmenorrhea may be especially suggestive of endometriosis if it begins after years of pain-free menses. Dysmenorrhea often starts before the onset of menstrual bleeding and continues throughout the menstrual period. In adolescents, the pain may be present after menarche without an interval of pain-free menses. The distribution of pain is variable but most often is bilateral.
Local symptoms can arise from rectal, ureteral, and bladder involvement. Lower back pain can occur. Most studies have failed to detect a correlation between the degree of pelvic pain and the severity of endometriosis (103). Some women with extensive disease have no pain, whereas others with only minimal disease may experience severe pelvic pain. Severe pelvic pain and dyspareunia may be associated with deep infiltrating peritoneal endometriosis (100, 119). Possible mechanisms causing pain in patients with endometriosis include local peritoneal inflammation, deep infiltraion with tissue damage, adhesion formation, fibrotic thickening, and collection of shed menstrual blood in endometriotic implants, resulting in painful traction with the physiologic movement of tissues (110, 119).

In rectovaginal endometriotic nodules, a close histologic relationship has been observed between nerves and endometriotic foci and between nerves and the fibrotic component of the nodule (120).

Subfertility

An association between endometriosis and subfertility is generally accepted, but most of the studies suggesting this link have been based on retrospective or cross-sectional analysis. When endometriosis is moderate or severe, involving the ovaries and causing adhesions that block tuboovarian mobility and ovum pickup, it is associated with subfertility (121). This effect has also been shown in primates, including cynomolgus monkeys and baboons (84,122). Although numerous mechanisms (ovulatory dysfunction, luteal insufficiency, luteinized unruptured follicle syndrome, recurrent abortion, altered immunity, and intraperitoneal inflammation) have been proposed (123), the association between fertility and minimal or mild endometriosis remains controversial (124).

Infertility Based on the number of asymptomatic women who are found to have endometriosis during tubal ligation, it would appear that the prevalence of endometriosis is not necessarily higher in infertile than in fertile women with endometriosis (5). In fertile women, endometriosis has been reported to be minimal or mild in 80% and moderate or severe in 20% (6,101,102,103,104 and 156).

In women with mild disease, some studies have reported a lower spontaneous monthly fecundity rate (MFR), which is the total number of pregnancies divided by the number of months of pregnancy exposure (i.e., 5% to 11% compared with 25% in a normally fertile population) (123). Other studies using artificial insemination with donor semen have reported that the MFR in women with minimal and mild endometriosis is either reduced (4%) or normal (20%) (124,125,126 and 127). Fertility is not reduced in baboons with spontaneous minimal endometriosis (122,128). In one study, the fecundity rate (probability of becoming pregnant in the first 36 weeks after laparoscopy and carrying the pregnancy to 20 weeks) was 18% in infertile women with minimal to mild endometriosis and 23.7% in women with unexplained infertility (no significant difference). None of these women had been surgically treated for endometriosis during the diagnostic laparoscopy. However, 10% of women in each group had been treated with intrauterine insemination, in vitro fertilization (IVF) or cystectomy-rynoctomy (129). It remains unclear whether the mere presence of peritoneal endometriosis directly correlates with infertility.

Spontaneous Abortion A possible association between endometriosis and spontaneous abortion has been suggested in mostly uncontrolled or retrospective studies. Some controlled studies evaluating the association between endometriosis and spontaneous abortion have important methodologic shortcomings: heterogeneity between cases and controls, analysis of the abortion rate before the diagnosis of endometriosis, and selection bias of study and control groups (357). Based on controlled prospective studies, there is no evidence that endometriosis is associated with (recurrent) pregnancy loss (132), or that medical or surgical treatment of endometriosis reduces the spontaneous abortion rate (133,134).

Endocrinologic Abnormalities

Endometriosis has been associated with anovulation, abnormal follicular development with impaired follicle growth, reduced circulating E2 levels during the preovulatory phase, disturbed luteinizing hormone (LH) surge patterns, premenstrual spotting, the luteinized unruptured follicle syndrome, and galactoanemia and hyperprolactinemia (135). Increased incidence and recurrence of the luteinized unruptured follicle syndrome has been reported in baboons with mild endometriosis, but not in primates with minimal endometriosis or a normal pelvis (136). Luteal insufficiency with reduced circulating E2 and progesterone levels, out-of-phase endometrial biopsies, and aberrant integrin expression has been reported in the endometrium of women with endometriosis by some researchers (135,137), but these findings have not been confirmed by other investigators (138). Therefore, no convincing data exist to conclude that the incidence of these endocrinologic abnormalities is increased in women who have endometriosis.

Extrapelvic Endometriosis

Extrapelvic endometriosis, although often asymptomatic, should be suspected when symptoms of pain or a palpable mass occur outside the pelvis in a cyclic pattern. Endometriosis involving the intestinal tract (especially colon and rectum) is the most common site of extrapelvic disease and may cause abdominal and back pain, abdominal distention, cyclic rectal bleeding, constipation, and obstruction. Ureteral involvement can lead to obstruction and result in cyclic pain, dysuria, and hematuria. Pulmonary endometriosis can manifest as pneumothorax, hemoptysis, or hemoptysis during menses. Umbilical endometriosis should be suspected when a patient has a palpable mass and cyclic pain in the umbilical area (18).

Clinical Examination

In many women with endometriosis, no abnormality is detected during the clinical examination. The vulva, vagina, and cervix should be inspected for any signs of endometriosis, although the occurrence of endometriosis in these areas is rare (e.g., episiotomy scar). Further possible signs of endometriosis include uterosacral or cul-de-sac nodularity, lateral or cervical displacement due to uterosacral scarring (139), painful swelling of the vulva, vaginal and unilateral ovarian (cystic) enlargement. In more advanced disease, the uterus is often in fixed retroversion, and the mobility of the ovaries and fallopian tubes is reduced. Evidence of deep infiltrative endometriosis (deeper than 5 mm under the peritoneum) in the rectovaginal septum with cul-de-sac obliteration or cystic ovarian endometriosis should be suspected by clinical documentation of uterosacral nodularities during menses, especially if CA125 serum levels are higher than 35 IU/mL (140,141 and 142). The clinical examination may have false-negative results. Therefore, the diagnosis of endometriosis should always be confirmed by biopsy of suspicious lesions that are obtained laparoscopically.

Imaging and Endometriosis

When filling defects (presence of hypertrophic or polypoid endometrium) are observed at hysterosalpingography (143), there is a significant positive correlation with endometriosis with a positive predictive value of 84% and a negative predictive value of 75%.

Gynecologic transvaginal or transrectal ultrasonography is an important diagnostic tool in the assessment of ovarian endometriotic cysts (differentiation from other adnexal masses) and of rectovaginal endometriosis (sensitivity, 97%; specificity, 96%). Other imaging techniques, including computed tomography (CT) and magnetic resonance imaging (MRI), can be used to provide additional and confirmatory information, but they cannot be used for determining the primary diagnosis (146). These techniques are more costly than ultrasound, and their added value is not clear.

CA125

There is no blood test available for the diagnosis of endometriosis. Levels of CA125, a marker found on derivatives of the coelomic epithelium and common to most nonmucinous epithelial ovarian carcinomas, have been found to be significantly higher in women with moderate or severe endometriosis and normal in women with minimal or mild disease (147,148). During menstruation, an increase in CA125 levels has been shown in women with and without endometriosis (149,150,151,152 and 153). Other studies have not found an increase during menses (154,155) or have found an increase only with moderate to severe endometriosis (156,157). The levels of CA125 vary widely, not only in patients without endometriosis (8 to 22 U/mL in the nonmenstrual phase), but also in those with minimal to mild endometriosis (14 to 200).
31 U/mL in the nonmenstrual phase) and in those with moderate to severe disease (13 to 95 U/mL in the nonmenstrual phase).

The reason CA125 levels are increased in moderate to severe endometriosis is unclear. It has been hypothesized that endometriosis lesions contain a greater amount of CA125 than normal endometrium and that the associated inflammation could lead to an increased shedding of CA125 (148).

The specificity of CA125 has been reported to be higher than 80% in most studies. This high level of specificity is achieved in selected women with infertility or pain who are known to be at risk for endometriosis. The low level of sensitivity of CA125 (20% to 50% in most studies) poses limitations for the clinical use of this test for diagnosis of endometriosis. Theoretically, the sensitivity might increase during the menstrual period, when the increase in CA125 levels is more pronounced in women who have endometriosis. However, studies using cutoff levels of 35 U/mL (156,157) or 85 U/mL (158) have not found a significant improvement in sensitivity. A sensitivity of 66% was found when CA125 was determined during both the follicular phase and the menstrual phase in each patient and when the ratio of menstrual versus follicular values (>1.5) was used instead of one CA125 level (157). More recent studies reported that the value of CA125 in diagnosis of endometriosis is limited but higher for moderate to severe disease, especially if serum CA125 concentrations are measured during the midfollicular phase (159,160).

Serial CA125 determinations may be useful to predict the recurrence of endometriosis after therapy (161,162). CA125 levels decrease after combined medical and surgical therapy or during medical treatment of endometriosis with danazol, gonadotropin-releasing hormone (GnRH) analogues, or gestrinone, but not with medroxyprogesterone acetate (MPA) or placebo (163,164 and 165). CA125 levels have been reported to increase to pretreatment levels as early as 3, 4, or 6 months after the cessation of therapy with danazol, GnRH analogs, or gestrinone (153,164,165,167 and 168). Posttreatment increases in CA125 levels have been reported to correlate with endometriosis recurrence (152,162,169). However, other studies have not substantiated a correlation between posttreatment CA125 levels and disease recurrence (163,166,170).

Laparoscopic Findings During diagnostic laparoscopy, the pelvic and abdominal cavity should be systematically investigated for the presence of endometriosis. This examination should include a complete inspection and palpation in a clockwise or counterclockwise fashion with a blunt probe of the bowel, bladder, uterus, tubes, ovaries, cul-de-sac, and broad ligament (Fig. 26.1).

Characteristic findings include typical (“powder-burn,” “gunshot”) lesions on the serosal surfaces of the peritoneum. These are black, dark brown, or bluish nodules or small cysts containing old hemorrhage surrounded by a variable degree of fibrosis (Fig. 26.2). Endometriosis can appear as subtle lesions (Fig. 26.3), including red implants (petechial, vesicular, polypoid, hemorrhagic, red flamelike), serous or clear vesicles, white plaques or scarring, yellow-brown discoloration of the peritoneum, and subovarian adhesions (89,90 and 91,171,172). Histologic confirmation of the laparoscopic impression is essential for the diagnosis of endometriosis (173), not only for subtle lesions but also for typical lesions reported to be histologically negative in 24% of cases (174).

Mild forms of deep endometriosis may only be detected by palpation under an endometriotic lesion or by discovery of a palpable mass beneath visually normal peritoneum, most notably in the posterior cul-de-sac (141) (Fig. 26.4). Reduced Douglas depth and volume in women with deep endometriosis suggest that such lesions develop not in the rectovaginal septum but intraperitoneally and that burial by anterior rectal wall adhesions creates a false bottom, giving an erroneous impression of extraperitoneal origin (175).
In a study of 44 patients with chronic pelvic pain, endometriosis was laparoscopically diagnosed in 88%, but histologic confirmation was obtained in only 11%. This resulted in a low diagnostic accuracy of laparoscopic inspection with a positive predictive value of only 45%, explained by a specificity of only 77%.

Microscopically, endometriotic implants consist of endometrial glands and stroma with or without hemosiderin-laden macrophages. It has been suggested, however, that using these stringent and unvalidated histologic criteria may result in significant underdiagnosis of endometriosis. Furthermore, problems in obtaining biopsies (especially small vesicles) and variability in tissue processing (step or partial instead of serial sectioning) may contribute to false-negative results.

Microscopic endometriosis is defined as the presence of endometrial glands and stroma in macroscopically normal pelvic peritoneum. It is believed to be important in the histogenesis of endometriosis and its recurrence after treatment. Deep endometriosis has been described as a specific type of pelvic endometriosis characterized by proliferative strands of glands and stroma in dense fibrous and smooth muscle tissue. However, smooth muscles are also frequent components of endometriotic lesions on the peritoneum, ovary, rectovaginal septum, and uteroasacral ligaments.

In contrast, other studies have been unable to detect microscopic endometriosis in 2-mm biopsy specimens of visually normal peritoneum. Examination of larger samples (5 to 15 mm) of visually normal peritoneum has revealed microscopic endometriosis in only 1% of patients studied. Similarly, a histologic study of serial sections through the entire pelvic peritoneum of visually normal peritoneum from baboons with and without disease indicated that microscopic endometriosis appears to be a marker for more extensive pelvic and intestinal disease. Exclusive ovarian disease is found in only 1% of endometriosis patients, with the remaining patients having mostly extensive pelvic or intestinal endometriosis.

Histologic Confirmation

Histologic confirmation is essential in the diagnosis of endometriosis. In a study of 44 patients with chronic pelvic pain, endometriosis was laparoscopically diagnosed in 36%, but histologic confirmation was obtained in only 18%. This resulted in a low diagnostic accuracy of laparoscopic inspection with a positive predictive value of only 45%, explained by a specificity of only 77%.

Microscopically, endometriotic implants consist of endometrial glands and stroma with or without hemosiderin-laden macrophages. It has been suggested, however, that using these stringent and unvalidated histologic criteria may result in significant underdiagnosis of endometriosis. Furthermore, problems in obtaining biopsies (especially small vesicles) and variability in tissue processing (step or partial instead of serial sectioning) may contribute to false-negative results. Endometrioid stroma may be more characteristic of endometriosis than endometrioid glands.

Microscopic endometriosis is defined as the presence of endometrial glands and stroma in macroscopically normal pelvic peritoneum. It is believed to be important in the histogenesis of endometriosis and its recurrence after treatment. Deep endometriosis has been described as a specific type of pelvic endometriosis characterized by proliferative strands of glands and stroma in dense fibrous and smooth muscle tissue. However, smooth muscles are also frequent components of endometriotic lesions on the peritoneum, ovary, rectovaginal septum, and uteroasacral ligaments.

In contrast, other studies have been unable to detect microscopic endometriosis in 2-mm biopsy specimens of visually normal peritoneum. Examination of larger samples (5 to 15 mm) of visually normal peritoneum has revealed microscopic endometriosis in only 1% of patients studied. Similarly, a histologic study of serial sections through the entire pelvic peritoneum of visually normal peritoneum from baboons with and without disease indicated that microscopic endometriosis appears to be a marker for more extensive pelvic and intestinal disease. Exclusive ovarian disease is found in only 1% of endometriosis patients, with the remaining patients having mostly extensive pelvic or intestinal endometriosis.

This resulted in a low diagnostic accuracy of laparoscopic inspection with a positive predictive value of only 45%, explained by a specificity of only 77%.

Microscopically, endometriotic implants consist of endometrial glands and stroma with or without hemosiderin-laden macrophages. It has been suggested, however, that using these stringent and unvalidated histologic criteria may result in significant underdiagnosis of endometriosis. Furthermore, problems in obtaining biopsies (especially small vesicles) and variability in tissue processing (step or partial instead of serial sectioning) may contribute to false-negative results. Endometrioid stroma may be more characteristic of endometriosis than endometrioid glands.

Microscopic endometriosis is defined as the presence of endometrial glands and stroma in macroscopically normal pelvic peritoneum. It is believed to be important in the histogenesis of endometriosis and its recurrence after treatment. Deep endometriosis has been described as a specific type of pelvic endometriosis characterized by proliferative strands of glands and stroma in dense fibrous and smooth muscle tissue. However, smooth muscles are also frequent components of endometriotic lesions on the peritoneum, ovary, rectovaginal septum, and uteroasacral ligaments.

In contrast, other studies have been unable to detect microscopic endometriosis in 2-mm biopsy specimens of visually normal peritoneum. Examination of larger samples (5 to 15 mm) of visually normal peritoneum has revealed microscopic endometriosis in only 1% of patients studied. Similarly, a histologic study of serial sections through the entire pelvic peritoneum of visually normal peritoneum from baboons with and without disease indicated that microscopic endometriosis appears to be a marker for more extensive pelvic and intestinal disease. Exclusive ovarian disease is found in only 1% of endometriosis patients, with the remaining patients having mostly extensive pelvic or intestinal endometriosis.

Histologic confirmation is essential in the diagnosis of endometriosis. In a study of 44 patients with chronic pelvic pain, endometriosis was laparoscopically diagnosed in 36%, but histologic confirmation was obtained in only 18%. This resulted in a low diagnostic accuracy of laparoscopic inspection with a positive predictive value of only 45%, explained by a specificity of only 77%.

Microscopically, endometriotic implants consist of endometrial glands and stroma with or without hemosiderin-laden macrophages. It has been suggested, however, that using these stringent and unvalidated histologic criteria may result in significant underdiagnosis of endometriosis. Furthermore, problems in obtaining biopsies (especially small vesicles) and variability in tissue processing (step or partial instead of serial sectioning) may contribute to false-negative results. Endometrioid stroma may be more characteristic of endometriosis than endometrioid glands.

Exclusive ovarian disease is found in only 1% of endometriosis patients, with the remaining patients having mostly extensive pelvic or intestinal endometriosis.
endometriosis is a rare occurrence (184). Therefore, it appears that macroscopically appearing normal peritoneum rarely contains microscopic endometriosis (183).

Classification

The current classification system of endometriosis is the former American Fertility Society (AFS) system (Fig. 26.5), which has been revised without major changes (121). It is based on the appearance, size, and depth of peritoneal and ovarian implants; the presence, extent, and type of adnexal adhesions; and the degree of cul-de-sac obliteration. In the new classification system, the morphology of peritoneal and ovarian implants should be categorized as red (red, red-pink, and clear lesions), white (white, yellow-brown, and peritoneal defects), and black (black and blue lesions).

This system reflects the extent of endometriotic disease but has considerable intraobserver and interobserver variability (195,196). Because the revised classification of endometriosis is the only internationally accepted system, it appears to be the best available tool to describe objectively the extent of endometriosis and relate it to spontaneous evolution and to therapeutic outcomes (pain relief, enhancement of fertility).

The classification system has also been criticized because several investigators failed to find a correlation between it and endometriosis-related pain or infertility, as will be reviewed in the section, Results of Surgical Treatment.

Spontaneous Evolution

Endometriosis appears to be a progressive disease in a significant proportion (30% to 60%) of patients. During serial observations, deterioration (47%), improvement (30%), or elimination (23%) was documented over a 6-month period (197). In another study, endometriosis progressed in 64%, improved in 27%, and remained unchanged in 9% of patients over 12 months (188). A third study of 24 women reported 29% with disease progression, 29% with disease regression, and 42% with no change over 12 months. Follow-up studies in both baboons and women (200,201) with spontaneous endometriosis over 24 months have demonstrated disease progression in all baboons and in 6 of 7 women. Several studies have reported that subtle lesions and typical implants may represent younger and older types of endometriosis, respectively. In a cross-sectional study, the incidence of subtle lesions decreased with age (203). This was recently confirmed by a 3-year prospective study that reported that the incidence, overall pelvic area involved, and volume of subtle lesions decreased with age, but in typical lesions, these parameters and the depth of infiltration increased with age (129). Remodeling of endometriotic lesions (transition between typical and subtle subtypes) has been reported to occur in women and in baboons, indicating that endometriosis is a dynamic condition (202,204). Several studies in women, cynomolgus monkeys, and rodents have shown that endometriosis is ameliorated after pregnancy (204,205).

The characteristics of endometriosis are variable during pregnancy, and lesions tend to enlarge during the first trimester but regress thereafter (206). Studies in baboons have revealed no change in the number or surface area of endometriosis lesions during the first two trimesters of pregnancy (209). These results do not exclude a beneficial effect that potentially may occur during the third trimester or in the immediate postpartum period. Establishment of a "pseudopregnant state" with exogenously administered estrogen and progesterons was based on the belief that symptomatic improvement may result from decidualization of endometrial implants during pregnancy (210). This hypothesis, however, has not been substantiated.

Treatment

Prevention

No strategies to prevent endometriosis have been uniformly successful. Although a reduced incidence of endometriosis has been reported in women who engaged in aerobic activity from an early age (16), the possible protective effect of exercise has not been investigated thoroughly. There also is insufficient evidence that oral contraceptive use offers protection against the development of endometriosis. In contrast, a recent report (211) showed an increased risk for endometriosis development in a select population of women taking oral contraceptives.

Regardless of the clinical profile (subfertility, pain, asymptomatic findings), treatment of endometriosis may be justified because endometriosis appears to progress in 30% to 60% of patients within a year of diagnosis and because it is not possible to predict in which patients it will progress (188). Unfortunately, elimination of the endometriotic implants by surgical or medical treatment often provides only temporary relief. Therefore, the goal should be to eliminate the endometriotic lesions and, more importantly, to treat the sequelae (pain and subfertility) often associated with this disease.

Surgical Treatment

In most women with endometriosis, preservation of reproductive function is desirable. Therefore, the least invasive and least expensive approach that is effective should be used. The goal of surgery is to excise or coagulate all visible endometriotic lesions and associated adhesions—peritoneal lesions, ovarian cysts, deep rectovaginal endometriosis—and to restore normal anatomy. Laparoscopy can be used in most women, and this technique decreases cost, morbidity, and the possibility of recurrence of adhesions postoperatively. Laparotomy should be reserved for patients with advanced-stage disease who cannot undergo a laparoscopic procedure and for those in whom fertility conservation is not necessary.

Peritoneal Endometriosis

Endometriosis lesions can be removed during laparoscopy by surgical excision with scissors, bipolar coagulation, or laser methods (CO₂ laser, potassium-titanyl-phosphate laser, or argon laser). Although some surgeons claim that the CO₂ laser is superior because it causes only minimal thermal damage, no evidence is available to show that one technique is better than the other. Comparable cumulative pregnancy rates have been reported after treatment of mild endometriosis with laparoscopic excision and electrocoagulation (212).

Ovarian Endometriosis

Superficial ovarian lesions can be vaporized. Small ovarian endometrioma (<3 cm in diameter) can be aspirated, irrigated, and inspected with ovarian cystoscopy for intracystic lesions; their interior wall can be vaporized to destroy the mucosal lining of the cyst (213). Large (>3 cm in diameter) ovarian endometrioma should be aspirated, followed by incision and removal of the cyst wall from the ovarian cortex. To prevent recurrence, the cyst wall of the endometrioma must be removed, and normal ovarian tissue must be preserved.

As well as little as one tenth of an ovary is enough to preserve function and fertility (214), there is increasing concern that ovarian cystectomy with concomitant removal of adnexal follicles may reduce ovarian volume and reserve and diminish fertility. A recent study reported reduced follicular response in patients with severe endometriosis when compared with controls of similar age with normal ovaries (215). Therefore, it has been proposed to replace cystectomy by fenestration and coagulation of the inner wall of the endometriotic ovarian cyst. In one study, cumulative clinical pregnancy rates and recurrence rates were comparable in women treated with cystectomy and with fenestration and coagulation after 36 months, but conception occurred more quickly in the fenestration and coagulation group (216). A more recent case-control study (217) indicated that a lower cumulative recurrence rate and a lower cumulative pregnancy rate in the fenestration and coagulation group than in the fenestration and coagulation group after 18 (6% versus 22%) and 42 (24% versus 59%) months of follow-up (217). A randomized controlled trial demonstrated that pain and subfertility caused by ovarian endometrioma were improved more by cystectomy than by fenestration and coagulation (218). A reduced recurrence of pain after 2 years (odds ratio (OR), 0.2; confidence interval (CI), 0.05 to 0.77), an increased pain-free interval after operation (19 months versus 9.5 months), and an increased pregnancy rate (67% versus 23%) were found in the cystectomy group when compared with the fenestration and coagulation group (218). Therefore, based on the current evidence, ovarian cystectomy appears to be the method of choice.

Adhesiolysis

The removal of endometriosis-related adhesions (adhesiolysis) should be performed carefully as described in Chapter 21. Routine use of pharmacologic or liquid agents to prevent postoperative adhesions after fertility surgery cannot be recommended based on evidence from randomized controlled trials (219).

Preoperative Hormonal Treatment

In patients with severe endometriosis, it has been recommended that surgical treatment be preceded by a 3-month course of medical treatment to reduce vascularization and nodular size (141). However, a recent randomized study comparing 3 months of preoperative treatment with GnRH and no treatment in 75 women with moderate to severe endometriosis failed to show a significant difference in ease of surgery between the two groups (220).

Deep Rectovaginal and Rectosigmoidal Endometriosis

The surgical excision of deep rectovaginal and rectosigmoidal endometriosis is difficult and can be
associated with major complications. Postoperative bowel perforations with peritonitis have been reported in 2% to 3% of cases (221).

Preoperative investigations, including gynecologic ultrasound, intravenous pyelography (to exclude ureteral endometriosis), and colon contrast radiography (to exclude transmural rectosigmoidal endometriosis), are essential. Preoperative laxatives, starch-free diet, and full bowel preparation are needed to allow peroperative bowel suturing, if needed. To allow complete excision of rectosigmoidal endometriosis, 80% of patients needed bowel wall resection, and 14% required partial resection of the posterior vaginal fornix (221). Segmental rectosigmoid resection can be performed by laparotomy, laparoscopy with intracorporeal suturing, or by laparoscopically assisted vaginal technique (222). The latter technique appears to be faster than laparoscopy with intracorporeal suturing and cheaper than laparotomy because of decreased hospital stay and lower operating room charges (222). Ureter stents may be required before excision of peritoneal endometriosis surrounding the ureter. A multidisciplinary approach involving gynecologic and gastroenterologic surgeons and urologists is desirable.

Oophorectomy and Hysterectomy Radical procedures such as oophorectomy or total hysterectomy are indicated only in severe situations and can be performed either laparoscopically or, more commonly, by laparotomy. However, it is important to note that women aged 30 years or younger at the time of hysterectomy for endometriosis-associated pain are more likely than older women to have residual symptoms, to report a sense of loss, and to report more disruption from pain in different aspects of their lives (223).

Postoperative Hormone Replacement Postoperative hormone replacement with estrogen is required after bilateral oophorectomy, and there is a negligible risk for renewed growth of residual endometriosis. To reduce this risk, hormone replacement therapy should be withheld until 3 months after surgery. The addition of progestins to this regimen protects the endometrium. Some cases of adenocarcinoma have been reported, presumably arising from endometriosis lesions left in women treated with unopposed estrogen (214).

Results of Surgical Treatment

Postoperative medical treatment with danazol, GnRH agonists, or progestins is designed to suppress further endometrial growth, to ablate endometriotic implants, to reduce scarring, and to reduce the risk of recurrence. Postoperative medical treatment has been shown to improve fertility in patients with minimal to mild endometriosis (234,235). However, recent prospective, controlled, randomized, double-blind studies suggest that postoperative medical treatment results in only a minor improvement in fertility compared with expectant management (236).

Endometriosis Stage and Pain Relief after Surgery In patients with endometriosis, the endometriosis stage was not related to pain symptoms in several studies (237,238). However, more recent studies reported a positive correlation between endometriosis stage and endometriosis-related dysmenorrhea or chronic pelvic pain (239,240). In a prospective, controlled, randomized, double-blind study, surgical therapy has been shown to be superior to expectant management 6 months after treatment of mild and moderate endometriosis (241). In women with mild and moderate disease treated with medical therapy, 74% achieved pain relief. Treatment was least effective in women with minimal disease. There were no reported operative or laser complications (242). One year later, symptom relief was still present in 90% of those who initially responded (199). Patients with severe disease were not included because it had previously been shown that surgery resulted in pain relief in 80% of patients who did not respond to medical therapy (236).

These results suggest that laparoscopic surgery may be effective for the treatment of pain associated with mild to severe endometriosis. In women with minimal endometriosis, laser treatment may limit progression of disease.

Effects of Postoperative Hormonal Treatment on Pain Substantial evidence from randomized controlled trials supports the postoperative medical treatment of endometriosis-associated pain for 6 to 12 months. Postoperative GnRH treatment resulted in reduced pain scores and in a delay of pain recurrence for more than 12 months if the agonists were given for 6 months but not if they were only administered for 3 months (237,238) and (239). Similarly, postoperative hormonal treatment with danazol, 100 mg/d (low dose), for 12 months after surgery for moderate to severe endometriosis resulted in a significantly lower pain score in the treated group when compared with the placebo group. In contrast, postoperative high-dose danazol, 600 mg/d for 3 months, was not superior to expectant management with respect to pain recurrence in an identical patient population (240).

Subfertility

Endometriosis Stage and Pregnancy Outcome after Surgery When endometriosis causes mechanical distortion of the pelvic, surgery should be performed if reconstruction of normal pelvic anatomy can be achieved. The success of surgery in relieving infertility is probably related to the severity of endometriosis. A recent review of 15 diagnostic laparoscopy (241) reported cumulative pregnancy rates of 39%, 31%, 30%, and 25% in patients with endometriosis stages I, II, III, and IV, respectively, 12 months after surgical treatment. Although there appeared to be a negative correlation between stage of endometriosis and fertility outcome, no significant difference was found between the four groups in this study. However, the study had many limitations, including retrospective design, lack of well-defined definition of male factor infertility as potential bias, multicenter data with significant interobserver variability, inclusion of only a limited number of patients with substantial adhesive disease, variable infertility treatment after 6 months of follow-up, and absence of a control group. A somewhat higher cumulative intrauterine pregnancy rate has been reported in 30 women with deep uterosacral endometriosis after surgery: 48% after 12 months (47% for AFS stages I to II and 46% for AFS stages III to IV) (242). A cumulative pregnancy rate of 24% was reported in patients 9 months after undergoing reoperation for stage III to IV endometriosis (243).

Other investigators reported a negative correlation between stage of endometriosis and fertility after surgical treatment. In an older study, using an older classification system, a significant decrease in fecundability was seen in women with severe or extensive endometriosis compared with women with mild or moderate disease (244,245). Other studies have reported a significant negative correlation between endometriosis stage and pregnancy rate and decreased pregnancy rates when the revised scores exceeded 70 (246,247).

Preoperative and Postoperative Medical Treatment Preoperative medical treatment with danazol, GnRH agonists, or progestins may be useful to reduce the extent of endometriosis in patients with advanced disease. Postoperative medical treatment is rarely indicated because it does not work based on randomized trials, because it prevents pregnancy, and because the highest pregnancy rates occur during the first 6 to 12 months after conservative surgery (238,239). If pregnancy does not occur within 2 years of surgery, there is little chance of subsequent fertility (248).

Minimal to Mild Endometriosis and Fertility after Surgery Surgical management of infertile women with minimal to mild endometriosis is controversial. The cumulative pregnancy rate after 5 years without therapy has been reported to be as high as 90% in women with minimal or mild endometriosis (249). This is comparable to the 93% rate reported in women who have undergone laparoscopy. Deconstructive destruction of endometriosis has been reported to improve fertility in patients with minimal to mild disease (250,251 and 252), but not all investigators share this conclusion (253,254 and 255). It has been hypothesized that the MFR is higher during the first 6 to 12 months after laparoscopic surgery than with expectant management (256,257).

Two randomized controlled studies have evaluated the effect of postoperative surgical treatment of endometriosis on fertility parameters (133,134). Marcoux and coworkers (133) reported that laparoscopic surgery enhanced fecundity in infertile women with minimal or mild endometriosis. They studied 341 infertile women, 20 to 39 years of age, with minimal or mild endometriosis. During diagnostic laparoscopy, the women were randomly assigned to undergo resection or ablation of visible endometriosis or diagnostic laparoscopy only. They were followed for 36 weeks after the laparoscopy or, for those who became pregnant during that interval, for up to 20 weeks of pregnancy. The study objects were recruited among infertile women scheduled for diagnostic laparoscopy with strict eligibility criteria. There was no previous surgical treatment for endometriosis and no medical treatment for endometriosis in the previous 9 months. There was no other medical or surgical treatment for infertility in the previous 3 months. They had no history of pelvic inflammatory disease and no severe pelvic pain precluding expectant management. The diagnosis of endometriosis required the presence of one or more typical bluish or black lesions. The stage of endometriosis was determined according to the revised AFS classification. During the diagnostic laparoscopy, the women were randomly assigned to undergo resection or ablation of visible endometriosis or diagnostic laparoscopy only. They found that resection or ablation of minimal and mild endometriosis increased the likelihood of pregnancy in infertile women. In the treated group, 31% of the patients became pregnant, compared with 18% in the nontreated group (p = 0.006).

In a multicenter Italian study, a similar study design was used to compare the effect of diagnostic laparoscopy with surgical resection and ablation of visible
endometriosis (on fertility parameters) in infertile women with minimal to mild endometriosis (134). Eligible patients were women aged less than 36 years who were trying to conceive and had a laparoscopically confirmed diagnosis of minimal or mild endometriosis, according to the revised AFS classification system. None of the women had had therapy for endometriosis or infertility. Treatment was randomly allocated during laparoscopy. There was a follow-up period of 1 year after the laparoscopy. The results of this study did not show a beneficial effect of surgery regarding fertility. During the follow-up period after laparoscopy, no statistically significant differences in conception and live-birth rates were observed in the treated group (24% and 20%, respectively) and in the control group (29% and 22%, respectively).

Based on these studies, and taking into account the larger patient population in the Canadian multicenter study, surgical treatment of minimal to mild endometriosis appears to offer a small but significant benefit with regard to fertility outcome. Furthermore, the surgical removal of peritoneal endometriosis may also be important to prevent progression of endometriosis. However, care is needed to prevent adhesion formation that could result as a consequence of overenthusiastic excision of minimal to mild endometriosis.

Medical Treatment

Because estrogen is known to stimulate the growth of endometriosis, hormonal therapy has been designed to suppress estrogen synthesis, thereby inducing atrophy of ectopic endometrial implants or interrupting the cycle of stimulation and bleeding. Implants of endometriosis react to gonadal steroid hormones in a manner similar but not identical to normally stimulated ectopic endometrium. Ectopic endometrial tissue displays histologic and biochemical differences from normal ectopic endometrium in characteristics such as glandular activity (proliferation, secretion), enzyme activity (17β-hydroxysteroid dehydrogenase), and steroid (estrogen, progestin, and androgen) hormone receptor levels. The use of dydrogesterone, medroxyprogesterone acetate, or other androgens is no longer advocated because they lack efficacy, have significant side effects, and pose risks to the fetus if pregnancy occurs during therapy. A new generation of aromatase inhibitors, estrogen receptor modulators, and progesterone antagonists may offer new hormonal treatment options in the future. Recent progress in the understanding of the pathogenesis of endometriosis has led to the expectation that new pharmaceutical agents affecting inflammation, angiogenesis, and MMP activity may prevent or inhibit the development of endometriosis.

Oral Contraceptives

Continuous Administration Manipulation of the endogenous hormonal milieu is the basis for the medical management of endometriosis. The treatment of endometriosis with continuous low-dose monophasic combination contraceptives (one pill per day for 6 to 12 months) was originally used to induce pseudopregnancy caused by the resultant amenorrhea and decidualization of endometrial tissue (210). Kistner was the first to introduce the concept of an adynamic endometrium through elimination of the normal cyclic hormonal changes characteristic of the menstrual cycle (259). This induction of a pseudopregnancy state with combination oral contraceptive pills has been shown to be effective in reducing dysmenorrhea and pelvic pain. In addition, the subsequent amenorrhea induced by oral contraceptives could potentially reduce the amount of retrograde menstruation (one of the many risk factors proposed in the etiology of endometriosis), decreasing the risk for disease progression. Pathologically, oral contraceptive use is associated with decidualization of endometrial tissue, necrosis, and possibly absorption of the endometrial tissue (259). Unfortunately, there is no convincing evidence that medical therapy with oral contraceptives offers definitive therapy. Instead, the endometrial implants survive the induced atrophy and, in most patients, reactivate after termination of treatment.

Any low-dose combination oral contraceptive containing 30 to 35 mg of ethinyl estradiol used continuously can be effective in the management of endometriosis. The objective of the treatment is the induction of amenorrhea, which should be continued for 6 to 12 months. Symptomatic relief of dysmenorrhea and pelvic pain is reported in 60% to 95% of patients (260,261). After a first-year recurrence rate of 17% to 18%, a 5% to 10% annual recurrence rate has been observed. In addition, a posttreatment pregnancy rate of up to 50% can be expected. Although oral contraceptives are effective in inducing a decidualized endometrium, the estrogenic component in oral contraceptives may potentially stimulate endometrial growth and increase pelvic pain in the first few weeks of treatment. The long-term significance of this effect remains to be determined. Oral contraceptives are less costly than other treatments and may be helpful in the short-term management of endometriosis with potential long-term benefits in some women.

Cyclic Administration There is no convincing evidence that cyclic use of combination oral contraceptives provides prophylaxis against either the development or recurrence of endometriosis. Estrogens in oral contraceptives potentially may stimulate the proliferation of endometriosis. The reduced menstrual bleeding that often occurs in women taking oral contraceptives may be beneficial to women with prolonged, frequent menstrual bleeding, which is a known risk factor for endometriosis (16). Further research is warranted to assess the effect of low-dose oral contraceptives in preventing endometriosis and in treating associated pain. In a recent randomized controlled study, a cyclic 2-day oral contraceptive (ethinyl estradiol 20 gamma + desogestrel 0.15 mg) combined with very-low-dose danazol (50 mg/day) was less effective in relief of dysmenorrhea than depot medroxyprogesterone acetate (150 mg every 3 months) (262).

Progestins

Progestins may exert an antieandrometrotic effect by causing initial decidualization of endometrial tissue followed by atrophy. They can be considered as the first choice for the treatment of endometriosis because they are as effective as danazol or GnRH analogues and have a lower cost and a lower incidence of side effects than these agents (263).

There is no evidence that any single agent or any particular dose is preferable to another. The effective doses of several progestins are summarized in Table 26.1. In most studies, the effect of treatment has been evaluated after 3 to 6 months of therapy. MPA has been the most studied agent. It is effective in relieving pain starting at a dose of 30 mg/d and increasing the dose based on the clinical response and bleeding patterns (264,265). However, a recent randomized placebo controlled study reported a significant reduction in stages and scores of endometriosis in both the placebo group and the group treated with MPA, 50 mg/d, and placebo at laparoscopy within 3 months after cessation of therapy (265). These findings raise questions about the need for medical therapy.

Table 26.1. Medical Treatment of Endometriosis-Associated Pain: Effective Regimens (Usual Duration: 6 Months)

Medroxyprogesterone acetate (150 mg) given intramuscularly every 3 months is also effective for the treatment of pain associated with endometriosis, but it is not indicated in infertile women because it induces profound amenorrhea and anovulation, and a varying length of time is required for ovulation to resume after discontinuation of therapy. Megestrol acetate has been administered in a dose of 40 mg/d with good results (276). Other treatment strategies have included dydrogesterone (20 to 30 mg/d, either continuously or on days 5 to 25) and lynestrenol (10 mg/d). The effectiveness of natural progesterone has not been evaluated.

Side effects of progestins include nausea, weight gain, fluid retention, and breakthrough bleeding due to hypoenostergenemia. Breakthrough bleeding, although common, is usually corrected by short-term (7-day) administration of estrogen. Depression and other mood disorders are a significant problem in about 1% of women taking these medications.

Local progesterone treatment of endometriosis-associated dysmenorrhea with a levonorgestrel-releasing intrauterine system for 12 months has resulted in a
significant reduction in dysmenorrhea, pelvic pain, and dyspareunia; a high degree of patient satisfaction; and a significant reduction in the volume of rectovaginal endometriotic nodules (267,268). Although the results are promising, none of these pilot studies included a control group. Further randomized evidence is needed to determine whether intrauterine progesterone treatment is effective in the suppression of endometriosis.

Progesterone Antagonists

Progesterone antagonists and progesterone receptor modulators may suppress endometriosis based on their antiproliferative effects on the endometrium, without the risk for hypo-estrogenism or bone loss that occurs with GnRH treatment. These products are soon to be introduced in the United States, but their clinical effectiveness remains to be proved.

Mifepristone

Mifepristone (RU-486) is a potent antiproggestagen with a direct inhibitory effect on human endometrial cells and, in high doses, an antiglucocorticoid action (269). The recommended dose for endometriosis is 25 to 100 g/d. In uncontrolled studies, mifepristone, 50 to 100 mg/d, reduced pelvic pain and induced 55% regression of the lesions without significant side effects (270,271). In an uncontrolled pilot study, mifepristone, 5 mg/d, resulted in pain improvement, but there was no change in endometriosis lesions, suggesting that this dosage is probably too low (272).

Onapristone

Onapristone (3α,21-dihydroxyprogestosterone) is an irreversible progestational antagonist and is structurally similar to progesterone. While it is a potent antiestrogen, it does not cause uterine abortion, but it may be useful in the treatment of some endometriosis lesions (273).

Danazol

Danazol is a 19-nortestosterone derivative, with antiestrogenic, antiglucocorticoid, and antigenadotropic properties. It acts centrally and peripherally to increase free testosterone and reduce sex hormone–binding globulin levels (androgenic effect), reduce serum estradiol values to early follicular phase levels (antiestrogenic effect), reduce mean LH levels, and obliterate the LH and follicle-stimulating hormone (FSH) surge (antigonadotropic effect). Danazol has been used for a variety of conditions, including endometriosis, and has been studied extensively in the treatment of this disorder (274). The side effects of danazol are significant and include deepening of the voice, hirsutism, acne, weight gain, and muscle cramps. It may also cause masculinization of the fetus. Danazol is contraindicated in patients with liver disease because it is largely metabolized in the liver and may cause hepatocellular damage. Danazol is also contraindicated in patients with hypertension, congestive heart failure, or impaired renal function because it can cause fluid retention. The use of danazol is contraindicated in pregnancy because of its androgenic effects on the fetus.

Gestrinone

Gestrinone is a 19-nortestosterone derivative with antiestrogenic, antiglucocorticoid, and antigenadotropic properties. It acts centrally and peripherally to increase free testosterone and reduce sex hormone–binding globulin levels (androgenic effect), reduce serum estradiol values to early follicular phase levels (antiestrogenic effect), reduce mean LH levels, and obliterate the LH and follicle-stimulating hormone (FSH) surge (antigonadotropic effect). Gestrinone causes cellular inactivation and degeneration of endometriotic implants but not their disappearance (277). Amenorrhoea occurs in 50% to 100% of women and is dose dependent.

Resumption of menses generally occurs 33 days after discontinuing the medication (278,279). An advantage of gestrinone is its long half-life (28 hours) when given orally. The standard dose has been 2.5 mg twice a week. Although it has been reported that 1.25 mg twice weekly is equally effective (280), a more recent randomized study demonstrated in women with mild to moderate endometriosis that 2.5 mg gestrinone, twice weekly for 24 weeks, is more effective and has a better effect on bone mass (+7% versus –7%) when compared with 1.25 mg gestrinone, 2 times weekly for 24 weeks (281).

The clinical side effects of gestrinone are dose dependent and similar to but less intense than those caused by danazol (278). They include nausea, muscle cramps, and androgenic effects such as weight gain, acne, seborrhea, and oily hair and skin.

In a multicenter, randomized, double-blind study, gestrinone was as effective as GnRH for the treatment of pelvic pain associated with endometriosis (282). However, gestrinone has fewer side effects and has the added advantage of twice-weekly administration. Pregnancy is contraindicated while taking gestrinone because of the risk for masculinization of the fetus.

Danazol

Danazol is not more effective than other available medications to treat endometriosis. Recognized pharmacologic properties of danazol include suppression of GnRH or gonadotropin secretion, direct inhibition of steroidogenesis, increased metabolic clearance of estradiol and progesterone, direct antiestrogenic and agonistic interaction with endometrial androgen and progesterone receptors, and immunologic attenuation of potentially adverse reproductive effects (283,284). The multiple effects of danazol produce a high-androgen, low-estrogen environment (estrogen levels in the early follicular to postmenopausal range) that does not support the growth of endometriosis, and the amenorrhea that is produced prevents new seeding of implants from the uterus into the peritoneal cavity.

The immunologic effects of danazol have been studied in women with endometriosis and adenomyosis and include a decrease in serum immunoglobulins, a decrease in natural killer cell activity, and an increase in interleukin-1 and tumor necrosis factor levels in patients with endometriosis (285). These immunologic findings may be important in the remission of endometriosis with danazol treatment and may offer an explanation of the effect of danazol on the regression of endometriotic lesions (274). In an uncontrolled pilot study, local danazol treatment using a vaginal ring (1,500 mg) has been shown to have effective local relief in deeply infiltrative endometriosis without the classic danazol side effects, or detectable serum danazol levels, while allowing ovulation and conception (284).

Gonadotropin-releasing Hormone Agonists

GnRH agonists bind to pituitary GnRH receptors and stimulate LH and FSH synthesis and release. However, the agonists have a much longer biologic half-life (3 to 8 hours) than endogenous GnRH (3.5 minutes), resulting in the continuous exposure of GnRH receptors to GnRH agonist activity. This causes a loss of pituitary receptors and downregulation of GnRH activity, resulting in low FSH and LH levels. Consequently, ovarian steroid production is suppressed, providing a medically induced and reversible state of pseudomenopause. A direct effect of GnRH agonists on ectopic endometrium is also possible because expression of the GnRH receptor has been documented in ectopic endometrium and because direct inhibition of endometriosis cells has been demonstrated in vitro (286). Furthermore, in rat models for surgical adhesion formation and endometriosis, GnRH agonist therapy decreased activity of plasminogen activators and matrix MMPs and increased the activity of their inhibitors, suggesting potential GnRH agonist–regulated mechanisms for reducing adhesion formation (286).

Various GnRH agonists have been developed and used in treating endometriosis. These agents include leuprolide, busrelin, nafarelin, histrelin, goserelin, deslorelin, and triptorelin. These drugs are inactive orally and must be administered intramuscularly, subcutaneously, or by intranasal absorption. The best therapeutic effect is often associated with an estradiol dose of 20 to 40 pg/mL (75 to 150 pmol/L). These so-called depot formulations are attractive because of the reduced frequency of administration and because nasal administration can be complicated by variations in absorption rates and problems with patient compliance (279). The results with
In rats with experimental endometriosis, recombinant human TNF-α–binding protein can reduce 64% of the size of endometriosis-like peritoneal lesions (310). Similarly, a recent prospective randomized placebo- and drug-controlled study in baboons showed that recombinant human TNF-α–binding protein effectively inhibits the development of endometriosis and endometriosis-related adhesions (311).

In mice with experimental endometriosis, a placebo-controlled double-blind study showed that intraperitoneal or subcutaneous injection of recombinant interferon-α2B resulted in smaller endometriotic lesions when compared with the placebo control group (312). In rats with experimental endometriosis, regression of endometrial explants was observed after treatment with immune-enhancing modulators loxoribine and levamisole (313).

In humans, a randomized placebo-controlled trial of oral pentoxifylline, 800 mg/d for 12 months, reported after life-table analysis a similar overall pregnancy rate in treated patients (314). In women with endometriosis, suppression of MMPs by progesterone or by a natural inhibitor slows the establishment of ectopic lesions by human endometrium (315). Thus far, no clinical reports have been published.

Aromatase Inhibitors

Treatment of rats with induced endometriosis using the nonsteroidal aromatase inhibitor fadrozole hydrochloride (306) or YM511 (307) resulted in a dose-dependent volume reduction of endometriosis transplants, but these products have so far not been used in published human studies. Treatment of severe postmenopausal endometriosis with an aromatase inhibitor, anastrozole, 1 mg/d, and elemental calcium, 1.5 g/d for 9 months, resulted in hypoestrogenism, pain relief after 2 months, and after 9 months a 10-fold reduction in the 30-mm diameter size of red, polypoid vaginal lesions, along with remodeling to gray tissue. No other data are available, except this case report (308).

Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators (SERMs) may be of interest for treatment of endometriosis, especially because treatment periods of longer than 6 months may be required. The goal is to suppress endometriosis and maintain serum estradiol levels of 30 to 45 pg/mL. More extreme estradiol suppression will induce bone loss (297). The dose of daily GnRH agonist can be regulated by monitoring estradiol levels, by the addition of low-dose progesterin or estrogen-progestin in an add-back regimen, or by draw-back therapy. The goal of add-back therapy is to treat endometriosis and endometriosis-associated pain effectively, while preventing vasomotor symptoms and bone loss related to the hypoestrogen state induced by GnRH analogues. Add-back therapy can be achieved by administering progestogens only, including norethisterone, 1.2 mg, and norethindrone acetate, 5 mg, but bone loss is not prevented by medrogestone, 10 mg/d (298,299 and 300). Add-back therapy can also be achieved by adding ibutalone, 2.5 mg/d (301,302), or by an estrogen-progestin combination (i.e., conjugated estrogens, 0.625 mg, combined with medroxyprogesterone acetate, 2.5 mg, or with norethindrone acetate, 5 mg, estradiol, 2 mg, and norethindrone acetate, 1 mg) (299,300,301,302 and 303). However, some concern remains about the long-term effects of GnRH analogues on bone loss. In one report, bone mineral density reduction occurred during long-term GnRH agonist use and was not fully recovered up to 6 years after treatment (304). Use of add-back therapy (2 mg estradiol and 1 mg norethisterone acetate) did not affect this process (304).

Draw-back therapy has recently been suggested as an alternative in a study showing that 6 months of intake of 400 μg/d of nafarelin was as effective as a draw-back regimen consisting of 1 month of intake of 400 μg/d of nafarelin followed by 5 months of 200 μg/d of nafarelin, with similar estradiol levels (30 pg/mL) but less loss of bone mineral density (305).

Modulation of Cytokines

In rats with experimental endometriosis, recombinant human TNF-α–binding protein can reduce 64% of the size of endometriosis-like peritoneal lesions (310). Similarly, a recent prospective randomized placebo- and drug-controlled study in baboons showed that recombinant human TNF-α–binding protein effectively inhibits the development of endometriosis and endometriosis-related adhesions (311).

In mice with experimental endometriosis, a placebo-controlled double-blind study showed that intraperitoneal or subcutaneous injection of recombinant interferon-α2B resulted in smaller endometriotic lesions when compared with the placebo control group (312). In rats with experimental endometriosis, regression of endometrial explants was observed after treatment with immune-enhancing modulators loxoribine and levamisole (313).

Antinflammation

In the future, leukotriene receptor antagonists could be of use in patients with endometriosis who do not respond to prostaglandin synthetase inhibitors (314). In humans, a randomized placebo-controlled trial of oral pentoxifylline, 800 mg/d for 12 months, reported after life-table analysis a similar overall pregnancy rate in treated patients (315) and in controls (18.5%) (315).

Inhibition of Matrix Metalloproteinase

In nude mice, suppression of MMPs by progesterone or by a natural inhibitor slows the establishment of ectopic lesions by human endometrium (315). Thus far, no clinical reports have been published.

Efficiency of Medical Treatment

Pain Medical treatment with progesterins, danazol, gestrinone, or GnRH agonists is effective in treating pain associated with endometriosis, as shown in several prospective, randomized, placebo-controlled double-blind studies (316,317,318). Based on published studies, medroxyprogesterone acetate, danazol, gestrinone, and norethindrone acetate have similar efficacy in resolution of the laparoscopic and clinical symptoms of endometriosis during and in pain alleviation (297). Postoperative medical therapy may be required in patients with incomplete surgical resection and persistent pain. Treatment should last at least 3 to 6 months, and pain relief may be of short duration, presumably because endometriosis recurs. Disadvantages of medical therapy over surgical therapy include the high cost of hormone preparations, the high prevalence of side effects, and the higher recurrence rate of endometriosis.

Subfertility

Conception is either impossible or contraindicated during medical treatment of endometriosis. There is no evidence that medical treatment of minimal to mild endometriosis leads to better chances of pregnancy than expectant management (197,249,317,318,319,320,321,322 and 323).

Adolescent Endometriosis

The incidental finding of minimal to mild endometriosis in a young woman without immediate interest in pregnancy is a common clinical problem. Seventy percent of girls with chronic pelvic pain unresponsive to oral contraceptives (OAC) or nonsteroidal antiinflammatory drugs are affected by endometriosis (324). Mild disease can be treated by surgical removal of implants at the time of diagnosis, followed by administration of continuous low-dose combination oral contraceptives to prevent recurrence. More advanced disease can be treated medically for 6 months, followed by continuous oral contraceptives to prevent progression of disease. GnRH agonists with add-back therapy can be considered for adolescents older than 16 years of age who have completed pubertal maturation (324).

Recurrence

Endometriosis tends to recur unless definitive surgery is performed. The recurrence rate is about 5% to 20% per year, reaching a cumulative rate of 40% after 5 years. The rate of recurrence increases with the stage of disease, the duration of follow-up, and the occurrence of previous surgery (325,326,327,328 and 329). The likelihood of recurrence appears to be lower when endometriosis is located only on the right side of the pelvis than when the left side is involved (330).

In a recent randomized controlled trial, postoperative low-dose cyclic oral contraceptive use resulted in a significantly lower cumulative recurrence rate after 1 year, but not after 2 to 3 years (331). In women treated with a second operation for recurrent endometriosis, the cumulative recurrence rate was comparable to those rates after laparoscopy or laparotomy (332).

The recurrence rates reported in women 5 years after therapy with various GnRH agonists were 37% for minimal disease and 74% for severe disease (325). In women treated with GnRH agonists or danazol for endometriosis associated with pelvic pain, the recurrence rates of endometriosis were similar, and associated pain symptoms usually returned after cessation of therapy (333). Pain recurs within 5 years in about one in five patients with pelvic pain treated by complete laparoscopic excision of visible endometriotic lesions (334).

Assisted Reproduction and Endometriosis

The treatment of endometriosis-related infertility is dependent on the age of the woman, the duration of infertility, the stage of endometriosis, the involvement of ovaries, tubes, or both in the endometriosis process, previous therapy, associated pain symptoms, and the priorities of the patient, taking into account her attitude toward the disease, the cost of treatment, her financial means, and the expected results. Assisted reproduction, including controlled ovarian hyperstimulation with...
In Vitro Fertilization

Based on several retrospective studies, several investigators [150,155] have suggested that the pregnancy rate after IVF may be lower in women with endometriosis than in women without the disease. In earlier studies, women with endometriosis may have been more likely to be treated with gamete intrafallopian transfer, reserving IVF for more advanced stages of disease (257). In one study, the gamete intrafallopian transfer pregnancy rate in patients with a primary diagnosis of endometriosis (32.5%) was lower than in matched controls (356). The current evidence suggests that patients with endometriosis have a poorer ovarian response and need a higher dose of gonadotropin therapy in IVF or ICSI programs, but no reduced endometrial implantation. It remains unclear whether the presence or degree of endometriosis is associated with impaired oocyte quality, fertilization rate, and implantation rate. Future studies evaluating the association between endometriosis and reproductive outcome after assisted reproduction should be prospective and should include the following components (131):

- Accurate and recent laparoscopic description of the stage of endometriosis
- Date, number of procedures, and interval between surgery
- Extent of histologic evidence of endometriosis, confirmed by cystology or histology when endometriotic cysts are aspirated during oocyte aspiration
- Effectiveness of interferon suppressive therapy between diagnosis and treatment with assisted reproduction
- Reliability and date of negative diagnosis
- Clear definition of implantation rate, pregnancy rate, abortion rate, and live birth rate per started cycle, per oocyte aspiration, and per embryo transfer

Infertility is defined as 1 year of unprotected intercourse without pregnancy. This condition may be further classified as primary infertility, in which no previous pregnancies have occurred, and secondary infertility, in which a prior pregnancy, although not necessarily a live birth, has occurred. Fecundity is the probability of achieving pregnancy within a single menstrual cycle, and fecundability is the probability of achieving a live birth within a single cycle. The fecundability of a normal couple has been estimated at 20% to 25% (1). On the basis of this estimate, about 90% of couples should conceive after 12 months of unprotected intercourse.

Infertility affects about 10% to 15% of reproductive-age couples in the United States. Despite the relatively stable prevalence of infertility in the United States, the use of infertility services has increased significantly. Between 1968 and 1984, the number of office visits for infertility increased nearly threefold to the current 1.6 million visits annually (2). There are several reasons for this increase. Recent media coverage of assistive reproductive technology (ART) and other fertility treatments has heightened awareness of the problem and its treatment; the aging of the post-World War II “baby boomers” has led to an increase in the number of reproductive-age women; and sociologic changes have led to delayed marriage with a consequent postponement of childbearing. Still, despite an increased awareness of available therapies, only 43% of infertile couples seek treatment, and only 24% seek specialized care. Fewer than 2% use in vitro fertilization (IVF) or other ART methods. The women most likely to obtain specialized treatment are 30 years of age or older, white, married, and of relatively high socioeconomic status (3).

Epidemiology

Data from the U.S. National Survey of Family Growth indicate that the prevalence of infertility among women who had not been surgically sterilized was 13.3% in 1965, 13.9% in 1982, and 13.7% in 1988 (4). In 1990, about 1 in 3 women in the United States reported 12 consecutive months of unprotected coitus without pregnancy at some time in her life (5).

A number of demographic variables, including age and socioeconomic status, have been associated with infertility. The delay in childbearing in the United States population has led to attempts to conceive by a higher percentage of women in the older reproductive age groups. As a result, although the overall prevalence of infertility has not changed in the United States since 1965, the percentage of women with primary infertility has increased significantly. In 1965, only one of six infertile women was nulliparous, whereas in 1988, more than half of infertile women had never been pregnant (6). The prevalence of infertility does not differ significantly among racial and ethnic groups. Although patients seeking treatment for infertility are predominantly of high socioeconomic status, infertility is more common among groups of relatively low socioeconomic status (6). Improved familiarity with and access to infertility services among the affluent and better-educated patients probably accounts for their greater use of these medical resources.

The Infertile Couple

Initial Visit

The physician's initial encounter with the infertile couple is the most important one because it sets the tone for subsequent evaluation and treatment. The male partner should be present at this first visit because his history is a key component in the selection of diagnostic and therapeutic plans. It cannot be overemphasized that infertility is a problem of the couple. The presence of the male partner beginning with the initial evaluation involves him in the therapeutic process. This essential involvement demonstrates that the physician is receptive to the male partner's needs as well as to those of the female partner, while allowing the male partner an opportunity to ask questions and to voice any concerns.

The physician should obtain a complete medical, surgical, and gynecologic history from the woman. Specifically, information regarding menstrual cyclicity, pelvic pain, and obstetric history is important. Risk factors for infertility, such as a history of pelvic inflammatory disease (PID), intrauterine device use, or pelvic surgery, should be reviewed. A history of intrauterine exposure to diethylstilbestrol (DES) is significant. In addition, questions should be asked about pituitary, adrenal, and thyroid function. A directed history, including past genital surgery, infections (including mumps orchitis), and previous genital trauma, should be obtained from the male partner. A history of occupational exposures that might affect the reproductive function of either partner is also important. Additionally, the interviewer should obtain information about coital frequency, dyspareunia, and sexual dysfunction.

The initial interview provides the physician with the opportunity to assess the emotional impact of infertility on the couple. It further gives the physician a chance to emphasize the emotional support available to the couple as they proceed with the diagnostic evaluation and suggested treatments. In some cases, referral to a trained social worker or psychologist at this point may be beneficial.

References

The physical examination of the female should be thorough, with particular attention given to height, weight, body habitus, hair distribution, thyroid gland, status with regard to galactorrhea, and findings of the pelvic examination. Referral of the male to a urologist for examination is often beneficial if historic information or subsequent evaluation suggests an abnormality. The initial encounter also gives the doctor the opportunity to outline the general causes of infertility and to discuss subsequent diagnostic and treatment plans. (Fig. 27.1, Fig. 27.2, Fig. 27.3, Fig. 27.4 and Fig. 27.5).

Causes of Infertility

The main causes of infertility include the following:

1. Male factor
2. Decreased ovarian reserve
3. Ovulatory disorders (ovulatory factor)
4. Tubal injury, blockage, or paratubal adhesions (including endometriosis with evidence of tubal or peritoneal adhesions)
5. Cervical and immunologic factors
6. Uterine factors
7. Conditions such as immunologic aberrations, infections, and serious systemic illnesses
8. Unexplained factors (including endometriosis with no evidence of tubal or peritoneal adhesions)

Factors from either or both partners may contribute to difficulties in conceiving; therefore, it is important to consider all possible diagnoses before pursuing invasive treatment. In some cases, no specific cause is detected despite an extensive and complete evaluation. The relative prevalence of the different causes of infertility varies widely among patient populations (Table 27.1).

Very few couples have absolute infertility, which can result from congenital or acquired irreversible loss of functional gametes in either partner or the absence of a uterus in the female. These specific couples should be counseled regarding their options of adoption, the use of donor gametes, or surrogacy. Rather, most couples who have difficulty conceiving have subfertility. According to this fundamental concept, most couples could conceive spontaneously in time, but because of known or unidentified causes, their spontaneous fecundity rate is so low that medical management is warranted. Another reason to seek medical attention, particularly among older women, is that as time passes during unsuccessful spontaneous attempts, fecundability will be further compromised by increasing age and concomitantly decreasing ovarian reserve. Although identification of apparent causes of subfertility (such as anovulation or oligospermia) allows treatment to be targeted, effective empiric treatments greatly increase the chance of a pregnancy even when no distinct cause is identified. Overall, these treatments aim at increasing the probability of conception and implantation by optimizing gamete (sperm and oocyte) and uterine factors.

The next section of this chapter outlines causes of male and female infertility, their methods of diagnosis, and the specific treatments for these conditions. The basic investigations that should be performed before starting any infertility treatment are semen analysis, confirmation of ovulation, and the documentation of tubal patency by hysterosalpingography (HSG). Some treatments, especially ART, are indicated for more than one diagnosis and are discussed in greater detail. Often, more than one cause is identified in a couple. For this reason, multiple directions of investigation and treatment may be undertaken in parallel.

Male Factor

The combined effects of our increased understanding of genetic causes in male factor infertility and the efficacy of intracytoplasmic sperm injection (ICSI) in ART have revolutionized modern treatment of male factor infertility. For men, semen analysis as the initial step in their diagnostic evaluation for infertility is a fairly simple one. Semen analysis is inexpensive and noninvasive, and it should be included at the initiation of every infertility workup. The assessment of semen parameters, however, is confounded by controversies regarding the proper range of normal values. Semen parameters in normal fertile men vary considerably over time and may even drop below established norms; this situation makes evaluation of the male patient more difficult. The value and interpretation of the semen analysis and other tests for male infertility should be considered within the context of male reproductive physiology.

Physiology

The male reproductive tract consists of the testis, epididymis, vas deferens, prostate, seminal vesicles, ejaculatory duct, bulbourethral glands, and urethra. The testes contain two cell types: the Sertoli cells, which line the seminiferous tubules (the site of spermatogenesis), and the Leydig cells (the site of androgen synthesis). In the male, the pituitary gland secretes luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which act on the testes. LH stimulates the synthesis and secretion of testosterone by the Leydig cells, and FSH stimulates the Leydig cells to secrete inhibin. FSH and testosterone act on the seminiferous tubules to stimulate spermatogenesis. In humans, it takes about 75 days for spermatogonia to develop into mature sperm cells. The immature spermatogonia undergo mitotic division, giving rise to spermatocytes. These spermatocytes subsequently undergo meiosis, or reduction division, which gives rise to spermatids containing 23 (rather than 46) chromosomes. Upon maturation, spermatids become spermatozoa, which enter the epididymis, where they continue to mature and become progressively moremotile during the 12 to 21 days that is required to traverse this tortuous structure.

During ejaculation, mature spermatozoa are released from the vas deferens along with fluid from the prostate, seminal vesicles, and bulbourethral glands. The semen released is a gelatinous mixture of spermatozoa and seminal plasma; however, it thins out 20 to 30 minutes after ejaculation by a process called liquefaction. Liquefaction occurs secondary to the presence of proteolytic enzymes within the prostatic fluid. The released spermatozoa are not usually capable of fertilization. Instead, a series of complex biochemical and electrical events, termed capacitation, must take place within the sperm's outer surface membrane before fertilization can occur. Normally, capacitation occurs in the cervical mucus; however, it can occur in physiologic media in vitro. Finally, as part of fertilization, the sperm must undergo the acrosome reaction, in which the release of enzymes of the inner acrosomal membrane results in the breakdown of the outer plasma membrane and its fusion with the outer acrosomal membrane. Several of the enzymes within the acrosome appear to be important to the sperm's penetration of the egg's zona pellucida. As the sperm penetrates the egg, it initiates a hardening of the zona pellucida (cortical reaction), which prevents penetration by additional sperm (§).

Semens Analysis

The basic semen analysis measures semen volume, sperm concentration, sperm motility, and sperm morphology. In addition, many laboratories measure pH, fructose levels, and white blood cell counts within the semen. Normal values suggested by the World Health Organization (WHO) are listed in Table 27.2 (18). These values represent only general guidelines, and normal values should be separately established by individual andrology laboratories.
anatomic and endocrine causes occur less frequently. The second distribution is the result of a study of 425 subfertile male patients (10). The figures include data from cases in which the male partner was normal and the presumed cause of the couple's infertility was a female factor. The second distribution is the result of a WHO study of 7,057 men with complete diagnoses based on the WHO standard investigation of the infertile couple (28). The figures indicate data from cases in which the male partner was normal and the presumed cause of the couple's infertility was a female factor. The second distribution is the result of a study of 425 subfertile male patients (24). Although the two studies represent different populations (one is from a study of couples, the other from a urologic practice) and differ in their distribution of male infertility diagnoses, idiopathic male factor and varicocele predominate. Other anatomic and endocrine causes occur less frequently.

Sperm Volume The normal ejaculated volume of semen is 2 to 6 mL. Volumes may be abnormally low in cases of retrograde ejaculation, and high volumes usually reflect relatively long periods of abstinence or inflammation of the accessory glands. Absence of fructose or high pH may be associated with ejaculatory tract obstruction or seminal vesicle dysfunction.

Sperm Concentration Sperm concentration or density is defined as the number of sperm per milliliter in the total ejaculate. Establishing a lower limit of normal for sperm concentration is difficult. Historically, cutoffs of 60 million sperm per milliliter for normal fertility have been advocated, but most WHO laboratories recognize the value of 20 million sperm per milliliter as a lower limit of normal (12). Some have advocated concentrations of 5 million sperm per milliliter as a lower limit of normal (13-14).

Sperm Motility An equally important parameter in the semen analysis is sperm motility, which is defined as the percentage of progressively motile sperm in the ejaculate. Lower limits of normal vary considerably and depend on the local laboratory's experience. The WHO and many laboratories use a cutoff of 50% motility as the lower limit of normal; whereas others require 40% motility as a criterion for defining male factor infertility (15). Computer-assisted semen analysis, in which computer-generated images of sperm specimens quantitate both sperm counts and sperm motility, may yield results very different from those of nonautomated semen analyses. Regardless of how motility is assessed, the interpretation of sperm motility—as with sperm concentration—is hampered by both significant variability among repeat samples obtained from a single individual and poor correlation of motility with fertility.

Sperm Morphology The WHO uses a fairly permissive visual assessment of sperm within a semen specimen to assess morphology values; greater than 30% normal forms is defined as acceptable. More stringent criteria have evolved from other sources. The strict Tygerberg criteria were introduced by Kruger and Menkveld in 1986 to assess sperm morphology (16). Using this system, the entire spermatozoon—including the head, midpiece, and tail—is assessed, and even mild abnormalities in head forms are classified as abnormal. Most sperm from normal men exhibit minor abnormalities when subjected to Tygerberg standards. One advantage of these strict criteria, however, is that the Tygerberg classification correlates with prognosis in IVF treatment. For example, greater than 14% normal morphology is associated with normal rates of fertilization in IVF programs; 4% to 14% normal morphology is associated with a “good prognosis.” Values of less than 4% normal sperm morphology are associated with poor prognosis for fertilization and pregnancy in IVF (17). In some studies, this sperm morphology classification has also been found to be predictive of pregnancy outcomes after intrauterine insemination (IUI) treatment, especially when the total motile sperm count is less than 1 x 10^7 (18). The disparity in assessment criteria for semen morphology mandates that to interpret semen analysis results properly, the clinician must thoroughly understand the methodology used by the local andrology laboratory.

White Blood Cells Although measurements of semen volume, sperm concentration, sperm motility, and sperm morphology make up the standard semen analysis, some laboratories also report numbers of round cells. These cells, which may be lymphocytes, can signify the presence of prostatitis or, alternatively, may actually be immature germ cells. These two cell types can be distinguished by an immunoperoxidase staining technique that identifies leukocytes (Endtz test) (19). The WHO views ejaculates with more than 5 million round cells per milliliter or more than 1 million leukocytes per milliliter as abnormal (20); however, the prognostic significance of leukocytes in the semen is controversial. The presence of immature sperm cells in the ejaculate suggests a defect in spermatogenesis and, therefore, may signify a relatively poor prognosis for fertilization (21). Although the standard semen analysis and associated tests provide a fairly reasonable picture of semen quality, they yield little information about sperm function. Consequently, several tests of sperm function have been devised in an effort to assess the physiologic properties of sperm and thereby predict the likelihood of fertilization of normal oocytes.

Sperm Penetration Assay The most commonly used test of sperm function is the sperm penetration assay (SPA), or hamster egg penetration test (22). This test attempts to measure the ability of an individual patient's sperm to undergo capacitation (i.e., the acrosome reaction), to fuse with and penetrate the oocyte membrane, and to undergo nuclear decondensation. In the SPA, golden hamsters are superovulated, and their eggs are collected and treated with enzymes to remove the cumulus and zona pellucida. Meanwhile, sperm are isolated from the patient's semen and placed in a protein-rich environment that promotes capacitation. Sperm from normal fertile men are used as positive controls. After this incubation, the zona-free eggs are exposed to patient and control sperm. The presence of one or more swollen sperm heads within the hamster oocyte after exposure to sperm demonstrates penetration. Most laboratories report the percentage of eggs successfully penetrated; however, some laboratories count the number of penetrations per egg (usually two or more is considered normal). Cutoff values for the lower limit of normal in the SPA differ remarkably among laboratories.

The prognostic value of the SPA has been controversial almost since its inception. On the basis of a metaanalysis of the SPA, the test does not discriminate between fertile and infertile men (23). The value of the test as a predictor of success in IVF has been less controversial. In most evaluations of the male partner, the SPA offers little definitive information; however, it may uncover sperm abnormalities in couples with otherwise unexplained infertility.

Several other tests attempt to correlate sperm function with fertility prognosis. The human zona-binding assay (the Hemizona test) examines the ability of the sperm to bind to zona. In this assay, human zona are bisected; half of the zona is exposed to the patient's sperm, and half is exposed to sperm from a known fertile donor control (24). Results compare the binding ability of samples of patients to those of controls. The hypoosmotic swelling test examines the normality of the sperm tail. When placed in a hypoosmotic solution of sodium citrate and fructose, the normal sperm tail swells and coils; when there is an abnormality in fluid transport across the tail membrane, the sperm tail fails to swell (25). To detect the acrosome reaction, some investigators have used monoclonal antibodies (26), whereas others have measured adenosine triphosphate (ATP) content in the semen (27). These functional tests should be considered experimental until more definitive evidence demonstrates their utility in clinical settings.

Further Evaluation If abnormalities in the semen are detected, further evaluation of the male partner by a urologist is indicated to diagnose the defect. Table 27.3 lists the differential diagnoses for male factor infertility (49). Several groups have attempted to assess the distribution of male infertility diagnoses; two such distributions are shown in Table 27.4 (24,25). The first is the result of a WHO study of 7,057 men with complete diagnoses based on the WHO standard investigation of the infertile couple (28). The figures include data from cases in which the male partner was normal and the presumed cause of the couple's infertility was a female factor. The second distribution is the result of a study of 425 subfertile male patients (24). Although the two studies represent different populations (one is from a study of couples, the other from a urologic practice) and differ in their distribution of male infertility diagnoses, idiopathic male factor and varicocele predominate. Other anatomic and endocrine causes occur less frequently.

Specimen Collection The method used for semen specimen collection is important to the achievement of accurate results. The optimal period of abstinence before semen collection is unknown; however, because a decrease in sperm concentration is associated with frequent ejaculation, a period of 2 to 3 days usually is recommended. The specimen should be obtained by masturbation and collected in a clean container. Because of the presence of spermicidal agents, collection into condom is generally unacceptable, although special sheaths that do not contain spermicides are available for semen collection. All semen specimens should be taken to the laboratory within 1 to 2 hours of collection. Even when collection is done under optimal circumstances, interpretation of the results of the semen analysis is complicated by wide differences in normal semen parameters (9), seasonal variability (10), variations among laboratories or technicians (11), and inconsistent correlation with fertility outcome. Semen parameters also may vary widely from one man to another and among men with proven fertility. In many circumstances, several specimens are necessary to verify an abnormality.

Specimen Collection The method used for semen specimen collection is important to the achievement of accurate results. The optimal period of abstinence before semen collection is unknown; however, because a decrease in sperm concentration is associated with frequent ejaculation, a period of 2 to 3 days usually is recommended. The specimen should be obtained by masturbation and collected in a clean container. Because of the presence of spermicidal agents, collection into condom is generally unacceptable, although special sheaths that do not contain spermicides are available for semen collection. All semen specimens should be taken to the laboratory within 1 to 2 hours of collection. Even when collection is done under optimal circumstances, interpretation of the results of the semen analysis is complicated by wide differences in normal semen parameters (9), seasonal variability (10), variations among laboratories or technicians (11), and inconsistent correlation with fertility outcome. Semen parameters also may vary widely from one man to another and among men with proven fertility. In many circumstances, several specimens are necessary to verify an abnormality.
The widely accepted concept of a global decline in sperm counts needs to be reassessed (30). A number of recent analyses reported no decrease in sperm counts over time (31,32). Other studies include reports of differences in the results of inclusion of azoospermic patients in previously published studies, and seminal fluid volumes not (34,35) and those with varicoceles their presence was associated with a reduction in testicular volume and a reduction in sperm concentration (36). Furthermore, the rate of male factor infertility has not increased significantly in recent decades. Thus, even if semen characteristics are changing, these changes do not appear to be having a dramatic clinical effect. Nevertheless, exposures to environmental toxins may certainly be harmful to sperm, and the incidence of some exposures (e.g., phthalates) may be on the rise. Marijuana and cocaine use can reduce sperm concentration (37,38). Certain drugs, such as anabolic steroids, chemotherapeutic agents, and tetracycline, also may reduce semen parameters. Finally, commonly ingested agents present in cigarettes and coffee have been associated with diminished semen quality (39).

### Treatment

Treatment of male factor infertility may be classified as medical, surgical, or ART-related therapies. Further, the diagnosis and treatment of azoospermia/no sperm on semen analysis will be discussed separately from other forms of male factor infertility.

Medical therapies for male factor infertility are severely limited. Medical correction of underlying treatable endocrine or infectious causes of subfertility tends to be efficacious. These conditions may include sexually transmitted diseases, thyroid disorders, and other rare causes of male infertility. Clomiphene citrate, an estrogen agonist and partial antagonist, has been used to treat male infertility of idiopathic origin. Clomiphene citrate acts on the hypothalamic–pituitary axis and, in men, increases serum levels of LH, FSH, and testosterone (40). Although efficacy of clomiphene for male factor infertility is controversial, most studies have shown little improvement in semen parameters and no improvement in pregnancy rates (41). However, severe idiopathic male factor infertility has been treated with pure FSH, with no notable improvement in semen parameters but a significant increase in fertilization rates during ART (42).

Surgical approaches to male factor infertility include procedures to correct varicocele, artificial insemination, and ART.

### Varicocele

A varicocele is an abnormal dilation of the veins within the spermatic cord. Varicoceles nearly always occur on the left side, presumably because of the direct insertion of the spermatic vein into the renal vein on that side. The pathophysiologic effects of varicocele on testicular function are uncertain but appear to be mediated by an associated rise in testicular temperature or a reflux of toxic metabolites from the left adrenal or renal veins (43). In either event, the effect on sperm production is bilateral. Our understanding of the role of varicoceles in infertility is complicated by two issues: the prevalence of varicoceles in the normal male population and the efficacy of varicocele repair in infertile men. One WHO study found varicocele to be present in 25.4% of men with abnormal semen analyses, as opposed to 11.7% of men with normal semen (44). This study failed to demonstrate a difference in the frequency of spontaneous pregnancies among couples in which the men did or did not have varicoceles. The presence of a varicocele was, however, associated with decreased testicular volume, impaired semen quality, and a reduction in serum testosterone levels.

Varicocele repair involves interruption of the internal spermatic vein and is commonly performed in the 40% of infertile men with clinically evident varicoceles. Currently, it is performed as an outpatient procedure and may involve laparoscopy, open surgery, or the injection of embolizing agents. Despite its widespread use, the therapeutic benefits of varicocele repair have remained controversial. Two multicenter trials have shown that pregnancy rates are significantly increased after varicocelectomy (45). However, the validity of the control groups in each of these trials has been criticized (46). A more recent metaanalysis on four randomized, controlled trials involving a total of 385 patients failed to demonstrate significantly altered pregnancy rates after varicocelectomy (47,48). Artificial insemination may be performed either with unwashed or with processed specimens. The success rates with intracervical insemination are consistently lower than those with IUI (49).

### Artificial Insemination

Artificial insemination encompasses a variety of procedures. All involve the placement of whole semen or processed sperm into the female reproductive tract, which permits sperm–oocyte interaction in the absence of intercourse. The placement of whole semen into the vagina as a mode of fertility treatment is now rarely performed (42). Exceptions include cases of severe hypospadias, retrograde ejaculation, erectile abnormalities, and psychosocial dysfunction precluding intercourse. Currently, all of the common forms of artificial insemination involve processed sperm obtained from the male partner or a donor before its use. Artificial insemination has mainly been used to treat unexplained infertility (usually combined with superovulation) and male factor infertility. The efficacy of each type of insemination method should be assessed separately for each of these two diagnoses.

#### Types of Insemination for Unexplained Infertility

Many techniques for artificial insemination have been described. Of intracervical, intrauterine, intraperitoneal, and intrafallopian insemination and fallopian tube sperm perfusion, only the first two methods have been routinely employed. **Intrauterine insemination (IUI) is the best studied and most widely practiced of all the insemination techniques.** It involves placement of about 0.3 mL of washed, processed, and concentrated sperm into the intrauterine cavity by transcervical catheterization. In contrast with IUI, intracervical insemination may be performed either with unwashed or with processed specimens. The success rates with intracervical insemination are consistently lower than those with IUI (50,51).

Fallopian tube sperm perfusion (FSP) differs from IUI in that a large volume of washed sperm (about 4 mL) is injected into the intrauterine cavity. This is a more expensive procedure because larger volumes of media are required during sperm processing. Technical performance of FSP may be complicated by efflux of sperm through the vagina during the intrauterine injection of such large volumes of fluid. Among several techniques of efflux prevention, use of an intrauterine Foley catheter with balloon inflation is most commonly described. Although many have demonstrated that fallopian sperm perfusion does not offer any general advantage over IUI (52,53), its benefit in the treatment of unexplained infertility remains controversial. Several prospective randomized trials have reported higher pregnancy

</table>
rates among patients with unexplained infertility in cycles treated with FSP compared with those using IUI (58,59,60 and 61). One recent metaanalysis found that FSP significantly improves pregnancy rates in patients with unexplained infertility undergoing controlled ovarian hyperstimulation (COH)/insemination with an odds ratio (OR) of 1.9 and a 95% confidence interval (CI) of 1.2 to 3 (60) (see Controlled Ovarian Hyperstimulation).

Direct intraperitoneal insemination involves the injection of washed, processed sperm into the intraperitoneal cavity by puncture of the posterior vaginal cul-de-sac. Evidence from prospective randomized trials showed that direct intraperitoneal insemination offers no advantage over IUI (62,63,64 and 65). Intracervical insemination as a treatment of male factor infertility has also been reported (66), but in a series of 50 patients with unexplained infertility, only one intrauterine pregnancy resulted (67). Its low efficacy has deterred further investigation of this technique. In summary, IUI is the best-studied insemination technique, with proven superiority to intracervical insemination in the treatment of IUI and unexplained infertility (53). FSP appears to be a viable alternative to IUI with COH/insemination in couples with unexplained infertility. However, the potential increase in pregnancy rates using FSP over IUI is unlikely to be as great as that of IVF/ICSI over IUI. Therefore, although COH/FSP may be chosen instead of COH/IUI in a center where FSP gives a higher pregnancy rate, there is no benefit to switch from COH/IUI to COH/FSP after three cycles of failed COH/IUI in patients with unexplained infertility. IVF/ICSI remains the best available treatment option in patients with unexplained infertility who have not become pregnant with COH/IUI treatment.

**Processing Semen**

Two important issues regarding the use of artificial insemination procedures are the mode of semen processing and the number and timing of insemination doses. These factors have been shown to affect the sperm penetration capacity. Seminal fluid usually is prevented from reaching the intraperitoneal space by the cervical barrier. The introduction of seminal fluid past this barrier may be associated with severe uterine cramping or anaphylactoid reactions, possibly mediated by seminal factors such as prostaglandins. Thus, protocols for processing whole semen include the washing of specimens to remove seminal plasma in an attempt to isolate pure sperm. Some semen preparation methods attempt to enhance sperm motility or morphology further by using additional separation protocols. These methods include centrifugation through density gradients, sperm migration protocols, and differential adherence procedures. Finally, phosphodiesterase inhibitors, such as pentoxiphylline, have been used during semen processing in an attempt to enhance sperm motility, fertilization capacity, and acrosome reactivity for IVF procedures (58).

**IUI as Treatment of Male Factor Infertility**

Studies of the efficacy of IUI in the treatment of male factor infertility have been generally difficult to assess because of variations in inclusion criteria. Further, sperm function tests are not consistently used in these studies, nor is their use standardized. Considering these limitations, the benefits of IUI in male factor infertility have been accepted because IUI appears to result in higher pregnancy rates than natural intercourse or intracervical insemination (OR, 2.20;95% CI, 1.43 to 3.38) (69). However, the IUI pregnancy rates are generally lower in couples with male factor infertility than in couples with unexplained infertility (4.8% versus 11.6%) (69). In a retrospective analysis of 1,841 couples undergoing 4,056 cycles of IUI for male factor infertility, pregnancy rates were found to be related to total motile sperm count. Optimal pregnancy rates (>8.2% per cycle) were reached with initial total motile sperm counts of greater than or equal to 5.0 × 10^6. Higher counts did not necessarily yield higher pregnancy rates. The minimal total motile sperm count that resulted in a pregnancy was 1.6 × 10^6 (70).

Some couples with male factor infertility fail treatment with artificial insemination, and some have initial semen parameters that make insemination a suboptimal approach. In these couples, use of ART, especially with ICSI, may be superior treatment options. The efficacy of ICSI in ART allows almost all cases of male factor infertility to be highly treatable. ICSI only requires that viable sperm be present. Therefore, ICSI should be considered if the total motile sperm count is less than 0.5 × 10^6 because the IUI success rates are extremely low with such sperm concentration (71). Finally, ICSI should be recommended after a maximum of three IUI cycles have failed in a couple with male factor infertility.

**Azoospermia: Classification and Treatment**

Azoospermia is the absence of spermatozoa in the ejaculate. Azoospermia is found on semen analysis in about 5% of all couples being investigated for infertility (72), and its incidence is 10% to 20% among infertile men who have abnormal semen analysis (73). Traditionally, azoospermia has been classified according to whether the sperm lack is pretesticular or posttesticular. Pretesticular azoospermia represents those conditions in which the hypothalamic–pituitary axis fails to stimulate spermatogenesis within the testis. Congenital, acquired, and idiopathic etiologies of hypogonadotropic hypogonadism are included in this category. A full endocrine history, including information on puberty and growth and a review of endocrine systems, should guide the physician in the evaluation of the hypogonadotropic hypogonadal patient. Laboratory investigations of particular importance in this population include measurement of serum LH, FSH, testosterone, and prolactin levels and imaging of the pituitary gland. Low levels of gonadotropins (LH and FSH) and low serum levels of testosterone are characteristic.

Hormonal treatment of hypogonadotropic hypogonadism has been conclusively demonstrated to be efficacious. In fact, pulsatile gonadotropin-releasing hormone (GnRH) therapy is both conceptually indicated and effective in infertile men with hypothalamic dysfunction (74), including those patients with Kallmann’s syndrome. Intrauterine males with hypogonadotropic hypogonadism secondary to parhypopituitarism also may respond to GnRH therapy (75). An alternative treatment uses human chorionic gonadotropin (hCG), 1,000 to 2,500 IU twice a week, with the dose titrated to maintain serum testosterone and estradiol levels within the normal range. Treatment with hCG is then combined with human menopausal gonadotropin (hMG), which is given at a dose of 150 IU three times weekly (76,77). Spermatogenesis and pregnancy can be achieved in up to 80% to 88% of patients after 1 year of therapy (78,79). However, aGVH.

**Pretesticular Azoospermia**

Pretesticular azoospermia represents those conditions in which the hypothalamic–pituitary axis fails to stimulate spermatogenesis within the testis. Congenital, acquired, and idiopathic etiologies of hypogonadotropic hypogonadism are included in this category. A full endocrine history, including information on puberty and growth and a review of endocrine systems, should guide the physician in the evaluation of the hypogonadotropic hypogonadal patient. Laboratory investigations of particular importance in this population include measurement of serum LH, FSH, testosterone, and prolactin levels and imaging of the pituitary gland. Low levels of gonadotropins (LH and FSH) and low serum levels of testosterone are characteristic.

Hormonal treatment of hypogonadotropic hypogonadism has been conclusively demonstrated to be efficacious. In fact, pulsatile gonadotropin-releasing hormone (GnRH) therapy is both conceptually indicated and effective in infertile men with hypothalamic dysfunction (74), including those patients with Kallmann’s syndrome. Intrauterine males with hypogonadotropic hypogonadism secondary to parhypopituitarism also may respond to GnRH therapy (75). An alternative treatment uses human chorionic gonadotropin (hCG), 1,000 to 2,500 IU twice a week, with the dose titrated to maintain serum testosterone and estradiol levels within the normal range. Treatment with hCG is then combined with human menopausal gonadotropin (hMG), which is given at a dose of 150 IU three times weekly (76,77). Spermatogenesis and pregnancy can be achieved in up to 80% to 88% of patients after 1 year of therapy (78,79). However, aGVH.

**Testicular Azoospermia**

Gonadal failure is the hallmark of testicular azoospermia. Causes of this condition may be congenital or genetic (e.g., Klinefelter’s syndrome, microdeletion of Y chromosome), acquired (e.g., radiation therapy, chemotherapy, testicular torsion, or mumps orchitis), or developmental (e.g., testicular maldescent). The latter disorder may be associated more closely with male factor infertility in the absence of complete testicular azoospermia. A large observational cohort study suggested that infertility was, in fact, associated with congenital bilaterally maldescent testes, but that men with congenital unilaterally maldescent testes did not have decreased fertility when compared with controls (81).

**Men with hypergonadotropic hypogonadism** (elevated levels of LH and FSH with low serum levels of testosterone) generally have primary gonadal failure. A karyotype should be obtained in such cases to detect chromosomal abnormalities such as Klinefelter’s syndrome (47,XY). Acquired causes of primary gonadal failure are usually evident on history, but they should be confirmed by assessment of the serum hormonal profile and biopsy. If the diagnosis of gonadal failure is confirmed on biopsy, endocrine therapy is contraindicated.

It is becoming increasingly evident that some cases of male factor infertility that have previously been categorized as idiopathic are actually the result of genetic defects. The two most common candidate gene families are the RNA-binding motif (RBM) and the “deleted in azoospermia” (DAZ) families, but microdeletions at various loci on the Y chromosome have been described. For example, microdeletions in Yq11.23 have been found in 10% to 20% of men with idiopathic azoospermia or severe oligozoospermia (82,83). In another study involving 200 infertile men, 7% were found to have microdeletions in the Y chromosome (84). Semen analyses in affected men varied between oligozoospermia and azoospermia. Interestingly, 2% of fertile men also have microdeletions in the Y chromosome. Thus, these microdeletions can be transmitted to the male offspring, who may then also suffer from infertility. Therefore, screening for genetic causes is indicated in nonacquired cases of testicular azoospermia so that proper genetic counseling can be provided before treatment. Treatment is focused on surgical retrieval of spermatozoa with subsequent fertilization of the oocyte by ICSI. These approaches have made fertility possible for some men with testicular azoospermia.

**Intracytoplasmic Sperm Injection**

ICSI is a micromanipulation technique commonly used in some ART procedures. It was first reported to result in human pregnancies in 1992 (85). ICSI is performed to increase the fertilization rate of oocytes retrieved during ART. The procedure involves stripping the aspirated cumulus ooplasm. This procedure is thought to bypass some of the physiologic events, such as capacitation and the acrosome reaction, that are normally required for fertilization in vivo.

In general, ICSI has allowed couples with male factor infertility to achieve ART pregnancy outcomes that are comparable with those of couples with non–male factor infertility using conventional IVF treatment. The indications of ICSI have evolved since its introduction. They will most likely continue to evolve as more is learned.
about risks and benefits of ICSI. One absolute indication for ICSI is severe male factor infertility as demonstrated by total progressively motile sperm counts (0.5 × 10^9/mL and <3% normal morphology according to strict Tygerberg criteria) (71). Sperm counts of less than 0.5 × 10^9/mL are associated with poor fertilization rates in IVF, and this finding alone is also an indication for ICSI (88). Other indications for ICSI include the sole presence of spermatozoa lacking an acrosome or those that are completely immotile, as well as the use of manipulated embryos resulting from epididymal or testicular sperm. Other absolute indications for ICSI are non–male factor–related and include a history of two previous fertilization failures with conventional IVF and the fertilization of oocytes before reimplantation genetic diagnosis (97). The benefit of combined IVF/ICSI in ART for unexplained infertility also is described under Unexplained Infertility.

Micromanipulation is a highly skilled technique. When performed by specially trained embryologists, the immediate risk for damaging the manipulated oocyte is less than 10% (71). The manipulative processes—capacitation, zona binding, and penetration of the oolemma—are bypassed by the spermatozoa used in ICSI. Because the particular spermatozoa used for ICSI might otherwise be incapable of fertilization, concerns have been voiced regarding possible increased risks for congenital abnormalities among ICSI offspring. Several large series have followed 1,987 (89), 1,139 (89), and 730 (90) children born after ICSI. Each has reported no increase in major or minor congenital malformations among offspring produced by ICSI when compared with the general population (89,89 and 90) and when adjusted for multiple gestation (89). However, an increased incidence of sex chromosome karyotypic abnormalities (88,91) and hypospadias (89) has been suggested. Because the prevalence of sex chromosome karyotypic abnormalities and other genetic etiologies is increased in infertile men with severe oligospermia or azospermia, genetic counseling should be offered before treatment with ART (92).

Posttesticular Azospermia

In posttesticular azospermia, the hypothalamic–pituitary axis and spermatogenesis are normal. No sperm appear in the ejaculate secondary to congenital absence or obstruction of the vas deferens or ejaculatory ducts, acquired obstruction of these ducts, or ductal dysfunctions, including retrOrg. Although low seminal pH (6.7 to 8.0) or low seminal fructose may signal the congenital absence or obstruction of the vas deferens, the diagnosis is confirmed by vasography. In some cases, testicular biopsy may be indicated to differentiate between primary testicular damage and outflow obstruction. Congenital bilateral absence of the vas deferens (CABVD) is found in 1% to 2% of infertile men and 95% of men with cystic fibrosis (93). Common mutations of the cystic fibrosis transmembrane conductance regulator gene (CFTR), which encodes a cyclic adenosine monophosphate (cAMP)-regulated chloride channel, can be found in some infertile men with CABVD, despite the absence of clinical symptoms of cystic fibrosis. Therefore, screening for mutations in the CFTR gene is indicated if men with CABVD plan to undergo sperm retrieval and ICSI in order to conceive using their own sperm. One cost-effective screening method addressing this problem involves screening the female partner for spermatozoa that may result from mutations in the CFTR gene. If negative, the couple has a risk of less than 1 in 1,500 for conceiving a child with cystic fibrosis, regardless of the paternal genotype (40).

Prior vasectomy is probably the most common cause of posttesticular azospermia in infertile men. The reversal of vasectomy by vasovasostomy (vaso–vaso anastomosis) is quite effective. In one study, vas deferens patency was obtained in 86% of cases, and pregnancy was achieved in 52% of cases after primary procedures (94). Rates of patency and pregnancy vary inversely with the length of time from vasectomy. For those patients with azospermia 3 months after the reversal procedure, either the reanastomosis has failed or the epididymis is obstructed. Repeat vasovasostomy is associated with patency rates of 75% and pregnancy rates of 43% (95).

Epididymal obstruction is best diagnosed by vasography or documentation of normal spermatogenesis on testicular biopsy. There are two approaches to the treatment of posttesticular obstruction if the use of donor sperm is not being considered. Epididymal aspiration proximal to the obstruction may be used in cases of epididymal obstruction in combination with ICSI, however, microsurgical vasal epididymostomy is associated with patency rates of 70% and postoperative pregnancy rates of 44% at 1 year if no other infertility factor is present (95).

Some men with reduced semen volume may have retrograde ejaculation, in which sperm is propelled into the bladder during ejaculation rather than through the urethra. This deficiency can be confirmed by examination of a postejaculatory-voided or catheterized urine specimen. This condition occurs in rare cases of patients with diabetes mellitus, in certain neurologic conditions, and after bladder or prostatic surgery. For subfertile men with retrograde ejaculatory dysfunction, a-adrenergic agonists such as phenylephrine have been reported to strengthen internal urethral sphincter tone (96). Sperm may also be isolated from the neutralized urine of men with retrograde ejaculation and processed for insemination or for ART (97).

Surgical Sperm Recovery for ICSI

Among the many surgical methods for sperm recovery, the most widely described are microsurgical epididymal sperm aspiration (MESA), percutaneous epididymal sperm aspiration (PESA), testicular sperm extraction (TESE), and percutaneous testicular sperm fine-needle aspiration (TESA, also called fine-needle aspiration, or FNA) (88). The choice of surgical sperm recovery method depends on the underlying diagnosis, whether the goal of the procedure is diagnostic or therapeutic, and whether isolated sperm will be used immediately or will be cryopreserved.

TESA may be performed to recover sperm in cases of posttesticular azospermia (in which spermatogenesis is expected to be normal), with a successful sperm recovery in 90% of patients (99). TESA is usually well tolerated by patients. It is typically performed with a 21-gauge needle with no anesthesia or with a 19-gauge needle or biopsy gun using local anesthesia. Fertilization and implantation rates have been reported to be similar in a retrospective analysis comparing TESA with open biopsy using TESE (99). Alternatively, if the nature of the obstruction needs to be investigated by a full scrotal exploration, or if attempted surgical correction of the obstruction fails, sperm retrieval by the preferred technique, microsurgical vasal epididymostomy is associated with patency rates of 70% and postoperative pregnancy rates of 44% at 1 year if no other infertility factor is present (95).

Sperm retrieval using PESA is another option for the treatment of posttesticular azospermia. PESA is performed using a 19-gauge needle with local or regional anesthesia. A sperm recovery rate of greater than 80% has been reported with 55% fertilization and 33% ongoing pregnancy rates after ICSI (103). Although this procedure appears less invasive than some of its alternatives, it is performed blindly. Bleeding and epididymal injury are possible, and postoperative swelling may result (104). In contrast, men with testicular azospermia or gonadial failure require TESE, and possibly multiple biopsies, to retrieve sperm (105). TESA followed by ICSI has resulted in ongoing pregnancies, even for patients with 47, XXY Klinefelter's syndrome (106,107). However, the sperm recovery rate with TESE is only about 50%, and clinical outcomes for ICSI after TESE among patients with testicular azospermia are variable.

Lower fertilization rates but comparable ongoing pregnancy rates have been reported for ICSI using testicular spermatozoa recovered from testicular azospermia, compared with epididymal spermatozoa, posttesticular azospermia (91,108). In addition, if an associated histologic diagnosis of testicular aplasia, Sertoli cell–only syndrome, or spermatogenesis arrest is noted, all measures of success are reduced when compared with patients who have normal testicular histology (109). These measures of success include the following: lower sperm recovery rates (100), lower ongoing pregnancy rates (18% to 19% versus 33.5%), and lower implantation rates (5% to 9% versus 12%) (107,109). Despite these findings, the histologic diagnosis alone should not be used to exclude patients from ICSI treatment. Among patients with testicular azospermia, surgically recovered sperm may be at various stages of maturation arrest (i.e., round spermatid, elongated spermatid, and motile and mature sperm) at all stages of the ICSI procedure. MESA is performed on semen with no prior sperm retrieval, and testicular sperm retrieval by the preferred technique, microsurgical vasal epididymostomy is performed on patients with azospermia (91,111). However, the fertilization and pregnancy rates associated with maturation-arrested spermatid are very low, and couples should be properly counseled regarding their prognosis and alternative options (112,113 and 114). Finally, cryopreservation of testicular tissues and of spermatozoa for use in subsequent ICSI treatment cycles has been reported (115).

Fertilization rates of 48%, ongoing pregnancy rates of 16%, and implantation rates of 9% were documented using cryopreservation in a mixed population of 247 patients diagnosed with unexplained infertility and posttesticular azospermia (115).

Donor Insemination

For men with azospermia, couples with significant male factor infertility who do not desire ART, or women seeking pregnancy without a male partner, therapeutic donor insemination offers an effective option. A number of important issues surround the use of this form of artificial insemination. Although the use of frozen sperm samples from donors is not supported by the Centers for Disease Control and Prevention (CDC) and the American Society for Reproductive Medicine, the use of frozen samples is supported by the use of frozen samples (117). These recommendations stem from the increasing incidence of human immunodeficiency virus (HIV) infection in the general population and the lag time between HIV infection and seeding. Donors who are likely to agree are typically younger than the patients who have genetic conditions that are known to cause abnormal sperm, including mitochondrial disorders, familial syndromes, and diseases of the blood.

A second issue surrounding the use of therapeutic donor insemination—which is most important to the patient—is the success rate of treatment. In patients
younger than 30 years of age who have no other infertility factors, conception rates approach 62% after 12 cycles of treatment with frozen sperm (118).

IUl was superior to intracervical insemination for donor insemination in several prospective randomized or crossover trials. Overall, the cycle fecundity rates ranged from 9.7% to 24% for IUl to 3.9% to 17.9% for intracervical insemination (119,120,121,122,123,124 and 125). A metaanalysis concluded that IUl had a significantly higher cycle fecundity rate when compared with ICSI (OR, 2.4; 95% CI, 1.5% to 3.8) (126). Moreover, the concomitant use of domperidone citrate or gonadotropin (hMG) for COH did not result in higher fecundity rates (126).

The length of recommended treatment also should be considered. When frozen donor semen is used, more than 80% of consecutive pregnancies will occur during the first 12 months of treatment (127). Thus, patients who do not conceive within 6 to 12 months should be assessed for female factors and encouraged to terminate treatment or move to alternative forms of therapy.

Last, but not least, one must consider the psychosocial aspects of pregnancies involving donor gametes. Among patients without a male partner, the potential repercussions of becoming a single mother and the issue of telling others about the father of the child must be discussed. If the couple is married, it is imperative that the husband be aware of the process of using donor gametes, and most programs require that the husband sign a consent form. A skilled infertility social worker or psychologist can be immeasurably helpful in addressing these concerns.

**Age and Decreased Ovarian Reserve**

An association between the age of the woman and reduced fertility has been well documented, with the decline in fecundability beginning in the early 30s but accelerating during the late 30s and early 40s. Chronologic age is the strongest determinant of reproductive success in spontaneous and ART cycles because it is a predictor of ovarian reserve (128,129). However, age has traditionally not been considered a "cause" of infertility, probably because it represents a physiologic rather than a pathologic state.

Data from rural Senegal, in which each female gives birth to an average of 7.9 children, show declining fertility rates with a peak of fertility at 25 years of age and a steep decline thereafter (130). In the United States, among the women attempting conception, the number of oocytes retrieved per cycle decreased steadily at the rate of 0.24 oocyte per year of increasing age (131). The fecundability of women undergoing donor insemination whose husbands are azospermic provides insight into the effects of age on the fertility of the female alone. A French group that studied women enrolled in artificial insemination programs found that fertility rates begin to drop after 30 years of age. The pregnancy rate after 1 year of inseminations was 74% in women aged 30 years and younger, 62% in women aged 30 to 35 years, and 54% in women older than 35 years of age (132).

The physiology of declining fertility in older women is better understood in light of data from oocyte donation programs. When embryos produced from oocytes retrieved from younger women are transferred to older women, the pregnancy rates among the older women approximate those of the younger women (133), and variations in pregnancy rates are directly dependent on the age of the donors, not that of the recipients (133,134 and 135). In fact, among 260 egg donors (mean age of 30 years) who underwent controlled ovarian stimulation (COH) with exogenous gonadotropins, the number of oocytes retrieved per cycle decreased steadily at the rate of 0.24 oocyte per year of increasing age (135). In another study, the use of oocytes from young donors provided cycle fecundity rates of 50% per cycle. The accumulated pregnancy and live birth rates in this investigation reached 95% and 89%, respectively, after up to four cycles of ART (136). These observations strongly support that it is the age of the oocyte, rather than the age of the endometrium, that accounts for the age-related decline in female fertility.

This oocyte-related decline in fertility is also known as decreased ovarian reserve. Absolute evidence of decreased ovarian reserve often can be ascertained only after ART treatment shows decreased ovarian responsiveness to COH. In ART, decreased ovarian reserve is reflected by an increased requirement for gonadotropins (FSH ± LH), small numbers of ovarian follicles and oocytes, and low estradiol levels during exogenous stimulation of folliculogenesis. These clinical outcomes probably reflect a decreased number of ovarian antral follicles as well as poor quality of granulosa cells and oocytes (137). Although age is the best predictor of ovarian reserve as reflected by ovarian responsiveness to COH, there is a subset of women who demonstrate an ovarian reserve that is prematurely diminished based on their chronologic age. Similarly, there are women who respond well to COH and achieve pregnancies despite their advanced age. Therefore, tremendous efforts have been expended to identify an ovarian reserve test that can be used to counsel patients and to guide their management.

Ovarian reserve screening tests that have been proposed include serum day 3 FSH, clomiphene citrate challenge test (CCCT), serum inhibin B, and transvaginal ultrasound to assess antral follicle number or ovarian size (138,139 and 140). Measurement of day 3 FSH is based on evidence that small increases in basal serum FSH levels correlate with the decreased fecundability seen among women in their late 30s. Clomiphene citrate is thought to have antiestrogenic effects in the hypothalamic–pituitary axis, resulting in a decrease in suppression of FSH production by the pituitary. In the CCCT, serum FSH is drawn on day 3, and again on day 10 after administration of clomiphene citrate (100 mg orally each day) from days 5 to 9. FSH levels vary depending on the assay used and the population being screened; therefore, each ART center typically sets its own reference range for evaluating the results of a CCCT. In a general infertility patient population, the incidence of an abnormal CCCT rises from less than 10% in patients younger than 35 years of age to 26% in patients older than 40 years of age (141). However, the results of day 3 FSH levels and CCCT must be interpreted with caution. These tests have mainly been studied in women with subfertility. Among these patients, day 3 FSH testing has a sensitivity of 8% in identifying women who will not conceive with subsequent IVF treatment. Day 3 FSH and CCCT each displays a high specificity (96%) in predicting IVF outcome; however, addition of the CCCT to a day 3 FSH assessment only increases the sensitivity of prediction to 26% (142,143 and 144). Although abnormal CCCT results portend poor prognosis for pregnancy independent of age, older patients with normal CCCT still have significantly decreased pregnancy rates. Because among older patients even a normal CCCT is not reassurance of good prognosis, chronologic age must still be considered a salient, independent predictor of treatment outcome (139).

A great deal of emotional, physical, temporal, and financial effort is involved in the process of fertility treatments involving ART. Day 3 FSH and CCCT results can be used to counsel patients regarding their potential for pregnancy with IVF treatment. In one study, 5% of 435 women beginning their first IVF cycle had a day 3 FSH level greater than 15 IU/L (145). These women were 3.9 times more likely to have an unsuccessful treatment cycle. Similarly, among 175 IVF cycles involving women older than 40 years of age, no pregnancies resulted when testing revealed a day 3 FSH greater than 11.1 mIU/mL or a day 10 FSH greater than 13.5 mIU/mL after CCCT (146). Therefore, it is reasonable to advise women with advanced age (>40 years) and abnormal day 3 FSH or CCCT results to strictly limit the number of IVF cycle attempts because of their overall poor prognosis. These tests should not, however, be used as the sole basis to exclude women from IVF treatment (142).

Recently, serum inhibin B has also been proposed as a potential screening test for ovarian reserve. Inhibin B is produced by ovarian granulosa cells predominantly during the follicular phase of the menstrual cycle. Inhibin B suppresses the production of FSH by the pituitary gland. The normal rise in circulating levels of FSH associated with menopause is thought to be secondary to the decrease in inhibin B production accompanying the age-related depletion of functional ovarian follicles. In fact, in the CCCT, the main mechanism by which FSH is normally suppressed is via inhibin B production by granulosa cells. Women with decreased ovarian reserve have a lower rise in the day 10 serum inhibin B levels in response to the CCCT (147). In addition, women who have clinical evidence of diminished ovarian reserve and normal day 3 FSH levels have been found to have decreased day 3 inhibin B levels. This observation suggests that a decrease in day 3 serum inhibin B...
levels may precede detectable changes in day 3 FSH levels (149). Although the degree of elevation in serum inhibin B levels 24 hours after administration of exogenous FSH appears to be positively predictive of good ovarian response (149), clinical application of serum inhibin B still requires further evaluation. In particular, basal inhibin B levels do not provide additional age-independent prognostic value for predicting pregnancy outcomes after ART (128). One possible reason for this is that levels of inhibin B may reflect granulosa cell function and thereby only forecast ovarian response in ART. Although granulosa cell competence is certainly associated with oocyte quality, clinical application of serum inhibin B testing will also depend on whether levels are predictive of normal meiotic division of the oocyte because fetal karyotype is an important determinant of pregnancy outcome (149).

Spontaneous Abortion

Another factor contributing to the decreased fecundity among older reproductive-age women is the increased risk for spontaneous abortion in this population. A large study based on the Danish national registry estimated the rates of clinically recognized spontaneous abortion for various age groups to be 13.3% (12 to 19 years), 11.1% (20 to 24 years), 11.9% (25 to 29 years), 15.0% (30 to 34 years), 24.6% (35 to 39 years), 51.0% (40 to 44 years), and 93.4% (>45 years) (150). In addition, using sensitive hCG assays in women during their reproductive years, 22% of all pregnancies were found to be lost before they could be clinically diagnosed (151). One might predict that this proportion would be increased among older women attempting pregnancy, making subclinical spontaneous pregnancy loss a significant consideration among older women who are thought to be having difficulty conceiving.

One major cause for the increase in spontaneous losses among older women is their increased incidence of chromosomally abnormal fetuses. A cytogenetic analysis of 750 spontaneous abortions revealed that the increase in chromosomally abnormal conceptuses seen with increased maternal age was mainly due to an increase in chromosomal trisomies. In particular, the incidence of trisomies 16, 21, 22, 18, and 20 were significantly increased, with 18 and 20 being the most dramatic. In contrast, the risk for monosomy X and polyoidly did not increase with advanced maternal age (152). In conclusion, an increased spontaneous loss rate, coupled with a reduced conception rate, significantly decreases the chance of a live birth among women older than 40 years of age.

Age of Male Partner

There is little doubt that increasing age is accompanied by reduced female fecundity; however, the age-related decline in fecundity for men is more controversial. Male fertility peaks at about 35 years of age and declines sharply after 45 years of age; however, men have reportedly fathered children into their 80s (8). Also, the risk for chromosomal trisomies appears to be related, at least in part, to increased paternal age (153). Recent observations have demonstrated an increase in the rate of autosomal recessive disorders among the progeny of men 35 years of age and older (154,155). These findings suggest an age-related decline in gamete quality among men, albeit one that is more subtle than that experienced by women.

Ovulatory Factor

Disorders of ovulation account for about 30% to 40% of all cases of female infertility. These disorders are generally among the most easily diagnosed and most treatable causes of infertility. The normal length of the menstrual cycle in reproductive-age women varies from 25 to 35 days; most women have cycle lengths of 27 to 31 days. Figure 27.7 shows the fluctuations of estradiol, progesterone, FSH and LH in a normal, 28-day ovulatory cycle. Women who have regular monthly menses (about every 4 weeks) with molinimal symptoms, such as premenstrual breast swelling and dysmenorrhea, almost invariably have ovulatory cycles. Because ovulation is an obligatory prerequisite to conception, ovulation must be documented as part of the basic assessment of the infertile couple. Initial diagnoses among women with ovulatory factor infertility may include anovulation (complete absence of ovulation) or oligoovulation (infrequent ovulation).

Methods to Document Ovulation

Luteinizing Hormone Monitoring Documentation of the LH surge represents a remarkably reproducible method of predicting ovulation. Ovulation occurs 34 to 36 hours after the onset of the LH surge and about 10 to 12 hours after the LH peak (156,157). Commercially available kits for documenting the LH surge are generally accurate, quick, convenient, and relatively inexpensive enzyme-linked immunosorbent assays (ELISAs) using 40 mIU/mL as the threshold for detection (158,159). The positive and negative predictive values of these kits have been described to be 90% and 98%, respectively (160). A 100% correlation between urinary LH prediction of ovulation and transvaginal ultrasound diagnosis of ovulation has further confirmed the value of urine LH detection kits for home ovulation detection (161). Still, there may be up to 5% to 10% of women for whom this ELISA test cannot detect urinary LH, probably either because of failed recognition by the antibody used or because their peak urinary LH concentration does not rise above the threshold set by the kit manufacturers. Serum LH measurements may be necessary to predict ovulation in such cases.

Basal Body Temperature The least expensive method of confirming ovulation is for the patient to record her temperature each morning on a basal body temperature (BBT) chart. The oral or rectal temperature should be determined before the patient arises, eats, or drinks. Smoking is forbidden before temperature measurement, and irregular sleep patterns can interfere with the test results. Patients monitoring BBT record their temperature daily but also record times when coitus occurs. Use of a BBT is preferred to use of a conventional thermometer because of the BBT instrument's precision in the temperature range under consideration. The principle behind temperature charting as a means to document ovulation is simple. Significant progesterone secretion by the ovary generally occurs only after ovulation has occurred. The increase in progesterone levels is associated with a temperature increase of about 0.5°F over the baseline temperature of 97° to 98.8°F typically recorded during the follicular phase of the menstrual cycle. Charting of daily BBTs produces a characteristic biphasic pattern in women with ovulatory cycles. Frequently, a nadir in charted BBT is noted at the time of the LH surge, but this finding is inconsistent. A normal luteal phase is characterized by a documented temperature elevation lasting at least 10 days.

BBT charting for documentation of ovulation, although simple, has several drawbacks. Presumptive ovulation can be identified only retrospectively (i.e., the test merely confirms rather than predicts ovulation). Even retrospectively, the exact time of ovulation is difficult to determine using BBTs, although in most instances, it is probably 1 day before documented temperature elevation. An unequivocal temperature rise generally occurs 2 days after the LH surge and correlates with serum progesterone levels of 0.4 ng/mL (162). Also, in a small percentage of patients, BBT charts are monophasic, despite the documentation of ovulation by other methods. Further, BBT charting is correlated with transvaginal ultrasound evidence of ovulation in only 30.4% of cases (161). Despite its limitations, for many patients, BBT charting is a simple way to document ovulation, and unequivocal biphasic cycles are almost certainly ovulatory. Patients with monophasic cycles require confirmation of ovulation using alternative methods.

Midluteal Serum Progesterone Elevations in serum levels of progesterone constitute indirect evidence of ovulation. When used to document ovulation, serum progesterone measurement should coincide with peak progesterone secretion in the midluteal phase (typically on days 21 to 23 of an ideal 28-day cycle). The lower limit of progesterone levels in the luteal phase varies among laboratories, but a level above 3 ng/mL (10 mmol/L) typically confirms ovulation. However, an appropriate interpretation of isolated luteal-phase measurements of serum progesterone is complicated by the frequent pulses that characterize the secretion of this hormone (163). Although ovulatory levels are often considerably higher than 3 ng/mL, low midluteal serum levels of progesterone are not necessarily diagnostic of anovulation.
Ultrasound Monitoring Ovulation can also be documented by monitoring the development of a dominant follicle by ultrasound until ovulation takes place. Ovulation is characterized both by a decrease in the size of a monitored ovarian follicle and by the appearance of fluid in the cul-de-sac (164). It most often occurs when follicular size reaches about 21 to 23 mm, although it may occur with follicles as small as 17 mm or as large as 29 mm (165,166). Because of the inconvenience and expense of serial measurements, routine use of ultrasound for documenting ovulation is discouraged. Instead, it is recommended that its use be confined to the monitoring of ovulation induction.

Follow-Up Tests If tests confirm that a patient is anovulatory or oligoovulatory, then diagnoses such as hypothalamic–pituitary disorder, hypothryoidism, anorexia nervosa, polycystic ovarian syndrome (PCOS), or ovarian failure need to be considered. In addition to history and physical examination, the basic investigations typically used to assess further these potential diagnoses include serum FSH, prolactin, and thyroid-stimulating hormone (TSH) testing. These three investigations are often sufficient to guide the initial management plan.

Polycystic Ovarian Syndrome PCOS is the most common cause of oligoovulation and anovulation—both in the general population and among women presenting with infertility. The diagnosis of PCOS is determined by a history of oligoovulation or anovulation in conjunction with physical evidence of hyperandrogenism. The exclusion of pregnancy (prior to pregnancy diagnostic ovarian hyperstimulation syndrome [OHSS]) and multiple pregnancies. In contrast, superovulation is indicated for the treatment of women with unexplained infertility who have been unable to conceive despite regular, monthly ovulation. The explicit goal of superovulation is to cause more than one egg to be ovulated, thereby increasing the probability of conception.

Ovulation induction can be achieved either medically or surgically in women with PCOS. There is no fixed protocol on how to approach ovulation induction in these patients, although there exists a reasonable tendency to progress from the least to the most invasive therapies. Appropriate patient selection for various therapies can be a significant determinant of successful ovulation induction among PCOS patients.

Regardless of which treatment is employed, one important concept to convey to couples is that pregnancy has a 35% to 60% incidence of multiple follicular recruitments (1). Discrepancies between ovulatory rates and conception rates are most likely associated with the number of cycles attempted or are secondary to the presence of additional, nonovulatory infertility factors among treated women. Most pregnancies resulting from induction of ovulation with clomiphene citrate occur during the first 6 months of therapy (180). Significant improvement in these parameters, which are thought to play a role in the pathogenesis of PCOS, helps restore spontaneous ovulation in many patients. In a study of 67 overweight women who had a mean weight loss of 10.2 kg/m², spontaneous ovulation and pregnancy occurred in 90% and 30%, respectively (169). Obese patients are at increased risk for medical conditions such as diabetes, hypertension, and cardiovascular disease. Because obesity also is a risk factor for obstetric complications, there should be tremendous incentive for the infertile patient to reduce weight (170). As with any other lifestyle change, promotion of weight loss can be difficult and frustrating for both patient and practitioner. Weight loss often requires multidisciplinary efforts, including the involvement of an experienced dietitian and promotion of an effective exercise program. Many women may be discouraged by the time it takes to reduce their weight and the uncertainty of successful weight reduction; thus, it is reasonable to pursue medical options in parallel with lifestyle changes.

Clomiphene Citrate Traditionally, clomiphene citrate (Clomid, Serophene) has been the first-line intervention for medical induction of ovulation in PCOS patients. Clomiphene citrate is a weak synthetic estrogen, but it mimics the activity of an estrogen antagonist when given at typical pharmacologic doses for the induction of ovulation. A functional hypothalamic–pituitary–ovarian axis is required for appropriate clomiphene citrate activity. More specifically, clomiphene citrate is thought to bind and block estrogen receptors in the hypothalamus for prolonged periods, thereby decreasing the normal ovarian–hypothalamic estrogen feedback loop (171). This blockade increases GnRH pulse amplitude in some anovulatory women (172). Increases in GnRH then feed forward to cause increased gonadotropin secretion by the pituitary, promoting ovarian follicular development. Clomiphene citrate also may affect ovulation through direct action on the pituitary (173) or the ovary (174,175). Unfortunately, the antidepressant effects of clomiphene citrate at the level of the endometrium (176) or the cervix (177) may have adverse effects on fertility in a minority of individuals (178,179).

Use of clomiphene citrate for ovulation induction is generally associated with excellent outcomes. In fact, in some populations, 80% to 85% of treated women will ovulate and 40% will conceive (180,181). Discrepancies between ovulatory rates and conception rates are most likely associated with the number of cycles attempted or are secondary to the presence of additional, nonovulatory infertility factors among treated women. Most pregnancies resulting from induction of ovulation with clomiphene citrate occur during the first 6 months of therapy (180). Side effects of clomiphene citrate therapy include infrequent OHSS, vasomotor flushes, nausea, pelvic discomfort, and breast pain (173). In the absence of visual abnormalities, clomiphene citrate should be promptly discontinued. Use of clomiphene citrate is associated with a 35% to 60% incidence of multiple follicular recruitments (182); however, the incidence of multiple gestation with this agent is only about 5% to 8%. Most of these multiple gestations are twin pregnancies; triplet pregnancies occur infrequently. Rates of spontaneous abortion and teratogenicity in humans are not increased with the use of clomiphene citrate (183).

Clomiphene citrate is typically used for ovulation induction in the following manner:

1. The drug is supplied in 50-mg tablets; the usual starting dosage is 50 mg/d. Therapy is typically begun on the fifth day after the onset of a spontaneous or progestosterone-induced menses and is continued through day 9 of the menstrual cycle. Treatment on days 2 to 6 after onset of menses has also been advocated (184). Some patients respond to a dosage as low as 25 mg/d.

2. Ovulation should be documented using a home urine LH kit. This information is valuable for future therapeutic planning because failure to conceive despite successful ovulation has different implications than failure to conceive because of failed ovulation induction. If ovulation does not occur at the initial dosage of clomiphene citrate, the dosage is increased in each subsequent cycle by 50 mg/d. The U.S. Food and Drug Administration recommends a maximum dosage of 100 mg/d; however, in patients who ovulate as a result of clomiphene citrate treatment, 11.8% do so only at doses of 150 mg/d or more (180). Considerable clinical experience with clomiphene citrate indicates that a dosage of up to 250 mg/d is safe.

3. Ovulation is expected to occur 5 to 10 days after the last day of therapy; thus, with standard clomiphene citrate regimens, ovulation testing should begin on day 12 or 13 and continued daily until results are positive. Once a pattern is established, ovulation testing can be confined to a 5-day period in subsequent months. intercourse every other day for 1 week beginning a day or two before anticipated ovulation is recommended. Alternatively, daily intercourse for 3 days beginning on day 12 or 13 after the last day of therapy is also reasonable. maximal chance of a pregnancy (e.g., 173).

4. If ovulation is not induced despite the use of increasing amounts of clomiphene citrate, ultrasound can be used to monitor follicular development during the treatment cycle. If a dominant follicle develops, but there is no spontaneous LH surge, hCG (10,000 units given intramuscularly) can be used for final follicular maturation/ovulation, followed by timed intercourse or IUI. The number of clomiphene citrate–treated and ovulatory cycles should not exceed six cycles because the maximum cumulative fertility rate has been achieved by that point, and further treatment with clomiphene citrate would have minimal predicted benefit.
Despite the high therapeutic success rates of clomiphene citrate in most anovulatory women, treatment has relatively low success in inducing ovulation in women with PCOS and insulin resistance, in whom obesity or elevated BMI also is evident. Before initiating therapeutic changes in such women, differential diagnoses should be reviewed and endocrinologic investigations repeated if necessary. Dexamethasone, 0.5 mg/d at bed time, combined with typical clomiphene citrate regimens may induce ovulation in patients who have elevated serum dihydroepiandrosterone sulfate (DHEAS) (185). At this low dosage, dexamethasone therapy is associated with minimal adverse effects. Alternatively, there is now increasing evidence that insulin sensitizers are particularly effective in inducing ovulation in PCOS women with insulin resistance.

**Insulin Sensitizers** PCOS is currently viewed as a disease that can result from different genetic causes with possible modification by environmental factors (186). Insulin resistance is thought to play a central role in the pathogenesis of PCOS in the subset of patients characterized by increased BMI, hyperandrogenemia, and significant hyperandrogenism (Table 27.5[188]). It is also thought that a different form of insulin resistance intrinsic to PCOS is part of the underlying disease mechanism in thin women with PCOS (187,188). Metformin and troglitazone are the best-studied of the insulin sensitizers used for ovulation induction.

**Table 27.5. Clinical Findings That Suggest Insulin Resistance and Hyperinsulinemia**

Metformin is an oral biguanide that is approved for the treatment of non-insulin-dependent diabetes. Metformin acts by several mechanisms, including inhibition of gluconeogenesis in the liver and an increase in the uptake of glucose in the periphery (189). When women with PCOS, hyperandrogenism, and hyperinsulinemia are treated with metformin for 12 weeks, their fasting insulin and total testosterone levels, free testosterone index, BMI, waist-to-hip ratio, hirsutism, and acne all decrease significantly (190). Moreover, among women who have PCOS, a BMI greater than 26 kg/m², and hyperandrogenemia, 89% ovulate after treatment with a combination of metformin and clomiphene citrate. This rate is significantly higher than the 12% of patients who ovulated using combined treatment with placebo and clomiphene citrate (191). Although metformin alone has also been reported to induce spontaneous ovulation, this monotherapy has not been compared with metformin plus clomiphene citrate or placebo in a prospective, randomized trial (187). Similarly, troglitazone, an insulin sensitizer under the category of thiazolidinediones, has beneficial effects on plasma androgen and fasting insulin levels, and increases the rate of spontaneous ovulation in obese women with hyperandrogenemia and insulin resistance, even in the absence of weight loss (192,193). Troglitazone, however, has recently been withdrawn from the market because it carries a 1 in 50,000 chance of fatal liver failure. In contrast, metformin has an excellent safety profile. Gastrointestinal complaints are its most common side effects, although isolated cases of fatal lactic acidosis have been reported in patients with underlying renal compromise. Metformin is typically discontinued once pregnancy has been established; however, it is a category B drug and its administration during pregnancy is not known to confer specific risk to the fetus. Two new insulin sensitizers have recently been approved for treatment of diabetes: rosiglitazone and pioglitazone. The safety and efficacy of these medications has not yet been assessed for use in ovulation induction.

**A typical treatment regimen using metformin with or without clomiphene citrate for ovulation induction in PCOS patients follows (187):**

1. Select PCOS patients. Failure of ovulation induction with clomiphene citrate alone is an indication but not a requirement for the use of metformin.
2. Confirm normal liver and renal function (serum creatinine <1.4 mg/dL). Serum hCG testing to exclude pregnancy, followed by a progestin withdrawal–induced menses, can be undertaken if indicated.
3. Start metformin therapy as follows:
   - **Metformin, 500 mg once a day with breakfast for 4 days**
   - **Metformin, 500 mg twice a day with breakfast and dinner for 4 days**
   - **Metformin, 500 mg with breakfast and 1,000 mg with dinner for 4 days**
4. Thereafter, **give metformin, 1,000 mg twice a day (at breakfast and dinner)**.
5. If a trial of metformin alone is chosen, evaluate single serum progesterone levels weekly to detect the occurrence of ovulation. It may take up to 2 months of therapy before spontaneous ovulation occurs.
6. If metformin plus clomiphene citrate is the desired regimen, **add clomiphene citrate at the usual starting dosage of 50 to 100 mg once a day from days 5 to 9 when the full dose of metformin has been reached, and if spontaneous ovulation has not occurred. Home LH detection kits can then be used to predict ovulation and time intercourse.**
7. **Clomiphene citrate can be increased incrementally by 50 mg once a day in subsequent cycles if ovulation still does not occur. Once ovulation occurs, the ovulatory dosage of clomiphene citrate can be used in combination with metformin for up to 3 to 6 cycles (in conjunction with ovulation detection and timed intercourse or inseminations).**

Metformin is usually discontinued once pregnancy is confirmed. It has been suggested that continuation of metformin in early pregnancy may decrease the risk for spontaneous abortion in PCOS patients (194). At present, this finding needs to be confirmed by a prospective, randomized trial before being widely accepted. If the combination of metformin and clomiphene citrate fails to induce ovulation, the diagnosis should be reviewed. Other treatment options, including gonadotropin therapy (see section on Gonadotropin Therapy and surgical ovarian diathermy, may be considered.

**Surgical Treatment** Pathophysiologic changes in the polycystic ovary have been the subject of many years of intense investigation. As early as 1935, with the initial description of the syndrome, ovarian surgical treatment of PCOS was considered (195). Initial surgical management of PCOS involved wedge resection of the ovaries in an effort to reduce the volume of androgen-producing tissue and thereby alleviate hyperandrogenic abnormalities. In fact, ovarian wedge resection does decrease circulating levels of testosterone (196), and this therapy is associated with resumption of menses in 91% of treated PCOS patients (197). Unfortunately, many patients treated with ovarian wedge resection suffer from postoperative intrauterine adhesions, often leading to iatrogenic tubal factor infertility (197,198).

Laparoscopic techniques aimed at treating PCOS appear to be associated with less adhesion formation in the pelvis than noted after ovarian wedge resection by laparotomy (199,200), while maintaining similar improvements in hormonal profiles (201,202). Compared with controls, patients undergoing laparoscopic ovarian diathermy or ovarian drilling have higher rates of subsequent ovulation and lower resistance to standard ovulation induction agents (203,204). In further support of this concept, 112 women with PCOS and anovulatory infertility in whom previous ovulation induction attempts using clomiphene citrate (up to 200 mg once a day) were unsuccessful were treated with laparoscopic ovarian diathermy. This surgical therapy resulted in a significant decrease in serum levels of LH, testosterone, DHEAS, androstenedione and in the LH-to-FSH ratio (205). Further, 73% of these patients ovulated spontaneously, 24% ovulated with clomiphene citrate therapy, and 1.8% ovulated only with gonadotropin use. The cumulative probabilities of pregnancy were 54%, 68%, and 82% at 12, 18, and 24 months of follow-up, respectively. The median time to conception was 10.2 months. Thus, laparoscopic ovarian diathermy may have particular application in ovulation induction among PCOS patients who are resistant to treatment with clomiphene citrate.

Laparoscopic ovarian diathermy appears to have an effect on IVF outcomes as well. In a prospective trial comparing IVF outcomes in PCOS patients with and without prior surgical intervention, both a higher ongoing pregnancy rate and lower peak estradiol levels were documented in PCOS patients with prior laparoscopic ovarian diathermy (206). If one interprets these results as an indication that laparoscopic ovarian diathermy favorably alters the response of PCOS patients to COH with gonadotropin therapy, then its effect on reducing the risk for OHSS among PCOS patients treated with these medications certainly warrants further investigation. It is of interest that laparoscopic ovarian diathermy has been linked to a decrease in the elevated rates of spontaneous abortions documented in PCOS patients (205,206).
A variety of techniques have been described for laparoscopic destruction of ovarian tissue in the treatment of PCOS, including the use of laser, unipolar cautery, and bipolar cautery. Although no single technique has been proved superior using randomized studies, recent reports have advocated diathermy by electrocautery (205,206 and 207). In this technique, the ovary is immobilized, and an insulated needle is inserted into the ovary in a direction perpendicular to the ovarian surface using a short duration of cutting current at 100 W. Coagulating current at 40 W is then applied for about 2 seconds. The needle is withdrawn, and the process is repeated at up to 15 puncture sites per ovary. At the end of the procedure, the ovaries are lavaged with copious amounts of normal saline (205).

In addition to the usual risks associated with laparoscopic surgery, laparoscopic ovarian diathermy involves the rare but potential risk for surgically induced premature ovarian menopause via inadvertent disruption of ovarian vascular supply. More common, however, is the possible formation of adnexal adhesions, which may further compromise fertility. In one study, 19% of the patients who had second-look laparoscopy after laparoscopic ovarian diathermy had adhesions (206). In a series of 112 PCOS patients reported (205), filmy adhesions confined to the ovarian surface were reported in 4 of 15 women who had not conceived at 1 year and who underwent second-look laparoscopy. At present, the impact of postsurgical adhesion formation on subsequent fertility and defined indications for use of second-look laparoscopy in treated patients remains undetermined.

**Gonadotropin Therapy for PCOS Patients**

Anovulatory PCOS patients who fail to ovulate or conceive after surgery or medical treatment with metformin and clomiphene citrate should be considered for induction with gonadotropin therapy (with or without GnRH agonist downregulation). A complete protocol is described in the section on Gonadotropin Therapy. This treatment involves daily injection of gonadotropins and close monitoring using serum estradiol measurements and transvaginal ultrasound monitoring of follicular development. IUI is often recommended in conjunction with ovulation induction to optimize the chances of pregnancy using this intense treatment. It is important to remember that PCOS patients tend to have a high number of small antral follicles in the unstimulated state. Theoretically, the potential for stimulation of an endogenous gonadotropin therapy. This effect could be potentially problematic because the goal of gonadotropin therapy in these patients, unlike that in ovulatory patients with unexplained infertility, is not to produce many eggs but rather to induce the release of only 1 or 2 oocytes. Treatment should therefore be monitored by an experienced physician because the risks for OHSS and multiple gestation are significantly increased when using gonadotropins in this patient population.

**Ovulation Induction for Other Anovulatory Disorders**

**Hyperprolactinemia**

Hyperprolactinemia can be associated with ovulatory factor infertility. After exclusion of a pituitary macroadenoma or other intracranial pathology, correction of the hyperprolactinemic state with bromocriptine is followed by restoration of ovulation in 90% of patients (208). Cabergoline has similarly high efficacy, but it has the advantage of a twice-weekly dosing schedule. More controversial is the use of bromocriptine alone or the addition of clomiphene to clomiphene citrate therapy in patients with normal or minimally elevated serum prolactin levels. Such therapy has, however, been associated with improved pregnancy rates among normoprolactinemic women with unexplained infertility and galactorrhea (209).

**Hypogonadotropic Hypogonadism**

Anovulation in the presence of low serum LH, FSH, and estradiol levels defines hypogonadotropic hypogonadism and reflects dysfunction within the hypothalamic–pituitary–secretory axis. Causes of hypogonadotropic hypogonadism, including craniopharyngiomas, pituitary adenomas, arteriovenous malformations, or other central space-occupying lesions, should be excluded using magnetic resonance imaging.

There is now increasing evidence for genetic and physiologic mechanisms linking the regulation of body fat content, caloric intake, and hypothalamic control of reproduction. For instance, leptin and its receptor have recently been demonstrated to have critical functions in body mass regulation, glucose homeostasis, and reproductive function at the hypothalamic level. Among other characteristic metabolic abnormalities, gene-targeted mice lacking leptin or leptin receptor were infertile secondary to hypogonadotropic hypogonadism (210). Homozygous mutation in the human leptin receptor gene also has been identified. In humans, abnormalities in leptin receptor function lead to early-onset morbid obesity and absent pubertal development, presumably secondary to defective hypothalamic function (210).

Low BMI also can cause anovulation and infertility in women, possibly by disrupting hypothalamic function (211). Examples of conditions characterized by low BMI include anorexia nervosa, professional athletic training, and malnutrition. In most men with these conditions, weight gain is the ideal treatment for ovulatory dysfunction, avoiding the use of ovulatory stimulatory medications and their complications. Other health benefits, including the reduction of complications from polycystic ovary syndrome, can result from the treatment. In one study, increased calorie intake and weight gain in the resumption of menses in 90% patients with amenorrhea related to low BMI; 73% had spontaneous conception (212). In another study, a mean weight gain of 3.6 kg was sufficient to promote the resumption of spontaneous ovulation (213).

Other conditions of hypothalamic dysfunction, such as congenital hypothalamic failure (Kallmann’s syndrome), can be treated using pulsatile GnRH therapy if the pituitary–ovarian axis is intact. Gonadotropin therapy should be chosen for patients in whom pituitary dysfunction is present, such as those with empty sella syndrome. Each of these treatment modalities is discussed in greater detail under Gonadotropin Therapy.

**Hyponothyroidism**

The prevalence of abnormal TSH levels in the general infertility population has been reported to be 6.3%, 4.8%, 2.6%, and 1.5% for women from couples diagnosed with anovulatory infertility, unexplained infertility, tubal infertility, and male infertility, respectively (214). This diagnosis is significant in the management of infertility. For instance, one study reported that among 171 women with hyponothyroidism, 23% had irregular menses, likely resulting from anovulation (215). Spontaneous ovulatory cycles typically resume when euthyroid status is achieved using thyroxine supplementation.

In contrast to the causal relationship between hyponothyroidism and anovulation, the association between hyperthyroidism or thyroid antibodies and spontaneous abortion is still unclear. Although hyperthyroidism has been associated with increased fetal wastage in some studies (216,217), thyroid antibody status was not associated with decreased fecundity rates or decreased pregnancy loss in women with unexplained infertility or with current or prior miscarriage (218). Others, however, have reported conflicting results, indicating that thyroid antibodies occur at a higher than average frequency in women with recurrent pregnancy loss, but not among women undergoing ART for infertility (219,220).

**Tubal, Paratubal, and Peritoneal Factors**

Tubal and peritoneal factors account for 30% to 40% of cases of female infertility. Tubal factors include damage or obstruction of the fallopian tubes and are usually associated with previous PID or previous pelvic or tubal surgery. Peritoneal factors include peritubal and periovarian adhesions, which generally result from PID, surgery, or endometriosis. The risk for infertility after a single bout of PID is surprisingly high and increases rapidly with subsequent episodes. In fact, the incidence of tubal infertility has been reported to be 12%, 23%, and 54% after one, two, and three episodes of PID, respectively (222). Still, about half of patients with documented tubal damage have no identifiable risk factors for tubal disease (223). Most of these women are presumed to have had subclinical chlamydial infections.

**Hysterosalpingography**

HSG is the initial diagnostic test used to assess tubal patency because it has a sensitivity of 85% to 100% in identifying tubal occlusion. The particular specificity of HSG in identifying PID-related tubal occlusion approaches 90% (224,225). Other causes of apparent tubal blockage include salpingitis, isthmica nodosa, benign polyps within the tubal lumen, endometriosis, tubal spasm, and intratubal mucous debris (226). Bilateral tubal pathology documented on HSG is associated with significantly reduced fecundity rates and warrants further evaluation using falloscopy, selective salpingography, or laparoscopy.

HSG is usually performed between cycle days 6 and 11. To reduce the chance of intrauterine infection, HSG should ideally follow the cessation of menstrual flow; to avoid infection and interference with resumption of ovulation, HSG should precede ovulation. It is estimated that infection follows 1% to 3% of HSG procedures and occurs almost exclusively in women with hydrosalpinges or with current or prior pelvic infection. Therefore, known hydrosalpinges, current PID or cervicitis, and palpable adnexal masses or tenderness on bimanual examination all constitute contraindications to HSG. Because there is a high prevalence of current or past chlamydial infection among infertile women and complications of HSG-associated pelvic infection could further compromise fertility, it is reasonable to prescribe antibiotic prophylaxis to patients scheduled for HSG. One typical regimen uses doxycycline 100 mg twice daily, beginning the day before HSG and continuing for 3 to 5 days. Other rare complications of HSG include uterine perforation, hemorrhage, and allergic reaction to the contrast dye. HSG often causes uterine cramping, and prophylaxis with a nonsteroidal antiinflammatory drug may minimize this discomfort.

Performing the HSG procedure itself is fairly straightforward. After a bimanual examination and vaginal cleansing, an acorn (Jarcho) cannula, a pediatric Foley catheter, or some other injection device is introduced into the uterine cervix. A paracervical anesthetic block is not routinely needed but may be used in selected patients. Either a water-soluble contrast medium, such as meglumine diatrizoate (Renografin-60), or a low-viscosity oil-based dye, such as ethiodized oil (Ethiodol), may be used for the procedure. Each contrast material has advantages. Water-soluble contrast material is more rapidly absorbed than oil-based dyes and does not
carry the risk for either lipid embolism due to dye extravasation or lipid granuloma formation. Oil-based dyes are associated with less uterine cramping, better resolution of tubal architecture, and a higher postprocedure pregnancy rate (227). A recent update of a 1994 metaanalysis has found that the use of oil-soluble media to flush the tubes during HSG significantly increases subsequent pregnancy rates (OR, 1.8; 95% CI, 1.29 to 2.50). Similar therapeutic benefit has not been demonstrated using water-soluble contrast media (228).

HSG should be performed using fluoroscopy, with care taken to minimize ovarian exposure to x-rays. Careful and slow initial injection of 3 to 4 mL of contrast media should give a clear outline of the uterine cavity. Further injection of about 5 to 10 mL of contrast media is usually sufficient to demonstrate bilateral tubal patency or tubal obstruction. Generally, only two radiographic views are needed, one demonstrating the filling of the uterine cavity and the other (at the completion of the procedure) showing tubal findings. The radiation exposure required for the completion of an HSG examination has been shown to be well below the documented limiting ovarian dose of 10 Gy (229).

**Laparoscopy**

The best technique for diagnosing tubal and peritoneal disease is laparoscopy. It allows visualization of all pelvic organs and permits detection of intramural and subserosal uterine fibroids, peritubal and periadnexal adhesions, and endometriosis. Abnormal findings on HSG can be verified by direct visualization of laparoscopy. For instance, tubal patency may be confirmed at laparoscopy by observation of the passage of a dye, such as methylene blue or indigo carmine, through the fimbrial openings of the tubes. Unlike HSG, laparoscopy allows careful assessment of the external architecture of the tubes and, in particular, visualization of the fimbria. Identified abnormalities, including tubal obstruction, pelvic adhesions, and endometriosis, can be treated laparoscopically at the time of diagnosis.

**Laparoscopic Sterilization**

Successful evaluation of proximal tubal obstruction using selective salpingography and falloposcopy has been described. Based on techniques derived from coronary angioplasty, salpingography uses small guidewires to permit selective tubal cannulation and radiographic visualization under fluoroscopic guidance. This has allowed direct fibropic visualization of tubal ostia and intraluminal architecture. Falloposcopy allows the visual identification of tubal ostial spasm, abnormal tubal mucosal patterns, and even intraluminal debris causing tubal obstruction. In fact, a tubal disease scoring system based on falloposcopy examination has been suggested to identify patients with poor prognoses for spontaneous conception (230). Complications associated with falloposcopy include a 5.1% rate of pinpoint perforations of the tube.

Abdominal and transvaginal, ultrasound-guided tubal catheterizations have also been used to identify tubal blockage. Each reports high diagnostic sensitivity and specificity. Alternatively, sonohysterography with contrast media offers a much less invasive method of diagnosing fallopian tubal obstruction while maintaining a sensitivity of 82% and specificity of 89% (231). Further prospective evaluation and cost analyses are necessary to determine the utility of tubal catheterization and sonohysterography with contrast media.

**Treatment of Tubal Factor Infertility**

Therapies that directly address correcting tubal factor infertility are entirely surgical and include (a) correction of periadnexal disease; (b) correction of proximal, distal, or combined tubal disease; and (c) correction of iatrogenic tubal abnormalities (e.g., tubal sterilization). As success rates continue to improve in ART, the indications for surgical approaches in the treatment of tubal factor infertility may become increasingly limited. Still, a number of the principles underlying surgical management remain important. Surgical treatment of periadnexal disease causing tubal factor infertility has been proved effective, regardless of whether the approach is by laparotomy (232) or laparoscopy (233). Adhesion prevention, however, becomes particularly vital when surgery is used to address prior adhesive disease causing infertility. The relative value of laparotomy versus laparoscopy for the treatment of tubal infertility has received considerable attention, as have their respective effects on postoperative adhesion formation. For example, one study comparing laparoscopy and laparotomy for the treatment of ectopic pregnancy demonstrated that adhesion formation occurred more frequently after laparotomy, even when meticulous technique was maintained during all procedures (234). Many adjuncts for postoperative adhesion prevention have been proposed, including the use of antiinflammatory agents, barrier agents, fibrinolytic substances, and anticoagulants. However, none of these interventions has consistently altered postoperative adhesive complications. Thus, careful hemostatic surgical technique and judicious use of the laparoscopic approach remain the only generally recommended principles guiding surgical treatment of tubal factor infertility.

**Proximal Tubal Occlusion**

Correction of proximal tubal occlusion may involve the use of those same techniques employed in establishing its diagnosis. For instance, selective salpingography performed under fluoroscopy may be used to inject contrast media directly into the tubal lumen in an attempt to overcome obstruction resulting from periadnexal disease. If selective salpingography fails to create tubal patency, proximal tubal cannulation can be performed using a guidewire under direct visualization or using radiologic guidance. Proximal tubal cannulation has reported a success rate of 85% in establishing tubal patency. Recurrence occurs in 30% of cases. The risk for tubal perforation with cannulation is reported to be 3% to 11%, but tubal damage is usually mild and heals spontaneously (226).

Until the mid-1970s, tubal sterilization was considered the best approach for treating proximal tubal obstruction. Since that time, microsurgical tubocornual anastomosis has become the preferred surgical approach, with post-surgical ongoing pregnancy rates averaging 47.4% in five reported series involving 175 patients (226,236,236,237 and 238). Hysteroscopic cannulation appears to have similar efficacy, with a 48.9% ongoing pregnancy rate among 133 patients treated for four sensitivity and specificity of 82% and 95% (239). Although ongoing pregnancy rates with microsurgical tubocornual anastomosis and hysteroscopic cannulation appear comparable, the delivery rate is generally less invasive and has fewer morbidity complications. Microsurgery, however, provides access to other pelvic structures, allowing the surgeon to assess the distal fimbrae and to lyse any periadnexal adhesions that may be present. In contrast to both microsurgical anastomosis and hysteroscopic cannulation, the ongoing pregnancy rates for selective salpingography and fluoroscopic tubal cannulation have averaged only 26% (226,243,244,245,246,247,248).

**Distal Tubal Occlusion**

Treatment of distal tubal disease involves surgical correction by fimbrioplasty or neosalpingostomy. By definition, fimbrioplasty is the lysis of fimbrial adhesions or the dilation of fimbrial phimosis, whereas neosalpingostomy involves the creation of a new tubal opening in an occluded fallopian tube (249). Distal tubal disease is usually treated either laparoscopically or by laparotomy using conventional microsurgical techniques. Regardless of the method used, the efficacy of neosalpingostomy or fimbrioplasty as treatment for distal tubal disease, as assessed by HSG and laparoscopy, Poor prognostic factors for a successful pregnancy after neosalpingostomy include hydrosalpinx greater than 30 mm in diameter, absence of visible fimbrae, and dense pelvic or adnexal adhesions (249). The appearance of the tubal mucosa has added prognostic significance for the fertility outcome of laparoscopic tuboplasty for distal tubal occlusion (250). In one study, laparoscopic distal tuboplasty produced an overall pregnancy rate of 27% and an ectopic pregnancy rate of 4.5% among 44 patients (251). Fimbrioplasty appeared to be more successful than neosalpingostomy; however, the choice of surgery might have been influenced by the extent of disease. Similarly, a more recent study on a series of 194 cases of laparoscopic fimbrioplasty and neosalpingostomy resulted in an intrauterine pregnancy rate of 27.3% and an ectopic pregnancy rate of 4.1% (252). Patients with both proximal and distal tubal disease represent the poorest candidates for surgical management of tubal infertility. Studies of surgical treatment for these patients have had small numbers of patients but have consistently yielded poor results (253). This select group of patients should benefit most from IVF.

**Sterilization Reversal**

About 0.2% of women who choose surgical tubal sterilization request reversal procedures (254,255). The success of tubal reanastomosis is dependent on the method of sterilization, the site of anastomosis, and the presence of other infertility factors. Pregnancy rates are lowest (49%) after the reversal of sterilization procedures involving unipolar electrocautery. In contrast, postprocedure pregnancy rates rose to 67% when the sterilization technique involved Fallope rings or spring-loaded clips and 75% when Pomeroy tubal ligation was employed. The prognosis is best when anastomotic sites have no significant differences in tubal diameter (e.g., isthmic-isthmic or cornual–isthmic anastomoses). Tubal length is also an important prognostic consideration: final anastomosed tubal lengths of less than 4 cm are associated with low pregnancy rates (256). Pregnancy rates higher than 40% have been reported after microsurgical fimbriectomy correction (257). Falloposcopy to assess surgical prognostic factors such as potential final tubal length, site of reanastomosis, method of sterilization (if not previously known), and presence of associated pelvic pathology, is often performed before microsurgical fallopian tubal reanastomosis by laparotomy.

Historically, all sterilization reversal procedures have involved laparotomy. More recently, excellent pregnancy rates have been reported after laparoscopic tubal anastomosis. In one study of 186 patients followed after laparoscopic tubal anastomosis with a two-layer closure, cumulative pregnancy postprocedure rates were 60.3%, 79.4%, and 83.3% at 6, 12, and 18 months, respectively (255). In another study, laparoscopic tubal reanastomosis was performed on 102 women, of whom 70% conceived and 65% had ongoing intrauterine pregnancies during the 15-month follow-up period (259). Rates of ectopic pregnancy were similar (3% and 7%) in both series (258,259). The surgical time of laparoscopic tubal reanastomosis most certainly depended on the surgeon’s experience as well as the number of layers involved in tubal closure. Reported operative duration ranged from 71.35 minutes to 140.2 minutes, ±53.3 minutes (258,259).

Recently, successful robotic-assisted laparoscopic microsurgical tubal anastomosis has been reported in humans. The reported procedures had a mean duration of 159 ± 33.8 minutes and were performed solely using robotic arms that were remotely controlled by surgeons with previous extensive experience with microsurgical tubal anastomosis. The reported success rates of tubal reanastomosis at the completion of the procedure, at 6 to 8 weeks, and then ongoing pregnancy rates have been 54% (229). This allows the advances in surgical technology, however, IVF should be considered for patients with prior sterilization and poor prognostic characteristics. Likewise, IVF is indicated.
Cervical and Immunologic Factors

Postcoital Test Cervical factor is a cause of infertility in no more than 5% of infertile couples. The classic test for evaluation of the potential role of cervical factor in infertility is the postcoital test (PCT). The PCT is designed to assess the quality of cervical mucus, the presence and number of motile sperm in the female reproducive tract after coitus, and the interaction between cervical mucus and sperm. The PCT does not yield sufficient information on sperm and, most importantly, morphology to allow assessment of semen quality. The PCT should be performed just before ovulation because its proper interpretation requires the examination of cervical mucus at a time of sufficient estrogen exposure. Serum estrogen levels peak just before ovulation, providing optimal stimulation to the estrogen-sensitive, mucus-producing cervical glands. Therefore, the PCT should be performed 1 or 2 days before the anticipated time of ovulation. For patients with irregular cycles, the patient's urinary LH surge may be helpful in scheduling the test.

Use and interpretation of treatment recommendations based on the PCT are all controversial. Even the appropriate timing of coitus preceding examination of the cervical mucus is unclear. Although an optimal interval may be 2 hours from intercourse to PCT, an adequate test can be performed within 24 hours of intercourse. Although the data are not definitive, intercourse after 2 days of abstinence and about 2 to 12 hours before the PCT is performed should yield adequate information. Couples should be reminded not to use lubricants that may contain spermicidal agents.

The PCT is inexpensive and easily performed. A small amount of cervical mucus is withdrawn by means of long oval forceps with small apertures at the tip. Alternatively, an angiocatheter syringe or tuberculin syringe may be used to withdraw mucus from the endocervical canal. The mucus is placed on a glass slide and covered with a cover slip. A small trail of mucus may be left to dry outside the cover slip so that grieving can be assessed. Many infertility specialists also take a "vaginal pool" specimen from the posterior vaginal fornix to document the presence of sperm in the vagina. Cervical mucus is rapidly evaluated for spinnbarkeit (i.e., stretchability), ferning, and clarity. The presence of, number per high-power field, and motility of sperm should be carefully assessed by the examination of several microscopic fields.

Normal estrogen-stimulated mucus should stretch 8 to 10 cm when it is pulled from the cervix with forceps or when the cover slip is lifted off the slide, should demonstrate a highly characteristic ferning pattern similar to that seen on examination of amniotic fluid, and should be clear and watery. The characteristics of cervical mucus change under the influence of progesterone after ovulation. At that time, the cervical mucus appears thick and opaque and lacks ferning. Although the number of motile sperm per high-power field should be documented, normal values have not been established. Some authors suggest that virtually any number of motile sperm seen on the PCT is normal (261), whereas others require greater than 20 sperm per high-power field (262).

There are several potential causes for an abnormal PCT. The most common is incorrect timing of the test within the menstrual cycle, leading to the production of cervical mucus optimal for sperm survival and motility (e.g., prior cervical conization or cryotherapy). Infection, and certain medications. Cervix citrate may exert detrimental effects on cervical mucus by its antibacterial action on cervical glands. This is one reason why clomiphene citrate should be offered to patients with unexplained infertility only when coupled with IUI. Abnormal semen characteristics are often reflected in the PCT and may be responsible for abnormal PCT results. An independent semen analysis is required for proper assessment for male factor infertility. Poor PCT results may, of course, reflect suboptimal mucus–sperm interactions. The observation of shaking or uniformly dead sperm on PCT suggests the presence of antisperm antibodies.

Although there is plausible biologic rationale behind the PCT, this test has been accepted without critical review of its prognostic value or of its impact on the overall management plan of the subfertile couple. The PCT lacks reproducibility, standard methodology, and uniform criteria for assessment. These factors, in conjunction with poor correlation between PCT test results and pregnancy outcome, argue against use of the PCT as a standard investigational tool in infertility patients (262,263,264, and 265). For example, one study reported no difference in pregnancy outcomes among women whose cervical mucus contained 0 to 11 motile sperm per high-power field (263), whereas another reported abnormal PCTs in 20% of fertile couples (262). A review of the world's English-language literature challenged the validity of the PCT and found that the sensitivity and specificity of the test ranged from 0.09 to 0.71 and from 0.62 to 1.00, respectively (264).

Couples seeking reproductive medical intervention undergo many tests that are considered necessary, although they are costly from physical, emotional, and financial perspectives. Therefore, any test performed should have proven value in determining the prognosis or the course of treatment. Management decisions based on the PCT should affect the treatment of the infertile couple. This is not the case for the PCT, for which the results seldom alter the management of patients with unexplained infertility because the accepted treatment of superovulation/IUI bypasses the cervical mucus. In a prospective, randomized control study, couples who underwent PCT had cumulative pregnancy rates after 24 months of therapy identical to those of a control group not using PCT (266). Therefore, PCT testing has no effect on treatment outcome. Finally, although the PCT may screen for the presence of antisperm antibodies, no proven treatment is accepted for this diagnosis. PCT is therefore not indicated for this application.

Antisperm Antibodies Injection of sperm from one animal into another can elicit an antibody response (267). Spermatozoa can also be autoantigenic. Thus, both males and females have the capacity to produce humoral response to sperm. Either alloergic or autoimmune response could, in turn, adversely affect fertility. Antisperm antibodies are most commonly limited to immunoglobulin G (IgG), IgM, and IgA isotypes, and each subclass has characteristic anatomic localization. Systemically produced IgG molecules may be found in serum as well as in cervical mucus and semen. Agglutinating antibodies of the IgA class are typically found in cervical mucus and seminal plasma. The larger IgM antibodies have difficulty traversing the genital tract mucosa and therefore are found exclusively in serum. In addition to subclassification by isotype, antisperm antibodies can be free, agglutinating, bound to sperm that is motile, or bound to sperm that is immobilized. Further complexity arises in that sperm-bound antisperm antibodies can bind to different parts of the outer sperm plasma membrane, including the head, body, or tail. One major challenge in understanding antisperm antibodies is to determine the relative importance of each of these factors with respect to disease pathogenesis, impact on fertility, and prognosis.

Many etiologies have been proposed to explain the formation of antisperm antibodies (268). In women, coital trauma that disrupts the vaginal epithelium could theoretically expose immune effectors to sperm antigens, thereby leading to antisperm antibody formation. However, it remains unclear why most women, who are repeatedly exposed to billions of spermatozoa, do not exhibit this immune response. In men, the blood–testis barrier normally shields the serum from exposure to sperm and their antigens. Conditions that cause breaks in this barrier could activate autoimmunity. Testicular trauma or torsion, occlusion of the vas deferens secondary to childhood inguinal herniorrhaphy or cystic fibrosis, vasectomy reversal, and genital tract infections have all been suggested to elicit antisperm antibody formation.

The mechanisms by which antisperm antibodies might adversely affect fertility continue to be contested. Many mechanisms have been proposed. One or more of these could be involved in a particular infertile couple. Distinct mechanisms might be operative under specific circumstances. Adverse antibody-mediated effects on semen quality (either before ejaculation or upon contact of ejaculate with the female reproductive tract) present obvious potential for subfertility. Other, more specific, proposed mechanisms include antisperm antibody–mediated interference with capacitation, with the acrosome reaction, with sperm–egg recognition and fusion, and with gene expression of the early embryo (268). Although some investigators have demonstrated that the presence and amount of antisperm antibodies is associated with fertilization failure during IVF or fertilization failure during IVF or subzonal sperm insemination (269,270 and 271). We are able to identify link K for IVF or fertilization failure during IVF or subzonal sperm insemination (269,270 and 271). Myriad tests presently are available for the detection of antisperm antibodies, making the appropriate evaluation of immunologic infertility even more bewildering. Sperm agglutination tests (Kibrick's or Franklin-Dukes) and sperm complement-dependent immobilization tests (Isojoma's) have largely been replaced by the immunobead or mixed agglutination tests (Fig. 27.8). The immunobead test uses commercially available anti-IgG-, anti-IgA-, or anti-IgM–coated polycarbonate beads. Washed spermatozoa are exposed to the labeled beads, and sperm binding is assessed. The test yields specific information on both the immunoglobulin class of antibody (constant region) and the site of binding to the sperm surface. The mixed agglutination reaction of bovine red blood cells sensitized with human IgG are mixed with "patient" semen. The presence of antibody-coated spermatozoa results in the formation of mixed agglutinates with the red blood cells (272). A comparison of these two methods of tests demonstrates good correlation of results; however, the last test is easier to perform (276).

for those patients whose tubal reanastomoses have not yielded a pregnancy by 12 to 18 months after surgery.
Despite recent improvements in techniques for the identification of antisperm antibodies, the clinical utility of these tests should be limited to very special cases until their prognostic value, impact on infertility management, or effectiveness in treatment can be demonstrated in prospective trials. Corticosteroid therapy for men with antisperm antibodies has been studied but does not demonstrate decreased antisperm IgG in response to corticosteroid therapy; however, no improvement in sperm-bound IgA or pregnancy outcomes could be documented (277). In fact, there is currently no support for the use of corticosteroid therapy in antisperm antibody–positive patients because IUI alone has been shown to result in higher pregnancy rates than the combination of corticosteroids and timed intercourse (272). In summary, in a couple with no identifiable cause of infertility, a positive or negative antisperm antibody test will not alter their proposed therapeutic plan: superovulation and IUI followed by IVF or ICSI (278). One potential use of antisperm antibody testing that warrants investigation is the identification of those couples predicted to have high fertilization failure rates with IVF who might benefit more from immediate use of ICSI.

Uterine Factors

Uterine anatomy and function are both critical determinants governing implantation of the embryo and subsequent fetal growth and development. Of course, these two elements are not distinct entities. They are intimately related; thus, most of the uterine factors implicated in infertility have defects in both structure and function. For example, the endometrial lining of uteri with congenital anatomic abnormalities exhibits functional aberrations. Endometrial molecular mechanisms of implantation and gestation are exquisitely controlled and remarkably complex; thus, even subtle defects in endometrial progression from the perimetrial implantation, luteal phase to the mature decidua supporting a placenta and fetus can result in infertility or early pregnancy loss.

Diagnostic Imaging for Uterine Pathology

Uterine abnormalities that have been implicated in infertility include congenital malformations, luteal-phase defects, and other acquired conditions such as leiomyomas, endometrial polyps, and intrauterine synechiae. For infertility patients who have had no recent imaging tests, it is reasonable to begin the workup with HSG because it has an 85% to 100% sensitivity for detecting tubal pathology among infertility patients (224–225). However, HSG has only 44% and 75% sensitivity rates in documenting uterine malformations and intrauterine adhesions, respectively (279).

Sonohysterography appears to be superior to HSG in the detection of uterine malformations, correctly identifying 90% of abnormalities among infertile patients (280). These data are consistent with those observed in patients with abnormal uterine bleeding in the general gynecologic setting, where sonohysterography has sensitivities of 87% and 93% in detecting any intrauterine pathology and endometrial polyps, respectively (281,282). In women with abnormal bleeding, compared with conventional transvaginal ultrasound, sonohysterography has both higher sensitivity (93% versus 65%) and specificity (94% versus 76%) for the detection of endometrial polyps. Sonohysterography also decreases the false-positive and false-negative rates from 25% to 5.4% and from 36% to 8%, respectively (283).

In most practices, diagnostic hysteroscopy is the preferred procedure for the diagnosis of uterine pathology in infertility patients. However, the ideal imaging test employed during an infertility workup would be one that is relatively noninvasive and has high sensitivity and specificity in the detection of uterine abnormalities as well as tubal blockage. The use of contrast media (i.e., Echovist) instead of saline during sonohysterography has been reported to have sensitivity comparable to that of HSG and laparoscopic chromotubulation in the detection of tubal blockage (225). This test has great potential for generalized use in infertility investigations but presently lacks prospective comparison with the combined use of HSG and diagnostic hysteroscopy in the infertile population.

Congenital Anomalies of the Uterus

Congenital uterine anomalies may be associated with infertility, spontaneous pregnancy loss in the first or second trimester, or late-trimester pregnancy complications. In women with didelephic, unicornuate, and septate uteri, the rates of spontaneous abortion and preterm delivery are highly increased at 25% to 38% and 25% to 47%, respectively (283). Endometrial dysfunction during the luteal phase may result in infertility, whereas dysfunction occurring after implantation results in pregnancy loss. Further, pregnancy outcome in the presence of a uterine anomaly may depend on the location of blastocyst implantation in a particular cycle. This may explain why a woman with a septate uterus might encounter recurrent pregnancy loss even after having delivered a term infant.

With the exception of a septate uterus, infertility associated with most congenital uterine anomalies is not amenable to surgical treatment (284,285). Hysteroscopic septolysis has been demonstrated to decrease significantly the risk for spontaneous abortion in women with septate uteri, and surgical therapy is indicated in patients with known uterine septi and who have recurrent spontaneous abortion (286). Indications for surgical correction of congenital uterine anomalies when the presenting complaint is infertility are less obvious. Among seven series of hysteroscopic metotomopies performed for infertility, the overall pregnancy rate after treatment was 48% (286). It is still reasonable to consider surgical options in some infertile patients with uterine septi because septoplasty may maximize the chance of having a live birth by decreasing the associated risks for spontaneous abortion and preterm labor.

In Utero Exposure to Diethylstilbestrol

Exposure to DES in utero increases a woman’s risk for congenital reproductive tract malformations and obstetric complications, including preterm labor and cerebral incompetence (287). In one study, almost 70% of women exposed to DES in utero were noted to have uterine malformations on HSG. The most common malformation was the T-shaped uterus (288). Whether DES-exposed women also have higher rates of infertility remains unclear (289,290). One investigator reported that DES-exposed women had a particular prevalence when constriction of the upper segment of the reproductive tract was present (291). This question is difficult to study; however, since there is great variation in the degree of congenital uterine, tubal, and cervical abnormalities associated with exposure (287).

Furthermore, some abnormalities may promote other infertility factors. For instance, cervical abnormalities may promote production of suboptimal cervical mucous, or cervical stenosis may promote retrograde menstruation and the subsequent development of endometriosis. Finally, some DES-exposed infertile patients will also have unresolved but additional reasons for their infertility state. Overall, when a DES-exposed woman has uterine anomalies on HSG and greater than 1 to 2 years of primary infertility, her prognosis for future pregnancy is extremely poor (292). Metroplasty for correction of T-shaped and hypoplastic DES-exposed uterus has unproven value and is not recommended. Results of IVF treatment are generally poor in infertile, DES-exposed women. Although ovarian response rates to COH are comparable in DES-exposed women and DES-exposed women with unexplained infertility, DES exposure is associated with significantly lower implantation rates in IVF (293).

Acquired Abnormalities of the Uterus

Leiomyomas Among women with infertility and uterine leiomyomas, many variables may affect pregnancy rates, including leiomyoma size, location, and number (solitary versus multiple) as well as the presence of symptoms associated with these tumors. Leiomyomas have never been shown to be a direct cause of infertility. It has been suggested, however, that uterine leiomyomas might alter uterine contractility and thereby disrupt normal sperm migration. Alternatively, the presence of leiomyomas might adversely affect vascular and molecular profiles of sites of implantation (294). No prospective, randomized trial comparing expectant management with myomectomy in infertile patients with uterine leiomyomas has yet been conducted. However, one recent case-control study compared pregnancy...
outcomes among 106 women who had laparoscopic myomectomy for fibroids, 106 women with uterine fibroids who did not have surgery, and 106 women who had unexplained infertility but no fibroids. Reported live birth rates were significantly different among the study populations: 42% for the laparoscopic surgery group, 11% for the group with myomas but no surgery, and 25% for the unexplained infertility group (295). A metaanalysis of 12 prospective series involving a total of 138 women who underwent abdominal myomectomy for infertility showed that cumulative postoperative pregnancy rates at 1 year were 57% to 67%. Not surprisingly, pregnancy rates were highest for patients with no other fertility problems than fibroids, with an infertility rate of 61% versus 38%. Women who had treatment for submucous fibroids had a postoperative pregnancy rate of 70% at 1 year (290). Vercellini and colleagues reported 24-month cumulative conception rates of 67%, 66%, and 47% in patients younger than 30 years of age, 30 to 35 years of age, and older than 35 years, respectively, after abdominal myomectomy in 138 infertile women (297). The presence of other causes of infertility and duration of infertility were associated with worse prognosis, whereas the size, number, or site of fibroids did not affect pregnancy outcomes. Others have reported success rates after abdominal myomectomy that are comparable to the 65% pregnancy rate and 50% live delivery rate reported for laparoscopic myomectomy (298). Successful laparoscopic myomectomy, however, is contingent on a number of factors, including stringent criteria for patient selection and the surgeon’s experience with the procedure. In addition, appropriate closure of the created uterine defect is essential to minimize the complication of uterine rupture during subsequent pregnancy (299–300). In short, both myomectomy and supervoltage/UAI are reasonable treatment options for women with uterine fibroids and otherwise unexplained infertility, particularly if the leiomyomata are large, submucous, solitary, or distorting the uterine cavity.

**Endometrial Polyps**

Even in the absence of symptomatic uterine bleeding abnormalities, endometrial polyps may be discovered in women with infertility. The incidence of asymptomatic endometrial polyps in women with infertility has been reported to be about 10% (301). The value of routine hysteroscopic removal of endometrial polyps before infertility treatment and the role of polyp recurrences during treatment are not known. It is intriguing that of 83 patients who were diagnosed with uterine polyps, 74% of whom were treated surgically with hysteroscopy and COH for IVF, only 18% subsequently went on to have children (302). The presence of polyps is not associated with a reduced implantation rate or spontaneous abortion. Treatment of luteal-phase defect can also be characterized by histologic asynchrony between endometrial epithelial and stromal compartments. A variety of factors could be responsible for such histologic alterations, including inadequate follicular development, inadequate FSH or LH secretion, hyperprolactinemia, and an inappropriate progesterone production by the corpus luteum (307). Regardless of its primary cause, LPD probably is marked by an aberrant molecular profile within the endometrium, which, in turn, can adversely affect endometrial receptivity to blastocyst implantation (308,309). Using murine gene knockout models, the genes Hoxa-10, Hoxa-13, and Hox-11, which encode homeobox-containing factor (LH), Lf receptor, and cyclooxygenase-2 (Cox 2) have each been determined to have a critical functional role in implantation in mice (310,311,312,313 and 314). The cycle-dependent expression patterns of these genes in the mouse endometrium and their high degree of conservation between mouse and human both serve to support their potential importance in human implantation (315). Thus, these mouse models serve as valuable tools in the dissection of molecular genetic pathways that are potentially relevant in human implantation.

In recent years, a temporal and functional “implantation window” has been proposed to occur during the midluteal phase of the human menstrual cycle. This concept has been helped to offer synthesis a growing body of data suggesting a defined period of optimal receptivity of the uterus for the implanting blastocyst. That an implantation window exists is supported by the finding that embryos implanting on postovulation days 8 to 10 have maximal viability, whereas the risk for early pregnancy loss is higher the later implantation occurs. The optimal duration of this postovulation window has been described by the temporal expression pattern of endometrial b, a, and a, integrins, the presence of steroid receptors, and the expression of specific cytokines (316). Although the implantation window has been defined by the temporal expression pattern of endometrial b, a, and a, integrins, there is controversy over length of this proposed window—between days 20 and 24 or much narrower, between days 22 and 23 or a 28-day cycle (317,318). At present, the diagnosis of luteal-phase defect based on testing for the expression of these integrins has not become standard clinical practice because endometrial integrin expression may be characterized by significant intercycle variability. Further, the value of assessing integrin expression levels in predicting pregnancy outcome is not yet known (319).

Perhaps the most crucial question is whether luteal-phase defect exists at all. In a series of 12 prospective endometrial biopsy specimens from normally fertile women, investigators documented isolated out-of-phase specimens in 31.4% of normally cycling participants and sequential out-of-phase specimens in 6.6%, suggesting that normal women often have out-of-phase endometria (320). Other authors have reported the frequency of out-of-phase endometrial specimens among infertile patients is no greater than the rate that would occur by chance alone (321,322).

Because of the discomfort and inconvenience associated with the multiple endometrial biopsies needed to confirm the diagnosis of luteal-phase defect, several investigators have attempted to identify alternative luteal-phase markers for this diagnosis. One possibility would involve definition of a luteal-phase serum progesterone level that would correlate sufficiently with endometrial biopsy results to allow its use as a screening tool for luteal-phase defect. Although some studies have advocated such testing, data that convincingly associate single midluteal phase serum progesterone levels with proposed luteal-phase abnormalities are lacking. The characteristic pulsatile secretory phase of progesterone is further reduced by such testing (323). Given the current uncertainties about the diagnosis and treatment of luteal-phase defect, attempts to diagnose this disorder should be confined to infertile patients who lack other identifiable diagnoses and to those in whom a subsequent biopsy to meet criteria for the diagnosis. The actual cycle day has conventionally been calculated by assigning the onset of the mensuration following biopsy as day 28 and counting backward to the day of biopsy. However, the use of the day of ovulation as a reference point may be more meaningful physiologically.

In addition to delayed endometrial maturation, luteal-phase defect can also be characterized by histologic asynchrony between endometrial epithelial and stromal compartments. A variety of factors could be responsible for such histologic alterations, including inadequate follicular development, inadequate FSH or LH secretion, hyperprolactinemia, and an inappropriate progesterone production by the corpus luteum (307). Regardless of its primary cause, LPD probably is marked by an aberrant molecular profile within the endometrium, which, in turn, can adversely affect endometrial receptivity to blastocyst implantation (308,309). Using murine gene knockout models, the genes Hoxa-10, Hoxa-13, and Hox-11, which encode homeobox-containing factor (LH), Lf receptor, and cyclooxygenase-2 (Cox 2) have each been determined to have a critical functional role in implantation in mice (310,311,312,313 and 314). The cycle-dependent expression patterns of these genes in the human endometrium and their high degree of conservation between mouse and human both serve to support their potential importance in human implantation (315). Thus, these mouse models serve as valuable tools in the dissection of molecular genetic pathways that are potentially relevant in human implantation.

Because of the discomfort and inconvenience associated with the multiple endometrial biopsies needed to confirm the diagnosis of luteal-phase defect, several investigators have attempted to identify alternative luteal-phase markers for this diagnosis. One possibility would involve definition of a luteal-phase serum progesterone level that would correlate sufficiently with endometrial biopsy results to allow its use as a screening tool for luteal-phase defect. Although some studies have advocated such testing, data that convincingly associate single midluteal phase serum progesterone levels with proposed luteal-phase abnormalities are lacking. The characteristic pulsatile secretory phase of progesterone is further reduced by such testing (323). Given the current uncertainties about the diagnosis and treatment of luteal-phase defect, attempts to diagnose this disorder should be confined to infertile patients who lack other identifiable diagnoses and to those in whom treatment specifically directed at luteal-phase defect is being contemplated.

Current treatments for presumed luteal-phase defect among infertile patients are empiric and reflect the hypothesis that progesterone insufficiency is causal. Treatment, therefore, involves the administration of vaginal or intramuscular progesterone (50 to 100 mg/d) beginning 3 days after documentation of an LH surge. Progesterone supplementation is typically continued until the first day of the next menstrual cycle or until documentation of a negative serum quantitative hCG value. If a patient becomes pregnant while on therapy, progesterone is continued until 8 to 10 weeks of gestation. If one accepts both that luteal-phase defect exists and that it is a reflection of luteal progesterone insufficiency, then it would seem prudent to begin therapeutic progesterone supplementation soon after ovulation and before implantation. Initiating therapy only after pregnancy is confirmed may be misguided. In fact, among patients with proposed luteal-phase defect, those pregnancies that survive to the point of confirmation by hCG may not require any treatment because they have already persisted beyond the perimplantation period. Studies supporting progesterone supplementation for luteal-phase defect have reported pregnancy rates after implantation that varied from 10% to 80%. All of these studies have been small and poorly controlled (324). A prospective, randomized trial studying the impact of progesterone supplementation on pregnancy rates and outcomes in infertile patients diagnosed with luteal-phase defect is warranted.
Infectious Factors

The relationship between subclinical infection and fertility has received considerable attention. Particular interest has focused on two potential pathogens: *Chlamydia trachomatis* and *Mycoplasma* species. The association of chlamydia with PID has been well established. Chlamydia is the predominant pathogen detected in about 20% of cases of acute salpingitis in the United States. Chlamydia may produce asymptomatic infection in the female genital tract, and it is likely that some women experience chronic fallopian tube infection. Despite few if any symptoms, these infections may result in tubal damage. A possible link between infection and infertility is suggested by evidence that the prevalence of positive chlamydial cultures may be higher among infertile patients than among controls (325). In a study of 286 women undergoing 344 oocyte retrievals, seropositivity for chlamydia and the presence of bacterial vaginosis were highly associated with tubal disease. Reproductive outcomes of IVF, however, were no different than those of controls (326).

In another recent study, the incidence of bacterial vaginosis among 771 current IVF patients was 25%. Although their pregnancy rates were not affected, those IVF patients with bacterial vaginosis had a significantly higher risk for spontaneous abortion than matched controls, even after adjusting for smoking history, maternal age, the presence of polycystic ovaries, history of recurrent miscarriage, and history of previous cesarean birth (327). It remains to be determined which factors directly caused this increased rate of spontaneous pregnancy loss. Likewise, it is not known whether treatment of bacterial vaginosis before or during IVF treatment would alter the rate of spontaneous abortion.

Mycoplasma species are pleuropneumonia-like organisms. Both *Mycoplasma hominis* and *Ureaplasma urealyticum* have been recovered from the cervical mucus and semen of infertile couples. There also appear to be higher rates of mycoplasma infection among infertile couples than among fertile controls. The effect of the presence of these organisms on fertility, however, remains unclear. For example, mycoplasma organisms have been isolated from the cervix of the female partner in 47% of previously infertile couples who conceived and 53% of couples who remained infertile (329). The role of treating these infections in an infertile population also is controversial. In one study, 60% of infertile men who were culture positive for ureaplasma and whose infection was subsequently cleared by antibiotic treatment impregnated their partners; the rate was only 5% among men whose infection was not cleared (329). In contrast, a double-blind study of doxycycline treatment for mycoplasma infection failed to show an effect on conception rates (328). Until a clear association has been established between mycoplasma infection or its treatment and fertility, testing for these organisms during an infertility evaluation remains controversial.

**Systemic Illness**

In general, any severe systemic illness, such as renal failure, liver failure, or metastatic cancer, can lead to disruption of the hypothalamic–pituitary–ovarian axis and cause infertility. However, because sporadic ovulation is always possible, even after a period of anovulation, use of contraception should be advised if pregnancy is not desired. If a patient with such severe systemic illness wishes to conceive, careful preconceptional assessment and counseling must be performed before any infertility treatment is undertaken because the risks to the mother and fetus may be tremendous.

The presence of antiphospholipid antibodies has been suspected to be associated with infertility and lower pregnancy outcomes. However, the high prevalence of antiphospholipid antibodies has not been found to be a prognostic factor in IVF in a prospective study and a metaanalysis of seven studies (330,331). Therefore, infertility is currently not an indication for antiphospholipid antibody testing.

**Unexplained Infertility**

The laboratory assessment of an infertile couple and should be performed consistently in order to establish a diagnosis and initiate appropriate therapy (Figs. 27.1, 27.2, 27.3, 27.4 and 27.5). Evaluation of the mate by semen analysis in an accredited laboratory skilled in andrology testing is essential. Ovulation should be documented in the woman using over-the-counter ovulation detection kits. If uncertainty surrounding the interpretation of such tests exists, then midluteal serum progesterone levels can be used to confirm ovulation. Unless laparoscopic surgery is already planned for some other indication, tubal obstruction should be excluded using HSG. If laparoscopy is indicated, laparoscopic chromotubation can be performed at the time of surgery. Any previous infertility investigations should be reviewed and repeated if the results are in doubt. This is particularly the case for previous semen analyses. If the man remains enigmatic after the aforementioned investigations, further endocrine evaluation should be undertaken, including measurements of serum TSH, day 3 FSH, and prolactin levels.

**Role of Diagnostic Laparoscopy**

One controversial issue in the management of unexplained infertility is whether diagnostic laparoscopy should be performed and, if so, when. Previously unsuspected conditions that may be detected during laparoscopy include uterine leiomyomas (especially intramural, subserosal, and pedunculated fibroids), peritubal adhesions, and endometriosis. Those uterine fibroids detected by laparoscopy, but not by physical examination, tend to be small, pedunculated, or subserosal and are seldom clinically significant. However, it is possible that clinically important submucosal and intramural fibroids that are too small to be detected on bimanual pelvic examination may distort the uterine cavity. Diagnostic laparoscopy is not sensitive in detecting these tumors, however. In the absence of data on the incidence of pelvic disorders in women with unexplained infertility and normal HSG findings, the value of diagnostic laparoscopy during their initial workup remains controversial. In a retrospective series of 100 such patients, 68 women had laparoscopic diagnoses relevant to their fertility, including 24 with intrinsic tubal disease, 34 with peritubal adhesive disease, and 43 with endometriosis (332). In another retrospective series, among 265 women who had a laparoscopic procedure after normal HSG findings, laparoscopy revealed the following diagnoses: normal pelvices (51%), minimal to mild endometriosis (32%), moderate to severe endometriosis (4.2%), adnexal adhesions (10.2%), subserosal myomas (6.4%), ovarian neoplasms (1.9%), distal hysterosalpingography (0.5%), and salpingitis isthmica nodosa (0.5%). Because prospective studies of laparoscopy to diagnose tubal disease or to confirm uterine patency in the presence of normal HSG findings. It is debatable whether lysis of mild adnexal adhesions found at the time of diagnostic laparoscopy significantly affects fertility. Therefore, the main argument for performing diagnostic laparoscopy in women with unexplained infertility and normal HSG findings would be the possibility of identifying and treating endometriosis.

**Endometriosis**

The value of diagnosing endometriosis in the absence of tubal obstruction and of its treatment in women with unexplained infertility has constituted another area of controversy. It is generally thought that there is a higher prevalence of endometriosis in women with infertility (333). In theory, endometriosis could alter fertility by its known association with elevations in a variety of cytokines, including tumor necrosis factor. These soluble mediators of inflammation may alter the peritoneal, intratubal or intracellular environment and adversely affect fertilization, early embryo development, or implantation (334,335 and 336). Clinical evidence linking the presence of endometriosis to infertility exists, but the mechanism remains unclear. Data on the effect of endometriosis on ART pregnancy rates demonstrate either no significant changes or lower pregnancy rates (337,338 and 339). The fact that pregnancy rates do not appear to correlate with disease stage (according to the Revised American Society for Reproductive Medicine's classification of endometriosis) further clouds arguments about the importance of endometriosis diagnosis and treatment among infertile couples (340).

Medical therapies for endometriosis that involve hormonal suppression (e.g., combination oral contraceptive pills, GnRH agonists, or danazol) are generally reserved for the treatment of pelvic pain because these treatments all prevent pregnancy. Subfertility associated with endometriosis requires alternative, nonsuppressive approaches. In a prospective cohort trial involving 168 infertile women with minimal or mild endometriosis on diagnostic laparoscopy and 263 women with unexplained infertility who were then matched to the Collaborative Group on Endometriosis found that fecundity rates were similar in both populations (18.2% versus 23.7%) during 36 weeks of expectant postoperative follow-up (341). The same group performed a randomized trial comparing 172 women who had ablation or resection of minimal or mild endometriosis with 169 women who were not laparoscopically treated for similar operative diagnoses at diagnostic laparoscopy. Cumulative pregnancy rates were significantly different between treated and control groups at 30.7% and 17.7%, respectively. By 36 weeks of follow-up, fecundity rates were 4.7 and 2.4 per 100 person-months, respectively. The rates of spontaneous abortion (20.6% and 21.6%) were nearly identical (342). In contrast, the Gruppo Italiano per lo Studio dell’Endometriosi reported that, after 1 year of follow-up, 54 patients with otherwise unexplained infertility who had resection or ablation of minimal to mild endometriosis had pregnancy rates similar to 47 women whose endometriosis was not treated (24% versus 29%, respectively) (345). Of course, it is possible that any improvement in the resulting pregnancy rates has been so small that a large randomized study would be required to document differences in posttreatment pregnancy rates. In fact, based on the Canadian prospective randomized trial, it has been calculated that laparoscopic treatment of 6.7 patients with minimal to mild endometriosis would yield one pregnancy (344). Assuming that 20% of couples with unexplained infertility by an otherwise negative workup have mild to minimal endometriosis, 33.5 patients would need to undergo laparoscopy to yield one pregnancy that can be attributed to the treatment of
In light of the continuing controversies, it is reasonable to start fertility empirically in women with unexplained infertility and normal HSG without assessment of the pelvis by diagnostic laparoscopy. This recommendation takes into consideration a number of issues, including the questionable value of diagnostic laparoscopy, minimal efficacy of treating minimal to mild endometriosis in these patients, known surgical risks of laparoscopy, and proven efficacy of empirical treatment. Diagnostic laparoscopy can always be reserved for later use if initial treatments fail. If the patient proceeds to IVF treatment, laparoscopy might be omitted altogether. The performance of diagnostic laparoscopy as part of an initial workup of unexplained infertility is neither correct nor incorrect. However, if laparoscopy is performed, visible endometriotic lesions should either be ablated or resected. One retrospective study has reported electrocoagulation and resection of endometriosis to be indistinguishable with respect to postprocedure pregnancy outcome (345). The best overall approach to patients with unexplained infertility involves offering both interventional options—empiric therapy or diagnostic laparoscopy—to patients, who can then participate more actively in their own management.

**Treatment of Unexplained Infertility**

As the requirements for both diagnostic laparoscopy and prior exclusion of endometriosis have become less stringent in the diagnosis of unexplained infertility, one must consider the potential impact of this broader definition of the disease on treatment efficacy. In a retrospective analysis, 131 women with more than 2 years of unexplained infertility managed expectantly (i.e., no therapy) had a fecundity rate of 0.9% per cycle (346). Their pregnancy rate was managed expectantly (i.e., no therapy) had a fecundity rate of 0.9% per cycle, whereas a similar group of 119 women receiving IVF treatment had a 17% pregnancy rate per cycle (346). Thus, the low spontaneous pregnancy rates in these patients promote the abandonment of expectant management and the rapid initiation of empiric therapies. These therapies are all aimed at increasing the chances of conception by increasing the available numbers and quality of healthy gametes. More specifically, this typically involves superovulation (more female gametes); collection of oocytes, washing, and concentrating the semen (more healthy sperm); and bypassing a potential cervical factor using IUI. Superovulation with clomiphene citrate and IUI is usually the initial treatment regimen employed. This therapy is fairly efficacious in many couples with unexplained infertility and is less invasive, less expensive, and associated with fewer complications than other forms of treatment. However, if clomiphene citrate with IUI is unsuccessful after 3 months of treatment, then COH using gonadotropins should be undertaken in conjunction with IUI (COH/IUI). If both these approaches fail to result in pregnancy, IVF or ICSI can be performed.

**Clomiphene Citrate and IUI** The rationale for using clomiphene citrate to increase the fecundity rate in ovariatic women with unexplained infertility is that of superovulation. IUI has become a standard part of the COH/IUI regimen in treating these women. The degree of superovulation using clomiphene citrate is much smaller than that achieved using hMG. The results of hMG were managed expectantly (i.e., no therapy) had a fecundity rate of 0.9% per cycle, whereas a similar group of 119 women receiving IVF treatment had a 17% pregnancy rate per cycle (346). Thus, the low spontaneous pregnancy rates in these patients promote the abandonment of expectant management and the rapid initiation of empiric therapies. These therapies are all aimed at increasing the chances of conception by increasing the available numbers and quality of healthy gametes. More specifically, this typically involves superovulation (more female gametes); collection of oocytes, washing, and concentrating the semen (more healthy sperm); and bypassing a potential cervical factor using IUI. Superovulation with clomiphene citrate and IUI is usually the initial treatment regimen employed. This therapy is fairly efficacious in many couples with unexplained infertility and is less invasive, less expensive, and associated with fewer complications than other forms of treatment. However, if clomiphene citrate with IUI is unsuccessful after 3 months of treatment, then COH using gonadotropins should be undertaken in conjunction with IUI (COH/IUI). If both these approaches fail to result in pregnancy, IVF or ICSI can be performed.

**COH and IUI** COH and IUI has now evolved to become a standard adjunct to any superovulation treatment in unexplained infertility. A metaanalysis of prospective, randomized trials comparing IUI and timed intercourse in women with unexplained infertility has determined that the pregnancy rate is higher with IUI (20% versus 11.4%; OR, 1.84; 95% CI, 1.30 to 2.62) (349). For optimal pregnancy rates, IUI should be performed twice. A prospective, randomized trial demonstrated that IUI performed 12 and 34 hours after ovulation with hCG resulted in significantly higher pregnancy rates per patient (30.4%) and per cycle (19.4%) than use of a single IUI at 12 hours or double IUI at 34 and 60 hours (350).

In a multicenter, prospective, randomized trial involving 932 couples with unexplained infertility, the combination of COH with gonadotropins and IUI has proved superior to IUI alone, intracervical insemination (IC) alone, or COH/IC (351). The National Cooperative Reproductive Medicine Network reported that the pregnancy rate was significantly higher in couples who were treated with COH/IUI (33%) than those treated with IUI alone (18%), COH/IC (19%), or IC alone (10%) (352). However, the multiple pregnancy rates were concomitantly increased.

Pregnancy rates using IVF have been reported to be higher than those using COH/IUI in the treatment of unexplained infertility (351,352). However, the risks and costs associated with IVF treatment are appreciably higher, making it standard practice to treat these couples with COH/IUI before attempting IVF (351). The question of how many COH/IUI cycles should be attempted before conversion to IVF can be a challenging one, especially because this decision is affected by financial as well as medical factors. The relatively low degree of invasiveness and low costs of COH/IUI must be balanced against the potential decrease in ovarian reserve that can compromise IVF success if treatment is delayed. This is a particularly important consideration for the older, infertile couple. Therefore, it is good practice to recommend, a priori, a maximum number of COH/IUI cycles that will be attempted. This definition of treatment expectations may help to temper reactions to unsuccessful therapeutic interventions and foster a sense of control among patients.

It has been recommended that patients with unexplained infertility experience no more than three to six COH/IUI cycles before therapy is discontinued or changed (353,354). One study has proposed a maximum of three trials of COH/IUI, based on the cycle fecundity and cumulative pregnancy rates observed in the National Cooperative Reproductive Medicine Network (355). However, the pregnancy rates were managed expectantly (i.e., no therapy) had a fecundity rate of 0.9% per cycle, whereas a similar group of 119 women receiving IVF treatment had a 17% pregnancy rate per cycle (346). Thus, the low spontaneous pregnancy rates in these patients promote the abandonment of expectant management and the rapid initiation of empiric therapies. These therapies are all aimed at increasing the chances of conception by increasing the available numbers and quality of healthy gametes. More specifically, this typically involves superovulation (more female gametes); collection of oocytes, washing, and concentrating the semen (more healthy sperm); and bypassing a potential cervical factor using IUI. Superovulation with clomiphene citrate and IUI is usually the initial treatment regimen employed. This therapy is fairly efficacious in many couples with unexplained infertility and is less invasive, less expensive, and associated with fewer complications than other forms of treatment. However, if clomiphene citrate with IUI is unsuccessful after 3 months of treatment, then COH using gonadotropins should be undertaken in conjunction with IUI (COH/IUI). If both these approaches fail to result in pregnancy, IVF or ICSI can be performed.

**Treatment Options**

**Gonadotropin Therapy**

Medical preparations of gonadotropins (LH, FSH) can be used to stimulate ovarian folliculiferous development and induce ovulation. Gonadotropin therapy can be used in the treatment of several conditions:

1. Ovulation induction in anovulatory PCOS that is resistant to ovulation induction by medroxyprogesterone acetate.
2. Ovulation induction in hypogonadotropic hypogonadism or pituitary dysfunction.
3. COH or superovulation combined with IUI in the treatment of unexplained infertility.
4. COH in IVF/ICSI.

The first gonadotropin preparation to become widely used in infertility treatment was human menopausal gonadotropins (hMG). A mixture of FSH and LH, hMG is purified from the urine of postmenopausal women (356) and supplied for intramuscular injection with 75 IU of FSH and 75 IU of LH per ampule. The mechanism of action of hMG is much less controversial than that of clomiphene citrate. It supplements or replaces the woman's own gonadotropins. Functional ovarian tissue is necessary for successful treatment because the major activities of gonadotropins are directed at the ovary itself. Recapitulating spontaneous ovulatory cycles, FSH and LH are presumed to act in concert to stimulate folliculogenesis; FSH acts primarily on the granulosa cells, and LH acts on the thecal lutein cells. Treatment with
hCG is typically added to hMG-stimulated cycles to promote oocyte maturation, induce ovulation, and allow appropriate corpus luteum formation and function.

Table 27.6 lists the different types of gonadotropins and their composition, and Table 27.7 lists the contraindications of gonadotropin treatment. The key differences among various preparations lie in the methods of extraction or synthesis of FSH and LH, the proportion of each hormone in the preparation, and the route of administration. The response to gonadotropins varies from one person to another. Even the same person may respond differently to the same gonadotropin regimen in different cycles. Therefore, one of the advantages of using recombinant FSH is an improved batch-to-batch consistency, allowing a more consistent response to the same gonadotropin dosage. An additional benefit of recombinant FSH is its subcutaneous route of administration, which is preferred over intramuscular injections by most patients.

Table 27.6. Different Types of Gonadotropin Preparations

Table 27.7. Contraindications of Gonadotropin for the Treatment of Infertility

The absence of LH in recombinant FSH preparations may minimize the amount of androgen production within the theca cells of the follicles, which presumably results in improved follicular quality. This property may be particularly desirable in the subset of PCOS patients who have an elevated LH-to-FSH ratio. A metaanalysis of prospective, randomized trials comparing purified FSH and hMG in the induction of ovulation among clomiphene citrate-resistant women with PCOS showed no difference in clinical pregnancy rates. However, a lower rate of moderate to severe OHSS appeared to be associated with the use of purified FSH (OR, 0.2; 95% CI, 0.09 to 0.46). Therefore, both purified FSH and recombinant FSH may be especially beneficial in the induction of ovulation in women with PCOS (359).

The relative efficacies of hMG, purified FSH, highly purified FSH, and recombinant FSH have been studied predominantly in ART cycles and are discussed in greater detail in the ART section. To summarize, one metaanalysis of randomized, controlled trials found that use of purified FSH or highly purified FSH was associated with significantly higher clinical pregnancy rates when compared with hMG use in IVF cycles not involving GnRH agonist downregulation (360). However, the same study found that there was no difference in clinical outcomes between the two types of gonadotropins in IVF protocols using GnRH agonist downregulation. Because GnRH agonist downregulation is not included in most COH/IUI cycles, FSH preparations may be particularly beneficial in these regimens.

Another metaanalysis of 12 randomized, controlled trials comparing urinary FSH (purified FSH and highly purified FSH) and recombinant FSH in ART cycles concluded that higher pregnancy rates resulted from recombinant FSH use (OR, 1.20; 95% CI, 1.02 to 1.42) (361). However, there is no evidence to suggest a difference in clinical outcomes between the two available recombinant FSH preparations. Overall, recombinant FSH appears to be superior to other gonadotropin preparations and is preferred in COH cycles, with or without ART. Nonetheless, there may be subsets of patients who respond better to hMG, perhaps because they need the LH component. Alternatively, the recombinant forms may not elicit optimal response in patients with particular FSH receptor variants. Therefore, if the ovarian response is poor with recombinant FSH, a trial of hMG should be considered.

Regardless of the indication, regimens involving gonadotropin therapy for ovulation induction or COH follow fairly similar protocols. All include close monitoring of folliculogenesis using transvaginal ultrasonography and serum estradiol levels. Such monitoring allows informed adjustment of gonadotropin dosages, timed hCG injection and IUI, and most importantly, limitation of complications such as OHSS and multiple gestation. Patient age, ovarian reserve, and infertility diagnosis help to individualize the initial gonadotropin dose, the maximum allowable number of follicles, and the speed of ovarian stimulation (or cycle length). Of the many protocols that have been proposed, the following sections illustrate the key points for gonadotropin stimulation in non-IVF/ICSI cycles.

Baseline Transvaginal Ultrasound Scan

Patients begin therapy on day 2 or 3 after the onset of a spontaneous or induced menses. (Day 1 is the first day of menses.) A baseline transvaginal ultrasound is performed on day 1 or 2, before the start of therapy, to identify uterine abnormalities such as endometrial polyps, submucosal fibroids, or congenital defects. Hormonally responsive pathology, including endometrial polyps and submucosal fibroids, may not be apparent at this point in the menstrual cycle, when tissues are in a hypoestrogenic state. Therefore, a systematic survey should be repeated in subsequent ultrasound examinations throughout the course of the stimulation protocol (363). The findings of a thin endometrium (<4 mm) and quiescent ovaries on the baseline scan reflect the hypoestrogenic state of the early follicular phase, which provide the optimal conditions with which to commence treatment. Conversely, a thick endometrium represents endogenous hormonal stimulation above normal basal levels and indicates that the patient should not initiate the cycle.

Unilocular, clear cysts may represent functional cysts or unruptured luteinized cysts. Complex ovarian cysts detected at baseline usually reflect old hemorrhagic corpus luteum and are commonly seen if the patient has been treated with gonadotropins in the previous cycle. Nevertheless, the differential diagnoses, including endometrioma, benign ovarian tumor, or malignancy, must be considered. The management of ovarian cysts present at baseline is controversial. In 174 prospective, non-IVF, COH cycles, a significantly lower cycle fecundity rate was observed with a baseline ovarian cyst larger than 10 mm (364). Confusion may have arisen because several IVF studies have reported no adverse effect on pregnancy outcomes associated with presence of a baseline ovarian cyst (365,366 and 367). Extrapolation of results from IVF studies to non-IVF, COH cycles is not appropriate; this issue is debatable even among IVF studies (368). More importantly, these ovarian cysts tend to resolve spontaneously within 1 to 2 months. Low-dose oral contraceptive has a lower efficacy than older, high-dose oral contraceptive in preventing the formation of new cysts (369,370). Since oral contraceptives do not affect the speed of resolution of old cysts, they are not necessary in this scenario.

Starting Dose of Gonadotropin

Gonadotropin dosages can be administered each day in the evening, allowing morning measurements of serum estradiol to reflect the steady state. If the patient has
had previous gonadotropin treatment, the starting dose should be based on review of ovarian response in previous cycles. The following guidelines can be used for determining the starting dose of gonadotropins in the first COH or ovulation induction cycle:

- In unexplained infertility, the patient's ovarian response is usually dependent on her age, and it may be difficult to predict. There are no strict guidelines; however, one should always start at lower doses and increase the dose on day 6, if necessary. For example, a maximum of 1 to 1.5 ampules of gonadotropin per day should be used for women younger than 30 years of age, whereas women older than 40 years of age can be started at a maximum of 2 to 3 ampules per day.
- Anovulatory PCOS patients should start at 1 ampule of gonadotropin per day. A smaller dose of 0.5 ampule per day is sometimes necessary to minimize the risk for OHSS.
- Patients with hypogonadotropic hypogonadism usually begin with 1 ampule per day.

**Monitoring and Adjustment of Dosage**

The chosen initial daily dosage of gonadotropins is maintained until day 6 or 7, when the serum estradiol level is first measured to document ovarian response. Transvaginal ultrasound also is done at this time to determine follicular response.

- If no response has occurred by these measurements, the gonadotropin dosage is increased by 1 or 2 ampules per day every 3 or 4 days until a response is evident by rising estradiol levels (or until the maximal dosage is reached). The maximal dosage is usually 6 to 8 ampules per day because an increase in ovarian response is not seen with higher dosages (371).
- Once an ovarian response is obtained, treatment typically is continued without further increase in dose.

**Cycle Progression and Monitoring**

Transvaginal ultrasound and serum estradiol measurements are performed every 1 to 3 days to evaluate follicular size, number, and quality. Follicles can be predicted to grow 1 to 2 mm per day, and follicular development is believed to be adequate when maximal follicular diameter exceeds 18 to 19 mm. When hMG is used, the serum estradiol level roughly corresponds to 150 to 250 pg/mL per mature follicle. However, serum estradiol levels may not be as closely correlated with the number of mature follicles when recombinant FSH is used. In general, the serum estradiol level can be expected to double every 24 hours if the same dosage of gonadotropins is maintained. Therefore, the main reasons for following the estradiol levels are as follows:

1. To detect missed spontaneous ovulation or premature luteinization, which may be reflected by a drop in serum estradiol levels
2. To identify patients at risk for OHSS:
   - Estradiol levels approaching 600 to 1000 pg/mL indicate increased risk for OHSS. A decrease in gonadotropin dosage should be considered, and monitoring is necessary daily for 24 hours. Withholding gonadotropins in this situation is referred to as “coasting” and is usually followed by a more than 25% decrease in serum estradiol while the follicle numbers and diameters increase. If follicle numbers increase and are excessive, the cycle should be canceled (372-373 and 374).
   - Estradiol levels in the range of 1,500 to 2,000 pg/mL indicate that treatment should absolutely be stopped because of the high risk for OHSS. All medications should be discontinued, and hCG should not be administered. The patient should be asked to abstain from intercourse until menses occurs because she may spontaneously ovulate. Under these conditions, ovulation and intercourse may lead to increased risk for multiple gestation.

**Human Chorionic Gonadotropin Administration**

When the largest measured follicle reaches a maximum diameter of 18 to 19 mm or more, 10,000 IU of hCG is administered intramuscularly. Recombinant hCG is also available now for subcutaneous injection. Optimal pregnancy rates are achieved with IUI performed at 12 and 34 to 36 hours after the hCG injection. If the plan is to have natural intercourse, it can be timed within 12 to 36 hours of hCG administration as well.

**Pregnancy Test or Plans for Next Cycle**

If menses does not ensue after a treatment cycle, testing for pregnancy should be performed about 15 or 16 days after hCG administration. Testing for serum or urinary levels of hCG should not be affected by prior administration of exogenous hCG at this point, and b-hCG should be detectable by either method. If pregnancy does not occur, the cycle should be reviewed. If appropriate follicle size, number, and estradiol levels have been reached, then there is no need to change the gonadotropin dosage. The dosage should be changed if COH was inadequate or excessive. If the length of the stimulated cycle was too short (i.e., the follicular stimulation was too fast), endometrial maturation could have been suboptimal, and gonadotropin dosage should be decreased in a subsequent cycle.

**Special Issues of COH and IUI in PCOS**

PCOS patients represent one of the most challenging subpopulations to treat safely and successfully using COH/IUI. The small multiple ovarian antral follicles characteristic of these patients may be very resistant to stimulation, but they are equally likely to respond and grow with minimal increases in gonadotropin dosage. The incidence of multiple pregnancy and OHSS is increased in these patients (375). Up to 30% or more of COH cycles may be canceled as a result of excessive follicular development. Several approaches that have been proposed to avoid complications of COH and cycle cancellation include downregulation with gonadotropin-releasing hormone GnRH agonists, dual suppression with oral contraceptives and GnRH agonists, pretreatment with metformin, and surgical ovarian diathermy (205,376,377,378 and 379).

A dual suppression protocol described for PCOS hyperresponders in IVF treatment could also be used to lower ovarian response in COH/IUI cycles. In this protocol, low-dose oral contraceptives were taken for 25 days, the last 5 of which utilized concurrent administration of the GnRH agonist leuprolide acetate (1 mg/d by subcutaneous injection). Low-dose gonadotropin was then started on day 3 of GnRH agonist treatment. This protocol resulted in significant improvements in clinical pregnancy rates, a decrease in cancellation as a result of excessive ovarian response, and a decrease in the incidence of OHSS (379).

Alternatively, PCOS patients can be pretreated for at least 1 month with metformin at the full dose of 1,500 mg/d, before COH/IUI with gonadotropins. In a randomized, prospective trial, pretreatment with metformin resulted in fewer follicles, lower estradiol levels, and no cycle cancellations due to excessive ovarian response during gonadotropin COH (379).

**Hypogonadotropic Hypogonadism Therapy with hMG**

hMG is most successful in patients with hypogonadotropic hypogonadism, yielding cumulative pregnancy rates of 92.1% after six treatment cycles using hMG alone (380). In this particular group of patients, hMG is recommended over purified FSH for ovulation induction because purified FSH has been associated with a significantly higher total dosage requirement, lower estradiol, and decreased number of lead follicles (381). Prior toovulation induction in these patients, one must first determine on baseline transvaginal ultrasound whether the ovaries appear PCO-like, with multiple small antral follicles, thick stroma, or enlarged ovarian volume. A subset of patients with isolated hypogonadotropic hypogonadism has been described to have PCO-like ovaries and respond to gonadotropins much like PCOS patients, exhibiting higher serum estradiol and a greater number of follicles (382). This finding, in conjunction with the fact that patients with hypogonadotropic hypogonadism typically are younger and have better ovarian reserve than patients with unexplained infertility, may make it prudent to start with small doses of hMG in this population. This practice should help to avoid complications of OHSS and multiple gestation.

**Hypothalamic Failure**

Most patients with acquired hypogonadotropic hypogonadism secondary to cranial surgery, or radiotherapy for various cranial tumors have hypothalamic failure as the source of their dysfunctional hypothalamic–pituitary axis (383). In these patients, GnRH stimulation testing and the assessment of endogenous pulsatile LH secretion often can confirm whether the hypothalamic–pituitary axis is intact. Patients with hypothalamic failure and subsequent ovulatory factor infertility represent the best candidates for ovulation induction with GnRH agonists. To mimic physiologic hypothalamic–pituitary interactions, GnRH agonists must be administered in a pulsatile fashion, thereby avoiding the downregulation of the GnRH receptors that accompanies continuous GnRH agonist stimulation. Coexistent growth hormone deficiency or prolactin abnormalities do not affect the efficacy of pulsatile GnRH agonist therapy (384). In these patients, GnRH stimulation testing and the assessment of endogenous LH secretion often can confirm whether the hypothalamic–pituitary axis is intact. Patients with hypothalamic failure and subsequent ovulatory factor infertility represent the best candidates for ovulation induction with GnRH agonists. To mimic physiologic hypothalamic–pituitary interactions, GnRH agonists must be administered in a pulsatile fashion, thereby avoiding the downregulation of the GnRH receptors that accompanies continuous GnRH agonist stimulation. Coexistent growth hormone deficiency or prolactin abnormalities do not affect the efficacy of pulsatile GnRH agonist therapy (385). Because GnRH agonists are rapidly degraded by gastric enzymes (and thus ineffective when administered orally), pulsatile GnRH agonists are administered either intravenously or subcutaneously with a minipump delivery system. Adverse effects of pulsatile GnRH agonist therapy are mainly related to pump function and route of delivery (i.e., phlebitis at the needle site). The intravenous route is superior (386), but it is recommended that women with a history of bacterial endocarditis be offered only subcutaneous therapy.

In hypothalamic hypogonadotropic hypogonadism, normal pituitary negative and positive feedback mechanisms are functional upon treatment with pulsatile GnRH
agonists. In this situation, pulsatile GnRH agonist therapy simulates normal physiology and offers some advantages over hMG as a treatment for ovulatory infertility. More than two dominant follicles are seen in only 16.9% of patients with hypogonadotropic infertility who are treated with pulsatile GnRH, and more than three follicles are seen in only 5.4% of patients (385). Because OHSS is a rare occurrence, less intensive monitoring is required during GnRH agonist treatment cycles. Moreover, the risk for multiple gestation approximates that associated with clomiphene citrate therapy—only 8% (385). These are important advantages when compared with gonadotropin therapies. Cumulative pregnancy rates among women with hypothalamic hypogonadism approach 50% after 6 treatment cycles and 53% after 12 GnRH agonist treatment cycles (386), with no documented increase in the rates of spontaneous abortion (387).

The optimal dosing interval for pulsatile GnRH agonist therapy is 60 to 90 minutes, and the usual recommended dosage is 75 to 100 ng/kg/pulse (381,382). Increased dosage of up to 250 ng/kg/pulse has been reported to be required in the successful treatment of a patient with known GnRH receptor mutation (388). With typical regimens of pulsatile GnRH, ovulation occurs on day 14 and can be documented by standard LH testing. Patients treated with pulsatile GnRH usually benefit from luteal-phase support through continuation of the GnRH pump, administration of hCG, or progesterone supplementation.

**Assisted Reproductive Technology**

All methods of ART, by definition, involve interventions to retrieve oocytes. These techniques include IVF, ICSI, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), cryopreserved embryo transfers, and the use of donor oocytes. A typical ART cycle has the following main components:

- Downregulation using GnRH agonist
- COH using gonadotropins with folliculogenesis monitoring using transvaginal ultrasound and assessment of serum estradiol levels
- Oocyte maturation using hCG
- Oocyte retrieval
- Fertilization by IVF, ICSI, or GIFT
- In vitro embryo culture (except in GIFT)
- Luteal support or endometrial preparation using progesterone supplementation
- Transfer of fresh embryos with possible cryopreservation of excess embryos
- First-trimester pregnancy monitoring

**Folliculogenesis in the Spontaneous Cycle** In unassisted ovulation, the cohort of follicles destined to begin folliculogenesis in any particular menstrual cycle are recruited in the previous cycle's luteal phase. By about the middle of the next follicular phase, one of these follicles will become dominant, and further development of this dominant follicle suppresses maturation of other follicles within the selected cohort of that particular cycle. Follicular-phase growth of a single dominant follicle in nonstimulated cycles induces an intricate series of hormonally regulated feedback loops, resulting in the midcycle LH surge, which is critical for maturation of the ovarian follicles. Progesterone production commences just before ovulation and becomes significantly increased after ovulation. Estradiol production during the follicular phase causes proliferation of the endometrial epithelium. However, progesterone is critical in the final maturation of the endometrial glands and stroma required for implantation of the blastocyst. In the presence of successful implantation, the hCG-stimulated corpus luteum will continue to be the critical source of progesterone until the placenta independently produces sufficient amounts of progesterone at 8 to 10 weeks of gestation.

**Downregulation Using GnRH Agonist** The use of GnRH agonist has become standard in ART protocols. It prevents spontaneous ovulation, decreases treatment complications, and allows the control of ovulation to rest exclusively on administration of exogenous medications. Commercial preparations of GnRH agonist consist of several peptides that differ from the endogenous GnRH agonist at 2 amino acid residues. This modification increases both the half-life and the receptor binding affinities of GnRH agonist. When used in a nonsuppressive fashion, GnRH agonist causes an initial agonist effect that is accompanied by upregulation of GnRH receptors within the pituitary gland. This initial activity may be manifested as increased gonadotropin effects, which are referred to as the flare response. However, continued administration of GnRH agonist downregulates GnRH receptors, resulting in minimal basal production of LH and FSH and no stimulation of the ovarian follicles. Therefore, GnRH agonist induces a quiescent hypothalamic–pituitary–ovarian axis and a menopause-like state characterized by low estradiol levels. Consequently, in the presence of follicular development, the GnRH agonist downregulates all GnRH receptors within the pituitary gland, thereby preventing ovulation. This prevents the flare response seen with GnRH agonist use or use commencing in the follicular phase of the ART cycle (called the short, or flare, protocol). GnRH agonist use or use commencing in the follicular phase of the ART cycle (called the short, or flare, protocol).

**Luteal Support or Preparation Using Progesterone** Since ovulation, the luteal phase of the menstrual cycle begins. Progesterone production commences just before ovulation and becomes significantly increased after ovulation. Estradiol production during the follicular phase causes proliferation of the endometrial epithelium. However, progesterone is critical in the final maturation of the endometrial glands and stroma required for implantation of the blastocyst. In the presence of successful implantation, the hCG-stimulated corpus luteum will continue to be the critical source of progesterone until the placenta independently produces sufficient amounts of progesterone at 8 to 10 weeks of gestation.

The most commonly used regimen for superovulation in ART is called the long, or luteal, downregulation protocol. In this protocol, GnRH agonist is started in the luteal phase (day 21) of the previous cycle, which minimizes its flare effect and prevents the follicular recruitment that is thought to occur during this time. The couple undergoing treatment is advised to abstain from intercourse during the cycle before the start of COH; however, concomitant use of GnRH agonist in the luteal phase has been shown to be safe and effective in the prevention of premature luteinization. During the luteal phase, progesterone levels increase significantly to maintain the pregnancy. By about the middle of the next follicular phase, one of these follicles will become dominant, and further development of this follicle is suppressed by the GnRH agonist treatment. The addition of progesterone to the GnRH agonist treatment regimen results in a decrease in the incidence of multiple gestations and an increase in pregnancy rates.
Controlled Ovarian Hyperstimulation Typical use of gonadotropins for COH in ART is similar to the superovulation protocol used in COH/IUI for unexplained infertility. There are several key differences:

- When the GnRH agonist luteal downregulation protocol is used, ovarian suppression should be confirmed by a baseline transvaginal ultrasound showing no ovarian cysts larger than 6 cm (365), a thin endometrium, serum estradiol level of less than 50 pg/mL, and serum progesterone level of less than 1.0 ng/mL. Ovarian suppression is usually achieved after about 10 days of GnRH agonist therapy. Once ovarian suppression is confirmed, COH using gonadotropins can be initiated.
- The aim of COH in ART is to recruit more follicles than in COH/IUI. Unlike COH/IUI, the risk for multiple gestation under ART regimens is strictly dependent on the number of embryos that are transferred and not on the number of follicles.
- In general, the monitoring during COH for ART is slightly less frequent than in COH/IUI. Spontaneous ovulation is prevented by the routine use of GnRH agonist, and slightly greater flexibility can be exercised on the day of hCG administration without affecting the pregnancy outcomes (398).
- The removal of granulosa cells during aspiration of each developing follicle with ART is believed to decrease the risk for subsequent OHSS (399). Thus, higher serum estradiol levels and larger follicular sizes are typically allowed before hCG administration in ART protocols. OHSS does, however, remain a major concern (400).

Choice of Gonadotropins In recent years, improved clinical pregnancy rates have been accompanied by progress in all facets of ART. Concurrent with improvements in embryo culture and embryo transfer techniques has been the introduction of several generations of gonadotropin formulations. The main theme of this pharmaceutical progress has been that of increasing the purity of the FSH component in novel preparations. As a result, current recombinant FSH preparations contain absolutely no LH and no other protein contaminants.

Although no difference in pregnancy rates can be shown between use of urinary FSH and hMG in downregulated ART cycles, urinary FSH has been linked to higher pregnancy rates in nondonorregulated ART cycles (360). Further, purified FSH appears to be superior to hMG in the COH of clomiphene citrate–resistant PCOS patients in that it reduces the incidence of moderate to severe OHSS without affecting pregnancy rates (399).

In contrast to the comparisons between purified FSH and hMG, the efficacy of recombinant FSH relative to purified FSH or highly purified FSH has not been as certain. In addition to the benefits discussed under the section on COH and IUI, the impact on clinical outcomes of recombinant FSH relative to purified FSH or highly purified FSH has been studied in many prospective, randomized trials involving predominantly IVF or ICSI treatment or both. The data are conflicting. Some studies have reported no differences among preparations in terms of number of embryos, fertilization rate, or total dosage requirement (401,402). Others have found recombinant FSH to be associated with shorter duration of stimulation (403,404 and 405), decreased total dosage requirements (403,405,406), greater number of follicles and oocytes (403,404), and greater number of embryos (405,406). Importantly, pregnancy rates per cycle have not increased significantly with use of recombinant FSH (401,402,403,404,405,406,407 and 408). Of course, this lack of demonstrable difference could be attributed to inadequate power in each individual study. A recent metaanalysis reported that recombinant FSH improved pregnancy rates when compared with studies using purified FSH or highly purified FSH with OR, 1.20 (95% CI, 1.02 to 1.42) (361).

Whether recombinant FSH affects the incidence of therapeutic complications in women undergoing ART deserves attention as well. Several randomized, controlled trials have reported a trend toward an elevated incidence of OHSS with the use of recombinant FSH, although this effect has not reached statistical significance (403,404 and 405). Taken together, results suggest an important role for recombinant FSH in ART regimens. This is based on its characteristic batch-to-batch consistency and subcutaneous route of administration, its possible superiority in outcomes over other gonadotropin preparations used in typical COH, its documented benefits over hMG in PCOS patients, and the small increase in ART pregnancy rates as determined by metanalysis. Whether new metanalyses that include recently published studies (401,402,403 and 404,406) will change current recommendations remains to be seen.

Role of Low-Dose Aspirin in ART A recent prospective, randomized trial demonstrated that the use of aspirin at a dose of 100 mg/d, initiated at the time of GnRH agonist luteal downregulation and continued throughout COH, resulted in an improvement in ovarian response, implantation, and pregnancy rates in IVF (409). Although low-dose aspirin has not become a standard part of the ART protocol, many patients are now taking it with or without recommendation. Significant complications have yet to be reported with the use of low-dose aspirin in ART. Still, the safety of this adjunctive therapy warrants close examination before its wide acceptance in ART.

Recombinant Human Luteinizing Hormone According to the two-cell theory of ovarian hormone production, stimulation of the theca lutein cells by LH is critical to the overall development of the ovarian follicle. Highly purified FSH contains minimal amounts of LH (<0.1%), and GnRH agonist suppresses endogenous pituitary LH and FSH production. Therefore, it has been suggested that supplemental LH might improve folliculogenesis and pregnancy rates when highly purified or recombinant FSH is used for COH in ART. A prospective, randomized trial comparing highly purified FSH and highly purified FSH combined with supplemental rhLH has reported a trend toward lower implantation and pregnancy rates when rhLH was added to GnRH agonist–downregulated ovulation induction cycles (410). Although it is possible that some yet-to-be determined subset of infertility patients might benefit from rhLH supplementation, the generalized use of this hormone in ART currently appears to be limited.

hCG Injection The injection of hCG serves to induce oocyte maturation before oocyte retrieval. The dosage of hCG is typically 10,000 IU given intramuscularly. Different criteria for hCG injection during COH for ART have been described, but all usually include the presence of one or two leading follicles with mean diameters larger than 16 to 18 mm, at least two other follicles with mean diameters larger than 14 mm, and serum estradiol levels above defined threshold levels of 300 to 500 pg/mL. Each IVF center sets site-specific criteria based on its own experience and pregnancy outcomes. The overall goal, however, is to avoid performing surgery (oocyte retrieval) on patients who have zero to minimal chance of conceiving because of poor ovarian response. In the past, serial hCG injections were given for induction of luteal support; however, that approach can lead to an increased incidence and severity of OHSS. Luteal-phase support now relies solely on exogenous progesterone supplementation.

Oocyte Retrieval Oocyte retrieval is typically performed 36 hours after the hCG injection. Although historically performed by laparoscopy, laparoscopic oocyte retrieval has now been replaced by the transvaginal ultrasound-guided approach. Transvaginal ultrasound-guided retrieval is markedly less invasive than its laparoscopic counterpart, and the use of ultrasound permits the surgeon to visualize the location of the needle within each ovarian follicle. Intravenous sedation is commonly used for transvaginal ultrasound–guided oocyte retrieval; however, spinal anesthesia may offer an advantage in certain cases, especially when the patient has numerous follicles or the retrieval is anticipated to be anatomically challenging (411,412 and 413).

Because the vaginal canal and wall are traversed using transvaginal ultrasound–guided oocyte aspiration, the possibility of iatrogenically inflicting the patient or her oocytes deserves particular consideration. Sterile normal saline typically is used for surgical preparation during oocyte retrieval. In one prospective, randomized trial comparing sterile normal saline to 1% povidone-iodine for this application, the former had higher associated pregnancy rates while maintaining low infection rates (414). Although the exact mechanism for this finding is unclear, it is hypothesized that contact with povidone-iodine could potentially harm oocytes. Therefore, if povidone-iodine is used, it is recommended that the vagina be lavaged with normal saline after preparation. In addition, routine antibiotic prophylaxis is recommended.
for transvaginal ultrasound procedures. Such prophylaxis reduces the incidence of postprocedure positive microbiology cultures of embryo catheter tips in 78% of patients undergoing embryo transfer. The importance of this effect is suggested by the fact that lower implantation and pregnancy rates are associated with positive microbial catheter-tip cultures (415).

Performance of the retrieval itself often is fairly simple. A long, 16-gauge needle, secured by a guide onto the transvaginal ultrasound probe, is used to traverse the upper vaginal wall and enter into a follicle under direct, real-time transvaginal ultrasound guidance. Follicular fluid is then aspirated using about 100 mm Hg of vacuum. Higher pressures may traumatize the oocyte. When the entire follicular fluid content has been aspirated into sterile, prewarmed culture tubes, the inner wall of the follicle is gently curedt with the needle. This process is repeated until all the follicles are aspirated. At the end of the procedure, a speculum is inserted into the vagina and cervix and vaginal walls are inspected for bleeding. Although transvaginal ultrasound-guided oocyte retrieval is both rapid and minimally invasive, all potential risks, albeit rare, should be clearly explained to the patient before IVF treatment begins. These risks include the following:

- Excessive bleeding, possibly requiring blood transfusion
- Potential needle-induced injury to structures in proximity to the ovaries, including bowel, bladder, and major blood vessels, may require repair by emergency laparotomy, resulting in an abdominal surgical scar.
- Late infectious complications, such as abscesses in the peritoneum, bowel, ova, or uterus, may require hospitalization for intravenous antibiotics or surgical interventions. In the specific case of intratubal tubovasal abscesses, failure of medical treatment may necessitate surgical removal of the tubes and ovaries.
- Risks associated with intravenous sedation or general anesthesia
- A remote risk that no oocytes will be obtained or fertilized

IVF, ICSI, GIFT, and ZIFT Fertilization of the human oocyte by human sperm in vivo requires the interaction of capacitated spermatozoa with ovulated oocytes, most often within the ampullary portion of the fallopian tube. Capacitation of sperm takes place in the female reproductive tract and involves both changes in sperm motility and changes in the sperm cell membrane that allow the acrosome reaction. Acrosome-reacted sperm are able to penetrate the oocyte’s cumulus oophorus and zona pellucida, binding to the oocyte cell membrane and promoting fertilization. The interaction of spermatozoa and oocyte is not a chance occurrence but involves a complex oocyte–sperm intercommunication that play an important role in this process (418).

The mandate of the ART team is to attempt to re-create precisely those processes known to occur in unassisted conception. In all ART procedures, male gametes are initially collected directly by ejaculation into a sterile cup. They are then processed, concentrated, and incubated in protein-supplemented media for 3 to 4 hours before being used for fertilization. This interval incubation allows for sperm capacitation. Before fertilization, retrieved oocytes are also cultured in protein-supplemented media for 6 to 8 hours. For IVF purposes, 50,000 to 100,000 capacitated sperm are placed in culture with a single oocyte; 16 to 18 hours later, fertilization is documented by the presence of two pronuclei within the developing embryo.

Indications for ICSI are discussed under Male Factor Infertility. The procedure itself begins by stripping all granulosa cells from the aspirated cumulus complex (oocyte and surrounding cells). This is followed by micromanipulation of egg and sperm under magnification. More specifically, a holding pipette is used to stabilize the egg while an injection pipette is used to insert a viable sperm into the ooplasm of the egg.

Techniques such as GIFT and ZIFT use the tubal microenvironment as the initial point of germ cell contact after transfer. As in standard IVF, all regimens typically involve GnRH agonist downregulation followed by COH with gonadotropins. GIFT and ZIFT differ both in the duration that the gametes remain in vitro and their time of transfer. In the GIFT procedure, oocyte retrieval can be performed transvaginally or laparoscopically. Aspirated oocytes and freshly processed sperm are then resuspended in a small amount of media and rapidly transferred into the fallopian tube by laparoscopy. Historically, GIFT was initially preferred over IVF for two reasons. The limited quality of transvaginal ultrasound at the time precluded reliable transvaginal ultrasound-guided oocyte retrieval and required laparoscopic approaches. At the same time, in vitro embryo culture techniques had significant limitations, and it was felt that minimization of the duration of in vitro gamete exposure was desirable. Today, however, transvaginal ultrasound quality is excellent, and dramatic improvements have been made in gamete and embryo culture techniques.

To its detriment, GIFT requires normally functioning fallopian tubes and precludes the assessment of fertilization. Taken together, there remain very few primary medical indications for GIFT; namely, that nearly all are social or religious. ZIFT also requires normally functioning fallopian tubes; unlike GIFT, however, the ZIFT procedure involves in vitro fertilization of retrieved oocytes and overnight culture. Zygot-stage embryos are then laparoscopically transferred to the fallopian tubes about 24 hours after oocyte retrieval. Fertilization can be assessed with ZIFT.

Luteal Support Because the act of retrieving oocytes and associated granulosa cells may adversely affect subsequent corpus luteal function, retrieval poses the possible risk of subsequent progesterone insufficiency. Therefore, the requirement for luteal support represents yet another way in which ART cycles differ from COH/UI protocols. Luteal support is usually initiated on the day after oocyte retrieval for ART. Commonly used regimens include the following:

- Progesterone in oil 50 mg, once a day, intramuscularly
- Vaginal progesterone suppositories, 200 mg twice a day.
- Oral micronized progesterone, 200 mg twice a day

Despite similar circumstances of progesterone, the last regimen is associated with decreased per-embryo implantation rates when compared with use of intramuscular progesterone (417).

Embryo Transfer In unassisted conception, the fertilized oocyte traverses through the fallopian tube for 2 to 3 days before entry into the uterus for implantation. This transport is dependent on directional ciliary movement within the fallopian tube, although tubal muscular contractions may be involved (418). The embryo is normally transported in a small amount of media and rapidly transferred into the fallopian tube by laparoscopy. Historically, GIFT was initially preferred over IVF for two reasons. The limited quality of transvaginal ultrasound at the time precluded reliable transvaginal ultrasound-guided oocyte retrieval and required laparoscopic approaches. At the same time, in vitro embryo culture techniques had significant limitations, and it was felt that minimization of the duration of in vitro gamete exposure was desirable. Today, however, transvaginal ultrasound quality is excellent, and dramatic improvements have been made in gamete and embryo culture techniques.

To its detriment, GIFT requires normally functioning fallopian tubes and precludes the assessment of fertilization. Taken together, there remain very few primary medical indications for GIFT; namely, that nearly all are social or religious. ZIFT also requires normally functioning fallopian tubes; unlike GIFT, however, the ZIFT procedure involves in vitro fertilization of retrieved oocytes and overnight culture. Zygot-stage embryos are then laparoscopically transferred to the fallopian tubes about 24 hours after oocyte retrieval. Fertilization can be assessed with ZIFT.

ART protocols for in vitro embryo culture and development attempt to recapitulate the timing and conditions of these events, albeit in an incredibly simplified fashion. The development of sequential media has allowed embryos to be grown in vitro until about 72 hours (or day 3 after oocyte retrieval), when they are transferred back into the cavity of the uterus. Embryo morphologic criteria—including such parameters as cell number, symmetry, fragmentation, and granularity—are used in most centers to judge the quality of a particular embryo; however, these methods of assessment do not correlate well with embryonic developmental potential (419).

In an effort to better assess and select for transfer those embryos that will result in successful pregnancy, investigators have recently evaluated the advantages of extended embryo culture period over transfer. In vitro culture to day 5 postembryo culture period of embryo culture. Embryo culture period selection and selection of embryos at the blastocyst stage. It is possible that this extended culture does, in fact, increase the ability to judge appropriately the quality of an embryo. For instance, grading of the blastocyst according to the morphology of the inner cell mass and trophoderm has been correlated with implantation and pregnancy rates (420). Because of its increased implantation rate, extended embryo culture may offer the advantage of limiting the number of transferred embryos while maintaining clinical pregnancy rates. The true value of this approach therefore lies in its potential to reduce the rates of high-order multiple gestation resulting from ART. However, for reasons that are unclear, there appears to be an increased risk for monochorionic twinning of embryos cultured to the blastocyst stage, which can lead to increased obstetric complications (421).

Pregnancy rates resulting from blastocyst embryo transfer range between 44% for low-scoring blastocysts and 87% for top-scoring ones. Another predictor of the success rate of day 5 transfer is the number of eight-cell embryos on day 3 (421). Extended culture to the blastocyst stage (day 5) has been advocated by some to be beneficial for all IVF patients, with overall pregnancy rates of up to 43.8% (420,422). Others recommend it only if there are three or more eight-cell embryos on day 3 of in vitro culture (422). Still others do not recommend it at all (423). The true application of extended embryo culture and blastocyst transfer remains to be determined.

Technical Aspects of Embryo Transfer Despite its theoretic simplicity, transcervical embryo transfer into the intrauterine cavity is a procedure that requires a significant amount of skill. Correct performance of the procedure is thought to exert significant impact on clinical outcome. Apart from the skill and experience of the operator, variables such as aspiration of cervical mucus (424), visualization by ultrasound guidance (425), duration of supine position immediately after embryo transfer (426), and type of bacteria cultured from the transfer catheter-tip postprocedure (427) have all been suggested to affect clinical pregnancy outcomes. Microbial contamination of the embryo transfer is especially relevant because it may be prevented by antibiotic prophylaxis at the time of oocyte retrieval and careful handling of the catheter. Clinical pregnancy rates are reduced by half in women with positive catheter-tip cultures (428).

Many different types of catheters have been used to perform embryo transfers, including hard catheters (Erlangen, Tefcat, Tom Cat, Norfluid) and soft catheters...
Treatment with Donor Oocytes

Women with premature ovarian failure have very few reproductive options. The use of donor oocytes may represent the only proven

---

Table 27.9. Reported Outcomes for Assisted Reproductive Technology Procedures Performed in 1997 in the United States

The age of the woman was a significant determinant of success in ART (437) (Table 27.10). Women aged 41 years and older had a delivery rate per retrieval of only 9.4%. The increase in cancellation rates with age—most likely the result of poor ovarian response—was consistent with significantly decreased ovarian reserve in older women. With the high efficacy of ICSI as a treatment for male factor infertility, the delivery rates per retrieval among couples with male factor infertility were comparable to those achieved in couples without male factor for a given female age group.

---

Table 27.10. In Vitro Fertilization (IVF) Procedures* by Maternal Age Group and Infertility Diagnosis

(Frydman, Wallace). The Frydman and Wallace catheters are currently the most popular because they are thought to be the least traumatic to the endometrium; however, no catheter has been demonstrated to be definitively superior (429,430).

In women with a history of tubal disease, the difficulty of embryo transfer has been associated with an increased risk for ectopic pregnancy (433). The number of transfer attempts, the time required for embryo transfer procedures, and the presence of blood inside the transfer catheter after the procedure do not affect clinical outcomes (433). In a series of more than 800 consecutive embryo transfer procedures, 85.9% were easy, 8.4% were difficult, 3.2% needed to be repeated, and 2.5% required cervical dilation. Technical difficulties, repeated embryo transfers due to retained embryos, and cervical dilation for stenosis did not affect the pregnancy rates in this study (433). The timing of the correction of cervical hindrances to embryo transfers may be crucial. Specifically, although it markedly facilitated the embryo transfers itself, cervical dilation at the time of oocyte retrieval in patients with a history of very difficult embryo transfer was associated with poor pregnancy outcome (1 in 41 cycles) (434). In contrast, if performed before commencement of IVF/embryo transfer, surgical treatments for anticipated problems with embryo transfer yield good pregnancy rates. For example, hysteroscopic examination of the cervical canal may reveal a ridge, which can be resected (435). Alternatively, transcervical placement of a Malecot catheter at the time of hysteroscopy has been successful in allowing facile entry into the uterine cavity during subsequent embryo transfer or IUI. The Malecot catheter can be left in place for several weeks after hysteroscopy, as long as doxycycline 100 mg twice daily is taken; it is easily removed using gentle traction in the office as the day of embryo transfer approaches (436). Good clinical pregnancy outcomes have been reported for both techniques.

Cryopreservation of Embryos

The success of modern ovulation induction and fertilization regimens often results in embryos in excess of the number appropriate for transfer in a single cycle. Cryopreservation of these embryos permits embryo transfer to the same patient in nonstimulated cycles in the future. Some patients receive cycles of superovulation and embryo transfer for "natural" cycles; others undergo endometrial preparation with sequential exogenous estrogen and progesterone. Either regimen is significantly less expensive than a gonadotropin-stimulated cycle. More importantly, the risks of surgical complications and OHSS are nonexistent in cycles using cryopreserved embryos. Therefore, pregnancies resulting from transfer of cryopreserved embryos effectively reduce both the financial and medical costs of pregnancy per ovulation stimulation. There is, of course, a perceived downside to cryopreserved cycles because not all embryos survive thawing and pregnancy rates are lower than those using fresh embryos. In transfers of cryopreserved embryos using nondonor eggs (eggs from the intended recipient), 90% of thawing procedures resulted in viable embryos for transfer. The rates of clinical pregnancy and delivery were 23.8% and 18.8%, respectively, for cryopreserved embryo transfer procedures (437). These are only perceived disadvantages, however, because the risk for cryocycles is minimal and excess embryos would otherwise not be used.

Pregnancy Testing and Follow-up of Early Pregnancy

The uncertainties surrounding ART treatment and its outcomes can be highly stressful and treated couples are understandably anxious to obtain a pregnancy test as early as possible (438). Serial quantitative hCG levels can be done starting on day 16 after oocyte retrieval. Serum hCG levels taken earlier than this day may give false-negative or false-positive results. The latter may reflect the use of intramuscular hCG to trigger ovulation because this exogenous hCG can be detected for up to 14 days after injection (439). Day 16 serum quantitative hCG levels lower than 50 IU/L are associated with a 35% chance of an ongoing intrauterine pregnancy; levels greater than 500 IU/L are predictive of successful outcome in more than 95% of cases (440). In this same study, a single serum progesterone level on day 16 did not provide further prognostic value and is therefore not recommended (440).

Patients are usually followed with serial serum hCG levels early in pregnancy, followed by transvaginal ultrasound at 5 to 6 weeks of gestation to document intrauterine location of the pregnancy and the number of gestational sacs. This is especially important for patients with risk factors for ectopic pregnancy, those who are experiencing vaginal bleeding, and those at high risk for multiple gestation. In addition, such close follow-up in early pregnancy is both indicated and necessary among ART patients because an ongoing pregnancy requires patients to continue daily self-administration of supplemental progesterone (until the luteal-placental shift at about 9 to 10 weeks of gestation). Transvaginal ultrasound at 7 to 8 weeks for identification of fetal cardiac activity can provide further reassurance.

Success Rates

Success rates of IVF vary from program to program; within a program, the rates of success vary with the patient's diagnosis and age. The most comprehensive assessment of the efficacy of ART in North American programs comes from the database of the Society for Assisted Reproductive Technology (SART) (437). The society's data collection began in 1985, and its annual summary is published in an effort to improve the quality of statistical reporting on ART. The database attempts to eliminate the effects of interprogram variation. The most recently published report of the society summarizes the results of ART in the United States and Canada for 1997, which are shown in Table 27.9 (437). Information on SART and registered ART clinics are accessible by the public at http://www.sart.org. Significant improvements in the overall ART outcomes have been made when compared with the last published results. In 1997, a 28.4% (16.8% in 1992) rate of delivered pregnancies was reported per oocyte retrieval for standard IVF, with a cancellation rate of 21.7% (15.4% in 1992), a pregnancy loss rate of 18.1% (20% in 1992), and an ectopic pregnancy rate of 0.9% (1.2% in 1992) per transfer. The delivered-pregnancy rate for cryopreserved embryo transfer was 18.8% in 1997 (11.6% in 1992). Although the rates of birth defects did not appear to be different from that of the general population, the SART reporting system was not designed to specifically address this issue.
method by which most of these patients can become pregnant. Other patients to be considered for donor oocyte technology may include those with poor oocyte quality (including some patients with failed fertilization), those with poor ovarian response to stimulation, and those with a history of multiple failed ART cycles. Using embryos fertilized from donor eggs in 418 fresh embryo transfer involving 276 recipients, clinical pregnancy and delivery rates were 36.2% and 29.3%, respectively. The cumulative pregnancy rate after four cycles reached 87.9% (441).

Treatment with donor oocytes is available in most ART programs. The method of donor selection is an important consideration. Some patients may wish to find their own donor in a sister or friend; others may choose to use a matching service to identify a donor, who can remain anonymous. Although some ART programs may choose to be excluded from the matching process, most will assume the responsibility of screening the donor for medical, reproductive, and psychological fitness. Like semen donors, potential oocyte donors must be stringently assessed, including screening for transmissible infectious or genetic diseases. Unlike semen, however, oocytes cannot presently be cryopreserved and quarantined; hence, the risk for transmission of infectious agents cannot be completely averted. Moreover, because oocyte donation involves COH, a donor is exposed to the same intensive monitoring and significant potential complications inherent to this intervention. Potential donors must be provided with detailed educational information and meticulous informed consent is mandatory. In addition to undergoing medical screening, oocyte donors are subjected to a comprehensive psychosocial evaluation before being accepted as program participants. Even with such extensive screening and preparation, there is a significant dropout rate for both anonymous and directed oocyte donors (442). It is advisable to obtain legal counsel in the development of any ovum donation center because many potentially litigious issues arise in the administration of such a program.

Oocyte cryopreservation is not generally available or successful and embryo cryopreservation reduces subsequent pregnancy rates. Considerable coordination is required to ensure that the recipient’s endometrium is appropriately prepared when embryos freshly fertilized from the donor oocytes are ready to be transferred (443). Regimens for ovulation induction and oocyte retrieval for the oocyte donor follow those of standard IVF protocols (Fig. 27.10). Note that the duration of a mock cycle is exposed to many of the adverse effects of COH protocols (OHSS, postoperative pelvic discomfort, surgical and anesthesia risks, and medication side effects), her risk for multiple gestation and ectopic pregnancy can be virtually eliminated if she abstains from intercourse during her stimulation cycle.

![Figure 27.10 Regimens of ovarian stimulation and hormone replacement used to synchronize the development of ovarian follicles in the oocyte donor and the endometrial cycle in the recipient. (hMG, human menopausal gonadotropin; hCG, human chorionic gonadotropin; b-hCG, the b subunit of hCG; OHSS, ovarian hyperstimulation syndrome; OCP, oral contraceptive pill, ART, assisted reproductive technology.) hape Reproduced with permission from: Chang PL, Sauer MY. To ensure adequate endometrial preparation, most recipients of donor oocytes are taken through a “mock” cycle before their actual treatment cycle. During the mock cycle, all hormonal agents are administered, and endometrial adequacy is determined. The impact that the completion of a mock cycle might have on the pregnancy rates of subsequent ART cycles with donor eggs has not been studied in a randomized trial. However, important factors such as patient compliance, histologic evidence of endometrial response to exogenous hormones, and the ease of embryo transfer can be assessed (444). Many regimens for endometrial preparation have been described, although successful pregnancies have also been reported after embryo transfer in natural cycles. The following is a typical regimen for endometrial preparation in recipients of donor oocytes:

- **If the recipient has no baseline ovarian function, no downregulation or baseline testing is required.** However, if the recipient has endogenous ovarian function, GnRH agonist is started on day 21 in the luteal phase of the previous cycle. At onset of menses, downregulation is confirmed with serum estradiol levels of less than 50 pg/mL and progesterone levels of less than 1.0 mg/mL. If confirmed, the dose of GnRH agonist is reduced.
- **Start estradiol (Estraderm patches 0.2 mg every 48 hours or Vivelle patches 0.2 mg every 48 hours or Estrace, 1.0 mg orally once per day).**
- **Monitor serum estradiol levels every 3 to 7 days and adjust dosage to maintain serum estradiol levels of 150 to 300 pg/mL, or continue fixed dose.**
- **Continue supplementation at dosages that maintain these estrogen levels for at least 21 days.**
- **The progesterone level is scheduled according to the day of embryo transfer (in a therapeutic cycle) or the day of endometrial biopsy (in the mock cycle).**
- **Start progesterone, 25–50 mg intramuscularly (day 1), then increase to 50–100 mg/d intramuscularly the following day.**
- **Discontinue GnRH agonist on day 2 of progesterone.**
- **Mock cycle: perform endometrial biopsy 10 to 12 days after progesterone is started. Therapeutic cycle: perform embryo transfer on day 4 of progesterone.**
- **Measure quantitative hCG 16 days or more after the day of donor oocyte retrieval.**

Many controversial issues and much ethical debate surround oocyte donation. Donors’ expectations regarding the process itself, the quality of their medical care, and their level of involvement in decisions can be addressed by a conscientious ART team (445). Other topics, such as methods of donor recruitment and amounts of financial compensation, are much more challenging issues (446, 447). Further effort is warranted to help clarify these issues and provide access to this highly efficacious ART treatment.

### Complications of ART

**Twins and Higher-order Multiple Gestation**

Multiple gestation, especially higher-order multiple gestation, is a serious complication of infertility treatment and has tremendous medical, psychological, social, and financial implications. In recent years, it has been reported that only 25% of higher-order multiple gestations are the result of spontaneous conceptions. The remaining 75% are attributable to reproductive interventions. Of these multiple gestations, half are attributable to ART and half to the use of ovulation drugs in non-ART cycles (448). Because the average age of women attempting pregnancy has risen during recent decades and increased maternal age affects the incidence of multiple gestation, rates of higher-order multiple gestation must be adjusted for maternal age when compared across time (449). For decades before 1971, higher-order multiple gestation occurred at a maternal age–adjusted incidence of about 30 per 100,000 live births from spontaneous conceptions (449, 450). This incidence rose to 173.6 per 100,000 live births in 1997 (449) (Table 27.11). Because higher-order multiple gestations are predominantly triplets (91.2% were triplets in 1997) (448), this rate represents 6,737 triplets born in the United States in 1997 alone (Table 27.12).
Significant medical risks accompany higher-order multiple gestation. There is an increased incidence of potentially life-threatening obstetric conditions such as acute fatty liver (452) and severe preeclampsia (453). The rate of fetal death during the third trimester is also unacceptable high at almost 17% (454). Obstructively, triplets are at increased risk for preterm birth, low birth weight (<2,500 g), and very low birth weight (<1,500 g) compared with singletons or twins (451,455). When adjusted for gestational age at birth, triplets have the same rates of neonatal morbidity and mortality as twins and singletons (456,457), but triplets typically deliver much earlier. One exception to this equalization is that premature triplets are at significantly greater risk for severe retinopathy of prematurity even when delivered at the same gestational age as a matched singleton or twin (457). Because of the extensive obstetric and neonatal intensive care required in higher-order multiple gestation pregnancies, enormous expenditure requirements are required to provide medical care to these families (458). Finally, although not fully described, the immediate and long-term emotional and psychological impact on the mother, her partner, and the family unit, including other siblings, is likely to be daunting.

To rectify this trend in higher-order multiple gestations, a number of medical and nonmedical causes are being identified. Non-ART COH with gonadotropins is a highly efficacious and commonly used treatment modality for infertile couples. It is significantly less expensive than ART and thereby more accessible to many patients. Unfortunately, it is associated with a 20% incidence of twin gestations and 10% incidence of higher-order multiple gestation (459). Current monitoring protocols for non-ART COH, based on serum estradiol levels and the number of large follicles on ultrasound, cannot entirely predict the risk of higher-order multiple gestation (460). The risk for higher-order multiple gestation is significantly increased with younger age, peak serum estradiol levels greater than 1,385 pg/mL, and a total number of follicles of seven or more (460). It is difficult to glean the significance of this latter measurement, however, because total follicle number depends on which follicles are monitored, and this is uncertain even in aneuploid embryos. Further, a high total number of follicles may result from overstimulation of a patient with normal ovaries but unexpectedly high ovarian response or from treatment of a patient with PCO-like ovaries. Because the prevention and management strategies would differ for these two conditions, further stratification of patients and characterization of the COH cycles may clarify relative risks and direct more efficacious prevention of multiple gestation and OHSS.

Suggestions to address non-ART COH as a cause of higher-order multiple gestation are being explored. None is without cost. One option would promote lowering the dosage of gonadotropins used in COH to aim at a lesser degree of ovarian response. This approach will almost certainly lower pregnancy rates. An alternative would be fewer interventions with non-ART COH and substitution with ART. In ART, the rate of higher-order multiple gestation is determined by the number of embryos transferred, not the ovarian response, so that there is a greater control of the higher-order multiple gestation rate by physicians. This approach, however, would require a dramatic change in the guidelines for insurance company reimbursement of infertility treatments or would necessitate the financing of such treatment by the couple. Currently, there are no accepted criteria guiding when a non-ART cycle should be cancelled in an attempt to reduce the risk for higher-order multiple gestation.

Informed recommendations for such standardization might be helpful.

More progress is being made toward reduction of higher-order multiple gestation in the area of ART. One approach, discussed under Embryo Transfer, would involve greater use of extended embryo culture, in which embryos are allowed to grow to the blastocyst stage in vitro. Blastocysts have been shown to have greater developmental potential and higher implantation rates than day 3 embryos, so that even if fewer (a maximum of one to two) blastocysts are transferred, pregnancy rates remain high (420). Another approach would follow the lead of countries outside the United States that have defined set limits for the maximum number of embryos transferred in a given ART cycle. The American Society of Reproductive Medicine has recently addressed this issue by publishing guidelines for embryo transfer during ART. Briefly, a maximum of three, four, and five embryos can be transferred to women with above-average prognosis (age < 35 years), average prognosis (age between 30 and 40 years), and below-average prognosis (age > 40 years or multiple failed ART cycles), respectively (461). In donor oocyte cycles, the age of the donor (not the recipient) should be used to determine the number of embryos to be transferred (461). Data on the efficacy of this protocol is expected to be available in a few years. Meanwhile, Templeton and Morris advocated even more stringent guidelines, promoting the transfer of a maximum of two embryos in ART cycles to minimize the risk for higher-order multiple gestation (462). Cryopreservation of excess embryos should certainly be encouraged further in order to promote more cycles involving transfer of cryopreserved embryos. Universal application of such changes will force patients and doctors to emphasize cumulative birth rates rather than pregnancy rate per cycle. By focusing on cumulative birth rates, patients can have more realistic expectations, and the demand to have an excessive number of embryos transferred would decrease (463,464). As discussed for non-ART COH, these changes will involve alterations in the entire financial reimbursement structure for ART services. There is no doubt that this approach will present many challenges.

Other factors contributing to the increased rates of higher-order multiple gestation have been identified. It has been suggested that government-mandated annual reporting of clinical specific pregnancy rates places undue emphasis on pregnancy rate per cycle. This may encourage the promotion of higher pregnancy rates at the expense of higher multiple pregnancy rates. If our goal in infertility therapy is the delivery of a healthy baby, both pregnancy rates and incidence of multiple gestation must be considered in determining treatment efficacy. Financial reimbursement schedules by insurance companies, lack of federal support for IVF research, and insufficient patient education regarding the true risk for higher-order multiple gestation are all being examined (465,466,467 and 468).

On the scientific front, new technologies, such as preimplantation genetic diagnosis, may ultimately eliminate the risk for higher-order multiple gestation. Preimplantation genetic diagnosis is a clinical diagnostic procedure that can be performed on the embryo itself in order to determine whether a particular genetic abnormality is present before its transfer into the uterus (469). Preimplantation genetic diagnosis has been developed in an effort to improve the chances of having healthy infants among families at high risk for a particular genetic disease. It is most frequently performed using blastomere (a cell from a day 3 embryo containing six to eight cells) biopsy, followed by genetic testing on the cell obtained. The technique chosen for diagnostic testing depends on the type of genetic defect being investigated. For example, fluorescence in situ hybridization (FISH) can be used to assess aneuploidy, translocation, and other chromosomal structural defects (470). FISH can also be used to exclude transmission of genetic diseases by identification of specific disease-causing alleles. Alternatively, familial single gene mutations can be identified by extracting blastomere DNA, followed by polymerase chain reaction, restriction enzyme digest, or sequencing. In a recent study involving 226 ART cycles, the embryos obtained from women with a poor prognosis (characterized by age older than 35 years with previous IVF failures and karyotypic abnormalities or aneuploidy for euploid embryos) were all screened for single gene mutations (471). Those embryos with single gene mutations (commonly involved in aneuploidies (X, Y, 13, 14, 15, 16, 18, 21, and 22) were assessed using FISH in the study group. Although fewer embryos were transferred in the preimplantation genetic diagnosis group, higher clinical pregnancy rates (37% versus 27%) and implantation rates (22.5% versus 10.2%) were reported when compared with controls (472). Therefore, preimplantation genetic diagnosis may assist in the selection of euploidic embryos, relegating to this technique a tremendous potential in lowering the risk of higher-order multiple gestation.

As progress is being made to eradicate the complication of higher-order multiple gestation, others have suggested ways to reduce subsequent risks once higher-order multiple gestation has occurred. One option for preventing some of the maternal and fetal complications of higher-order multiple gestation involves the judicious use of selective pregnancy termination or multifetal reduction. Although any higher-order multiple gestation is a candidate for this procedure, the reduction of triplet to twin pregnancies is most common and best studied. Overall, about 14% of triplet pregnancies reduce spontaneously to twin pregnancies after fetal heart activity is documented on transvaginal ultrasound at 6 to 9 weeks (473,474). Although some studies have not found multifetal reduction to result in significant improvement in gestational length or intrauterine growth restriction (474,475), many centers have reported improved outcomes after reductions to twin gestations. Twin gestations

Table 27.11. Rate* of Triplet and Higher-order Multiple Births, by Mother's Age; United States, 1980–1997

Table 27.12. Contribution of Assisted Reproductive Technology (ART) to Triplet and Higher-order Multiple Births († Triplet)—United States, 1989–1997
after reduction have similar outcomes when compared with spontaneous twin gestations (476,477). Reduction of triplet to twin gestation has been reported to decrease the risk for preterm birth (478), low birth weight (478), preeclampsia (477), and delivery before 36 weeks (477). Specifically, preterm birth before 28, 32, and 34 weeks of gestation, as well as birth weights of less than 1,000, 1,500, and 2,000 g were significantly lower in twins after reduction from triplet pregnancy compared with triplets who did not undergo reduction (479). However, any benefits achieved for newborn health often incur tremendous emotional, psychological, and physical costs. The major complications of fetal reduction include a 13% risk for premature rupture of the membranes for triplet reduction (480). There is a 5% to 10% risk for losing the entire pregnancy (481) after reduction has occurred. Further, major depression occurs in 80% of women who lose the pregnancy as a complication of fetal reduction and in one third of women who have live twins after fetal reduction (482).

Ovarian Hyperstimulation Syndrome

OHSS is a medical complication that is both completely iatrogenic and unique to the treatment of infertility. Although the pathophysiology of OHSS is not well understood, the signs and symptoms of this disease can be attributed to local and systemic increase in capillary permeability. These changes, in turn, result in the depletion of intravascular volume at the expense of third-space fluid accumulation.

OHSS has been directly associated with increasing numbers of stimulated follicles and retrieved oocytes (483,484), the presence of PCOS (485,486 and 487) and high serum estradiol levels (483,485,489). Despite these associations, however, hyperestrogenemia is not currently thought to be the main cause of OHSS (480,491,495 and 493). Rather, the increased production of vasoactive substances, such as prorenin, renin, angiotensin-converting enzyme, angiotensin I, angiotensin II, and angiotensinogen, by the hyperstimulated ovaries has been implicated in this disease (494,495,496,497,498,499,500,501 and 502). Still, it remains possible that hyperestrogenemia, especially in the presence of hemoconcentration, has important effects on the thromboembolic risks demonstrated with OHSS.

Inflammatory responses are certainly present in OHSS patients, with possible roles for cytokines, histamine, and prostaglandins in the disease pathogenesis (503,504,505,506,507,508 and 509). In particular, the link between vascular endothelial growth factor (VEGF) and OHSS has been extensively studied. VEGF has been shown to exhibit a dose-related response in human granulosa cells upon stimulation by hCG (510). Further, serum VEGF levels correlate with OHSS severity (511,512) demonstrating a sensitivity and specificity of 100% and 60%, respectively (512). The central role of an inflammatory response is supported by a number of other findings. For instance, mast cells are abundant in ovulatory follicles (513), and histamine blockade has been reported to ameliorate and, in some cases, even prevent OHSS in animal models (505,506 and 507,514). Further, it is clinically well recognized that allergy or hypersensitivity act as risk factors for the development of OHSS (493). However, to date, scientific evidence for these factors is still considered preliminary, and further investigation is warranted to clarify their true role in OHSS (493).

Recently, a distinction between early- and late-onset OHSS has been described (515). Early OHSS, with onset arbitrarily set within 9 days of oocyte retrieval, is associated with higher serum estradiol levels and follicle numbers during COH. In contrast, late-onset OHSS has been associated, not with measures of follicular response, but rather with multiple gestation. Early and late OHSS may even reflect somewhat distinct pathophysiologic mechanisms. It has been proposed that early OHSS may result from ovarian stimulation by the exogenous hCG given to trigger ovulation, whereas late OHSS may be more closely linked to the endogenous hCG produced when pregnancy ensues (515).

OHSS has a varied spectrum of clinical presentation. An attempt to better understand this heterogeneity led to the development of a staging system for OHSS that would reflect symptom severity. This classification categorizes patients into mild, moderate, and severe disease (516). In mild OHSS, patients often complain of mild abdominal distention and soreness, nausea, and vomiting. Ovarian enlargement can be 5 to 12 cm. Moderate disease is marked by the presence of abdominal ascites on ultrasound examination. Severe disease is diagnosed when there are clinical signs of tense ascites, hydrothorax, shortness of breath, hemoconcentration, hypercoagulability, or any complications of OHSS such as renal failure, thromboembolism, or acute respiratory distress syndrome (ARDS).

This classification may serve as a useful guide; however, its application may sometimes be misleading. For example, ovarian enlargement is common after COH and, by itself, is not informative. Further, many patients experience mild pelvic soreness and abdominal bloating after COH, and their ovaries may be enlarged when viewed on transvaginal ultrasound. Whether these patients reflect an abnormal response to COH or merely represent a subset of normal responders is debatable. The fact that reported incidence of OHSS after COH has ranged from 7.3% (mild or moderate disease) and 4.2% (severe disease) to 33% overall may suggest that the staging system is itself open to interpretation (493,516).

Management of OHSS

Patients undergoing COH with or without ART should be educated about the signs and symptoms of OHSS. They should be instructed to contact their health care provider if they experience abdominal bloating, abdominal discomfort or pain, early satiety, nausea, vomiting, decreased urine output, or weight gain of more than 2 lb per day. Patients with these symptoms should be fully assessed to establish their baseline condition for future comparisons, if that should become that necessary. Following are those points most pertinent in the assessment of patients with OHSS potential:

**History**

- Age, history of OHSS in previous infertility treatment, history of PCOS
- Characteristics of COH (dose of gonadotropins, number of follicles, number of eggs for an ART cycle, peak serum estradiol level, date of NCG administration, date of oocyte retrieval, date of embryo transfer, number of embryos transferred at embryo transfer)
- Onset of symptoms, their progression (stable versus rapidly worsening), and their severity

**Specific questions should address the presence of the following symptoms:**

- Abdominal discomfort, pain, bloating; increased abdominal girth; early satiety
- Shortness of breath, chest pain
- Nausea, vomiting
- Weight gain (total amount gained since start of COH and pounds gained per day)
- Decreased urine output

A complete physical examination should be performed, with specific attention to the following areas:

- Signs of hypotension, hemodynamic instability, and dehydration
- Chest: evidence of pleural effusion, congestive heart failure, limited chest expansion because of ascites
- Abdomen: ascites (mild, moderate, tense), peritoneal signs
- Peripheral exam: pitting edema
- Pelvic exam is contraindicated because enlarged ovaries can be fragile

**Investigations**

- Complete blood count, prothrombin time, partial thromboplastin time, serum electrolytes, liver function tests, creatinine, blood urea nitrogen
- Chest x-ray if there is significant shortness of breath or abnormalities on chest exam (shifting the pelvis can protect potential pregnancy from irradiation)
- Transvaginal ultrasound to document the baseline amount of ascites and size of ovaries
- Documentation of oxygen saturation is indicated if there is evidence of respiratory compromise
- Serum hCG on day 16 after oocyte retrieval if embryo transfer has occurred

This initial assessment should decide whether the OHSS patient needs to be admitted to the hospital for observation and supportive care. Accepted indications for hospitalization include inability to tolerate oral hydration, hemodynamic instability, respiratory compromise, tense ascites, hemoconcentration, leukocytosis, hyponatremia, hyperkalemia, abnormal renal or liver function, and decreased oxygen saturation. If the diagnosis and its severity remain in doubt after initial assessment, it is reasonable to observe patients overnight while further assessing fluid balance and the presence of oliguria. The need for more prolonged hospitalization often becomes rapidly evident. The presence of peritoneal signs, such as abdominal rebound tenderness or guarding, in a patient with possible OHSS may indicate ovarian torsion, hemorrhage, or rupture of enlarged ovarian cysts. These signs may also represent those rare cases of postoocyte retrieval tuboovarian abscess. Further, admission to hospital is mandatory, and admission to an intensive care setting should be seriously considered if the patient has complications of
OHSS such as renal failure, ARDS, thromboembolic disease, or severe hydrothorax.

The onset of OHSS after hCG administration or oocyte retrieval is associated with an increased risk for progression to severe disease. Pregnancy is also known to cause worsening of OHSS, most likely due to ovarian stimulation by endogenous hCG. Therefore, in cases of very-early-onset OHSS, the benefits of withholding embryo transfer, cryopreserving these embryos, and performing ET in a future unstimulated cycle should be considered and discussed.

**Outpatient Management** If hospitalization is not indicated at initial presentation, the patient can be managed as an outpatient, she should be instructed to limit her activity, to weigh herself daily, and to monitor her fluid intake (at least 1 L/day of mostly electrolyte-balanced fluid) and output. Daily follow-up by telephone or visit is important because the severity of OHSS may change any time. The patient should contact her health care provider if she notes worsening of the symptoms or if her weight gain increases to more than 2 lb per day. Reassessment is indicated in these situations.

**Inpatient Management** Inpatient management of patients with OHSS is composed of meticulous vital sign and fluid balance monitoring as well as supportive care. This typically involves use of intravenous hydration and prevention of complications such as thromboembolic prophylaxis, although more invasive interventions, such as paracentesis, may become necessary. The following is a typical inpatient protocol used for management of the patient with moderate to severe OHSS:

**Perform the initial assessment as outlined previously.**

- Vital signs (including oxygen saturation monitoring if respiratory compromise is present) every 4 hours initially
- Fluid intake and output measurements
- Daily abdominal girth
- Daily hematocrit, leukocyte count, serum electrolytes, renal function tests
- Liver function tests, prothrombin time, partial thromboplastin time on admission and then repeated only as necessary

**Supportive Care**

- If there is hypotenion or oliguria, give a bolus of 1 L of normal saline (NS) over 1 hour, then maintain with D5NS (or D5 _NS) at 150 mL/h. If there is no hypotenion or oliguria, but the hematocrit is greater than 45%, start maintenance at D5NS at 150 mL/h. The maintenance rate for intravenous fluids can be lowered when the hematocrit is normal. Although the administration of intravenous fluids will certainly lead to an increase in third spacing, it is important to maintain adequate intravascular volume and urine output. The hematocrit may need to be monitored twice a day initially; the intravenous fluid maintenance can be titrated downward as the hematocrit normalizes. This should help to minimize third-spacing side effects. Lactated Ringer's solution should not be used for intravenous hydration in patients with OHSS.

- If oliguria persists, a small bolus of 250 to 500 mL of NS can be given to increase urine output. The efficacy of albumin (or other plasma expanders) in the treatment or resolution of OHSS has not been studied in a prospective, randomized fashion. However, it is reasonable to attempt gentle diuresis in a patient who has normal blood pressure and hematocrit but in whom oliguria or weight gain persists. This may be accomplished using sequential administration of 50 mL of 25% or 50% dextrose and 1 L of saline infused intravascularly. This can be repeated up to 4 times per 24 hours as necessary. Serum sodium, potassium, and creatinine must be monitored closely when employing albumin or dextrose solutions.

- Small amounts of fluid can be taken orally. As the OHSS improves, amount of intake can be increased as the intravenous fluid maintenance decreases. During the resolution of OHSS, a maximum total input of 1 L/h has been recommended to prevent increases in third spacing (593).

- Paracentesis is indicated if the patient has severe abdominal discomfort and respiratory compromise due to large volumes of ascites. Hydrothorax has also been reported to resolve after paracentesis. Presence of massive ascites combined with persistent oliguria or hypotension despite medical therapy is also an indication for paracentesis because diuresis often results after the severe abdominal pressure is relieved. Both abdominal paracentesis under ultrasound guidance and thoracentesis are successful procedures to drain fluid from the peritoneal and pleural cavities. Both are described and accepted practices (517,519).

- If embryo transfer has already been performed or is scheduled, progesterone supplementation should be given as indicated by the ART protocol. Administration of progesterone is not thought to affect OHSS adversely. However, pregnancy may cause worsening of OHSS as a result of the stimulation of the ovaries by increasing levels of endogenous hCG.

- Anticoagulants and antiplatelets (i.e., acetaminophen) can be given symptomatically.

- Complications of OHSS, such as ARDS, thromboembolism, and renal failure, should be treated in the intensive care setting when indicated.

**Preventive Measures**

- Hemococoncentration and severe leukocytosis are considered risk factors for thromboembolic disease among OHSS patients (493). Therefore, heparin, 5,000 IU subcutaneously twice a day, should be given to all OHSS inpatients to prevent thromboembolism. In addition, high-high vascular support stockings should be used in ambulatory patients. Intermittent compression stockings should be used for patients who are not ambulating.

**Prevention of OHSS** Because OHSS has the potential to cause severe and sometimes life-threatening complications, it is prudent to aim toward disease prevention. It is usually not possible to identify patients who are at risk for OHSS during COH. However, when high estradiol levels (³300 pg/mL) are noted before hCG administration, prevention of OHSS can be attempted using a technique called coasting. Coasting involves withholding gonadotropin and delaying hCG until serum estradiol levels decrease or follicular diameter of greater than or equal to 18 mm is seen on transvaginal ultrasound (372,373) and (374). Coasting does not completely prevent the risk for severe OHSS or cycle cancellation, but it does minimize the risk for severe OHSS while maintaining high pregnancy rates. An alternative strategy to minimize the risk of OHSS is to cryopreserve embryos and delay transfer of thawed embryos to the uterus in a subsequent cycle using endometrial preparation without COH. The strategy of prezygote cryopreservation results in excellent pregnancy and live birth rates comparable to similar cycles with ultrasound-guided transvaginal paracentesis are described and accepted practices (517,519).

**Ectopic and Heterotopic Pregnancies**

- The incidence of ectopic pregnancy is 2% in the general population (525). However, its incidence is increased in IVF and can be as high as 4% (526). The main risk factors for ectopic pregnancy in IVF treatment are tubal factor infertility and possibly, previous myomectomy (526). The incidence of heterotopic pregnancy, which is normally rare, is particularly high (1%) after IVF treatment. Multiple gestation and high hormonal levels during COH and early pregnancy have been suggested to be possible causes. It is important to have a high index of suspicion for the occurrence of heterotopic pregnancies because only 40% to 84% of cases can be diagnosed on transvaginal ultrasound at the initial presentation (527,528). After treatment of the heterotopic gestation with laparoscopy, laparotomy, or ultrasound-guided KCI injection into the extrauterine pregnancy, the overall delivery rate for the intrauterine pregnancy is 66% (527).

**Risk for Cancer after Fertility Therapy**

The possibility that ovulation-inducing medications might promote the development of cancers of the reproductive tract was first introduced in the early 1990s by Whittemore and colleagues, specifically with regard to ovarian cancer (529). One theory behind this proposed risk is that ovarian cancer may arise, in some cases, as the result of damage to the ovarian epithelium during ovulation. Lactation, oral contraceptives, late onset of menarche, early menopause, and multiparity are known to protect against ovarian cancer. Moreover, each is associated with a reduction in the total lifetime number of ovariule cycles. The decreased risk for ovarian cancer noted among women with increased length of anovulation begged the question of whether dramatic increase in the number of eggs ovulated during superovulation therapy would, in turn, increase the risk for ovarian cancer. Alternatively, some believe that because gonadotropins (FSH and LH) increase cellular proliferation and division within ovarian follicles, their use might create a predisposition toward the occurrence of cancer cells. Both of the most common hormonal therapies used for induction of ovulation—clomiphene citrate and exogenous gonadotropins—result in increased gonadotropin stimulation to the ovary. These therapies therefore
increase the incidence of ovarian cancer in fertility patients. Concern about this potential risk for cancer after fertility therapy has also been extended to other ovarian and uterine cancers. The authors reported no overall increased incidence of uterine, breast, or ovarian cancers in women exposed to medications used for IVF (535). Results from a recent prospective, randomized trial support the value of group cognitive-behavioral therapy among infertile couples (536). This therapy uses a variety of approaches, including relaxation training such as yoga, cognitive restructuring, methods for emotional expression, and information on nutrition and exercise with respect to infertility. Although the mechanism by which relaxation therapies aid fertility is unknown and such as high dropout rates need to be addressed by further research, the option of psychological support and counseling, on an individual or group basis, should be offered to patients experiencing infertility (537).

**Preservation of Fertility in Cancer Patients**

Aside from helping subfertile couples build families, technologic advances in tissue and gamete cryopreservation, in combination with ART, have made future fertility possible for some men and women who are faced with surgery, radiotherapy, or chemotherapy for cancer treatment. Sperm cryopreservation has become a widely available option to allow fertility preservation in young men whose cancer treatment may render them infertile. The wide range of neoplastic disorders for which sperm cryopreservation have been successful include leukemia, lymphoma, Hodgkin's lymphoma, non-Hodgkin's lymphoma, and testicular cancer (538). Although most patients with these disorders are systemically ill and therefore exhibit decreased total molar sperm counts when compared with patients who do not have cancer, less than 20% have azoospermia, and cryopreservation is possible in most patients (538). Further, cryopreserved sperm from cancer patients tolerate thawing as well as samples obtained from patients without cancer (539).

Unfortunately, the efficacy of oocyte cryopreservation lags far behind that of sperm preservation. Married women who are scheduled to undergo sterility-inducing cancer treatments may take the option of completing an IVF cycle so that oocytes can be fertilized and the resulting embryos can be cryopreserved for transfer later in life. However, an IVF cycle may require 2 weeks to complete, rendering this option unrealistic for patients in whom a delay in cancer treatment would compromise their prognosis. Even patients who are able to undergo IVF treatment usually do not have the time necessity for use of a downregulation protocol. Consequently, these women are usually prescribed the shorter, flare protocol, which may give suboptimal response (396). GnRH antagonists may have a special advantage in this situation. GnRH antagonists can induce hypothalamic–pituitary downregulation after being started on day 6 of gonadotropin treatment, which obviates the need for the more time-consuming use of GnRH agonists (540).

Patients who are single or who have medical contraindications to IVF treatment may be candidates for ovarian tissue cryopreservation. Ovarian cortical biopsy is an available option to allow fertility preservation in young men whose cancer treatment may render them infertile. The wide range of neoplastic disorders for which sperm cryopreservation is possible in most patients (538). Further, cryopreserved sperm from cancer patients tolerate thawing as well as samples obtained from patients without cancer (539).

References

9. Carlsen E, Giwercman A, Keiding N, et al. First, contemporary fertility treatments and their dosages remain relatively new and are usually used in women younger than 40 or 45 years of age. Because ovarian, uterine, and some breast cancers typically occur in older women, the number of patients who were treated with fertility drugs and are now in their middle to late 60s may still be too small to allow a detailed comparison of infertile cancer risk. Second, it is hard to differentiate the effect of fertility treatment from the effect that being infertile might itself have on future development of malignancies of the breast, uterus, or ovary. Finally, most of the studies addressing these risks are limited by small numbers, intake of a variety of medications, and recall bias. All these factors make the interpretation of data difficult (530).
10. Two of the most recent studies failed to attribute an increased risk for breast, uterus, or ovarian cancer to medications used for superovulation in the treatment of infertility (531,532). One study evaluated more than 20,000 women with exposure to fertility drugs used for IVF and compared them to nearly 10,000 infertile controls. The authors reported no overall increased incidence of uterine, breast, or ovarian cancers in women exposed to medications used for IVF (532). Two other interesting findings represent some of the limitations to these types of studies. The authors reported that the risk for ovarian and uterine cancer was higher in women with unexplained infertility, regardless of whether they had received ovulation induction medications. This may suggest risks associated with the unexplained infertility itself, instead of the presence of undiagnosed polycystic ovarian syndrome. In addition, the authors reported an increased risk for breast and uterine cancer only within the first year after receiving infertility medications for IVF. Again this result is confusing. Patients undergoing IVF are followed closely and may therefore be more likely to report early signs or symptoms of these cancers to their physicians. Alternatively, rather than causing these cancers, fertility medications may only stimulate the growth and subsequent diagnosis of preexisting tumors.

**Psychological Support**

Stress, as manifested by anxiety or depression, is thought to be increased in women experiencing infertility. The relationship between stress and infertility is complex and may represent a vicious cycle in which infertility results in stress, which results in further difficulty in conceiving (533,534 and 535). Results from a recent prospective, randomized trial support the value of group cognitive-behavioral therapy among infertile couples (536). This therapy uses a variety of approaches, including relaxation training such as yoga, cognitive restructuring, methods for emotional expression, and information on nutrition and exercise with respect to infertility. Although the mechanism by which relaxation therapies aid fertility is unknown and such as high dropout rates need to be addressed by further research, the option of psychological support and counseling, on an individual or group basis, should be offered to patients experiencing infertility (537).

**Other Considerations**

One of the most important aspects of the treatment of patients with subfertility or infertility is the process of deciding when no further treatment will be pursued. Couples should be warned about the risk of early in vitro fertilization (IVF) treatment. Patients with personal or family history of infertility should be forewarned about the possibility of infertility. It is equally important to identify an end point to medical intervention at the outset of treatment. This end point offers patients a mental time frame in which they can both make medical and personal decisions. One viable alternative for adoption, although the process of adoption has recently become increasingly complex. Many patients may want to explore simultaneously infertility therapy and adoption. The choice of course to pursue is a very difficult decision that may be facilitated by both physician input and strong psychosocial counseling and support.

**Preservation of Fertility in Cancer Patients**

Aside from helping subfertile couples build families, technologic advances in tissue and gamete cryopreservation, in combination with ART, have made future fertility possible for some men and women who are faced with surgery, radiotherapy, or chemotherapy for cancer treatment. Sperm cryopreservation has become a widely available option to allow fertility preservation in young men whose cancer treatment may render them infertile. The wide range of neoplastic disorders for which sperm cryopreservation have been successful include leukemia, lymphoma, Hodgkin’s lymphoma, non-Hodgkin’s lymphoma, and testicular cancer (538). Although most patients with these disorders are systemically ill and therefore exhibit decreased total molar sperm counts when compared with patients who do not have cancer, less than 20% have azoospermia, and cryopreservation is possible in most patients (538). Further, cryopreserved sperm from cancer patients tolerate thawing as well as samples obtained from patients without cancer (539).

Unfortunately, the efficacy of oocyte cryopreservation lags far behind that of sperm preservation. Married women who are scheduled to undergo sterility-inducing cancer treatments may take the option of completing an IVF cycle so that oocytes can be fertilized and the resulting embryos can be cryopreserved for transfer later in life. However, an IVF cycle may require 2 weeks to complete, rendering this option unrealistic for patients in whom a delay in cancer treatment would compromise their prognosis. Even patients who are able to undergo IVF treatment usually do not have the time necessity for use of a downregulation protocol. Consequently, these women are usually prescribed the shorter, flare protocol, which may give suboptimal response (396). GnRH antagonists may have a special advantage in this situation. GnRH antagonists can induce hypothalamic–pituitary downregulation after being started on day 6 of gonadotropin treatment, which obviates the need for the more time-consuming use of GnRH agonists (540).

Patients who are single or who have medical contraindications to IVF treatment may be candidates for ovarian tissue cryopreservation. Ovarian cortical biopsy specimens containing numerous primordial follicles have been successfully retrieved by a laparoscopic approach in healthy volunteers and in cancer patients (541,542 and 543). It remains to be determined whether this promising technology creates a risk for reintroduction of malignant cells after autotransplantation of ovarian tissue and whether thawed immature oocytes should be used in in vitro maturation protocols.

Advances in the ability to document and diagnose early pregnancy have revealed that spontaneous pregnancy loss is a common event. Spontaneous pregnancy loss is, in fact, the most common complication of pregnancy. About 70% of human conceptions fail to achieve viability, and an estimated 50% are lost before the first missed menstrual period (1). Most of these pregnancy losses are unrecognized. Studies using sensitive assays for human chorionic gonadotropin (hCG) indicate that the actual rate of pregnancy loss after implantation is 31% (2). Of pregnancies that are clinically recognized, loss occurs in 15% before 20 weeks of gestation (from last menstrual period) (3,4).

Traditionally, recurrent abortion has been defined as the occurrence of three or more clinically recognized pregnancy losses before 20 weeks from the last menstrual period. Using this definition, recurrent pregnancy loss occurs in about 1 in 300 pregnancies (2). Clinical investigation of pregnancy loss, however, should be initiated after two consecutive spontaneous abortions, especially when fetal heart activity is identified before any of the pregnancy losses, when the woman is older than 35 years of age, or when the couple has had difficulty conceiving. If clinical intervention is undertaken in the form of investigation after two spontaneous abortions, about 1% of pregnant women require evaluation (3). Even with a history of recurrent pregnancy loss, a patient is more likely to carry her next pregnancy to term than to miscarry. For patients with a history of recurrent pregnancy loss, the risk for subsequent pregnancy loss is estimated to be 24% after two clinically recognized losses, 30% after three losses, and 40% to 50% after four losses (5). These data make clinical study of recurrent pregnancy loss and its treatment difficult because very large groups of patients must be studied to demonstrate the effects of any proposed therapeutic intervention.

Etiology

Parental chromosomal abnormalities and thrombotic complications of the antiphospholipid antibody syndrome (APAS) are the only undisputed causes of recurrent abortion. However, collectively these abnormalities account for less than 10% to 15% of recurrent pregnancy losses. Although the exact proportion of patients diagnosed with a particular abnormality may vary among the populations studied, other associations have been made with anatomic abnormalities (12% to 16%), endocrine problems (17% to 20%), infections (0.5% to 5%), and immunologic factors, including those associated with APAS (20% to 50%). Other miscellaneous factors have been implicated and account for about 10% of cases. Even after a thorough evaluation, however, the potential cause remains unexplained in about half of cases (6) (Table 28.1).

</tr>
</tbody>
</table>
parent carries an overall normal gene content but has a piece of one chromosome inappropriately attached to another. Depending on the nature of the translocation (reciprocal or robertsonian), the gametes produced by the translocation carrier are either normal (reciprocal only), balanced, or unbalanced for the translocated DNA. Once fertilized by a chromosomally normal gamete, the resulting embryos may be either chromosomally normal (reciprocal only) or balanced or unbalanced carriers of the translocation. Most gametes and their resulting embryos with abnormal chromosomal status do not survive. Of those that do, live offspring are either carriers of a balanced translocation or, for robertsonian translocations, monosomic or trisomic for the translocated chromosomal DNA.

Among the possible chromosomal monosomies, only that of the X chromosome typically permits viable offspring. On careful examination, however, many of these offspring may, in fact, exhibit mosaicism. Recent evidence also suggests that embryonic chromosomal monosomy may be particularly prevalent among patients with a history of recurrent pregnancy loss who are undergoing in vitro fertilization (10). Compared with monosomies, chromosomal trisomies (e.g., trisomies 13, 18, and 21) appear to be tolerated a bit more readily, although mosaicism may be implicated with these abnormalities as well.

Neither family history alone nor a history of prior term births is sufficient to rule out a potential parental chromosomal abnormality. Whereas the frequency of detecting a parental chromosomal abnormality is inversely related to the number of previous spontaneous losses (9), the chance of detecting a parental chromosomal abnormality also is increased among couples who have never experienced a live birth. Of course, abnormalities may be detected upon parental karyotype analysis of some couples with a history of spontaneous abortions interspersed with stillbirths and live births (with or without congenital anomalies) as well. Unfortunately, the use of parental karyotyping in evaluating structural chromosomal etiologies of recurrent pregnancy loss may soon become an insufficient screening modality. Evidence now suggests that, in some cases, paternal chromosomal abnormalities may be isolated within a particular fertilizing spermatozoa (11). Further, aneuploid spermatozoa may be particularly motile (12).

Other structural chromosome abnormalities, such as inversions and insertions, also may contribute to recurrent abortion, as can chromosomal mosaicism and single gene defects. X-linked disorders uncommonly may result in recurrent abortion of male but not female offspring (13). Single gene defects and their resulting disorders (e.g., the delta F 508 mutation and cystic fibrosis) typically are recognized through either analysis of detailed family histories or the identification of some pattern of anomalies characteristic of a known heritable syndrome.

Recently, there has been a great deal of interest in the role of inherited thrombophilias in recurrent pregnancy loss (14,15). This heterogeneous group of disorders results in increased venous or arterial thrombosis. Their associations with pregnancy loss rest on both proven (16) and hypothetical alterations in placental growth and development, particularly placental vascular development. Abnormal placental vascularization and inappropriate placental thrombosis would limit the thrombophilic states to pregnancy loss. Although some thrombophilic states may be acquired, most are heritable. Those heritable thrombophilias most often linked with reference to recurrent pregnancy loss include hyperhomocysteinemia, activated protein C resistance associated with mutations in factor V Leiden deficiencies in proteins C and S, mutations in prothrombin, and mutations in antithrombin III.

Circulating homocysteine is derived from dietary methionine. Homocysteine, in turn, is metabolized either into cystathione or back into methionine (Fig. 28.1). The latter process involves the enzyme methylene tetrahydrofolate reductase (MTHFR) (15). The nutritional supplements folic acid, vitamin B\textsubscript{9}, and vitamin B\textsubscript{12} are all required for proper metabolism of homocysteine; therefore, their deficiency is associated with acquired elevations in circulating homocysteine levels (17,18). Although heritable deficiencies in the enzymes required for metabolism of homocysteine have been described for the pathways leading to cystathione formation and to methylation to methionine (14,15), the latter has received considerable attention. Point mutations in MTHFR are surprisingly common (19,20), are associated with hyperhomocysteinemia, and are linked to thrombosis (15). Data directly linking hyperhomocysteinemia, folic acid, vitamin B\textsubscript{12}, and MTHFR mutations to recurrent pregnancy loss have been contradictory (21,22,23,24 and 25). However, two recent studies have evaluated pooled data from previous investigations (one using metaanalysis), and both studies show these disorders to be linked to risk for recurrent pregnancy loss (15-25).

![Figure 28.1 Homocysteine metabolism. Dietary methionine is metabolized either to cystathione or back into methionine. Conversion of homocysteine to methionine requires transfer of a methyl group from methyltetrahydrofolate. The conversion of folate to methyltetrahydrofolate is a multistep process requiring vitamin B\textsubscript{9} and a functional enzyme, methylene tetrahydrofolate reducetase (MTHFR). Vitamin B\textsubscript{12} is also required for metabolism of sulfur-containing amino acids such as methionine.

The final steps in the clotting cascade involve the conversion of factor X to factor Xa, a process catalyzed by activated factor IX (in the presence of factor VIII) (Fig. 28.2). Activated factor X (Xa), in turn, catalyzes the conversion of prothrombin (factor II) to thrombin (factor IIa). This conversion involves factor V. Thrombin, in turn, converts fibrinogen to fibrin, an essential building block for stable clot formation. A number of thrombotic control mechanisms have evolved to limit inappropriate clotting. These involve antithrombin III, protein C, and protein S. Fibrinolytic mechanisms, including plasmin-mediated clot dissolution, help limit downstream thrombotic effects.

![Figure 28.2 Final pathways involved in clot formation and dissolution. Pathways in black are part of the clotting cascade and are prothrombotic. Pathways in red limit or inhibit clot formation and aid in clot dissolution. FSP, fibrin split products; TPA, tissue plasminogen activator.

Antithrombin III is a serine protease that inhibits the activity of thrombin as well as factors Xa, Xa, Xla, and Xlla. Although antithrombin III mutations are fairly uncommon, their association with thrombotic complications during pregnancy is quite dramatic (15). Some have demonstrated antithrombin III deficiency to represent the worst prognostic factor of all heritable thrombophilias in terms of pregnancy outcome (27). Protein C and protein S both exert their antithrombotic effects at those steps in the clotting cascade that involve conversion of factor X to Xa and conversion of prothrombin to thrombin. Heritable deficiencies in factors C and S have been demonstrated, and each is associated with thrombophilia and pregnancy complications (27). Most recently, genetic mutations in factor V have been described that disallow appropriate interactions with protein C. All mutations may be linked to recurrent fetal loss (27,28 and 29). One of the multiple mutations causing this resistance to activated protein C has been called factor V Leiden. Factor V Leiden results from a heritable point mutation at the cleavage site for factor V (30), and
among white populations, it represents the most common of the genetic causes of thrombophilia (31). Although the available data are limited by studies with small patient numbers, most large studies have noted association between factor V Leiden and recurrent pregnancy loss (19,22,24,27,28 and 29,32,33,34 and 35).

Heritable point mutations in prothrombin (factor II) have been linked to thrombosis and, more specifically, to pregnancy loss (35,36). Factor XII deficiencies have also been shown to be particularly prevalent among Japanese women with recurrent pregnancy loss (37)). Associations between fibrinogen and factor XIII defects and fetal loss suggest that interactions between the clotting cascade and pregnancy maintenance involve mechanisms more complex than simple placental thrombosis and infarction (38,39).

In light of the recent completion of the human genome project and the rapid development of novel and improved molecular cytogenetic techniques (40), many advances and additional insight into the contribution of parental genetic abnormalities to recurrent pregnancy loss can be anticipated in the coming years.

Anatomic Abnormalities

Anatomic abnormalities of both the uterine cervix and the uterine body have been associated with recurrent pregnancy loss. These anatomic causes may be either congenital or acquired. During development, the uterine forms by the apposition of a portion of bilateral hollow tubes called the müllerian ducts. The dissolution of the walls of these ducts along their site of apposition allows formation of the intrauterine cavity, the intracervical canal, and the upper vagina. Congenital uterine anomalies may, therefore, include incomplete müllerian duct fusion, incomplete septum resorption, and uterine cervical anomalies. Although the causes underlying many of the congenital anomalies of the female reproductive tract are unclear, it has been well documented that prenatal exposure to maternally ingested diethylstilbestrol (DES) results in complex congenital uterine, cervical, and vaginal changes.

Historically, all congenital reproductive tract abnormalities have been linked to both isolated spontaneous pregnancy loss and recurrent pregnancy loss (4,12,42), although the presence of an intrauterine septum and prenatal exposure to DES demonstrate the strongest associations. In fact, women with an intrauterine septum may have as high as a 60% risk for spontaneous abortion (43). Uterine septum-related losses most frequently occur during the second trimester. However, if an embryo implants into the poorly developed endometrium overlying the uterine septum, abnormal placentation and resultant first-trimester losses may occur as well (44). The most common uterine cervical anomaly associated with in utero DES exposure is hypoplasia, which may contribute to first- or second-trimester spontaneous abortions, incompetent cervix, and premature labor (45,46). Congenital anomalies of the uterine arteries also may contribute to pregnancy loss through adverse alterations in blood flow to the implanted blastocyst and developing placenta (47).

Acquired anatomic anomalies have likewise been linked to both isolated and recurrent pregnancy losses. These abnormalities include such disparate conditions as intrauterine adhesions, uterine fibroids, and endometriosis. Endometrium that develops over an intrauterine synechia or over a fibroid that impinges in the intrauterine cavity (submucous) may be inadequately vascularized (45). This may promote abnormal placentation for any embryo attempting to implant over such lesions. Although data supporting these concepts are a bit tenuous, this abnormal placentation may lead to spontaneous pregnancy loss.

Endocrine Abnormalities

The endocrinology of normal pregnancy is complex. Because spontaneous pregnancy is critically dependent on appropriately timed endocrinologic changes of the menstrual cycle, it is not surprising that those endocrine abnormalities that ultimately alter pregnancy maintenance may mediate their effects during the follicular phase of the cycle in which conception occurs, or even earlier. Modifications in follicular development and ovulation, in turn, may be reflected in abnormalities of blastocyst transport and development, alterations in uterine receptivity to the implanting blastocyst, and improper functioning of the corpus luteum. Beginning with ovulation and lasting until about 7 to 9 weeks of gestation, maintenance of early pregnancy depends on the production of progesterone by the corpus luteum. Normal pregnancies are characterized by a luteal-placental shift at about 7 to 9 weeks of gestation, during which the developing placental trophoblast cells take over progesterone production and pregnancy maintenance (49). Spontaneous pregnancy losses occurring before 10 weeks of gestation may result from a number of alterations in normal progesterone production or use. These include failure of the corpus luteum to produce sufficient quantities of progesterone, impaired delivery of progesterone to the uterus, or inappropriate use of progesterone by the uterine endometrium. Pregnancy failures may also occur near the time of the expected luteal–placental shift if the trophoblast is unable to produce biologically active progesterone after demise of the corpus luteum. Endocrinologic factors associated with recurrent abortion include luteal-phase insufficiency, diabetes mellitus thyroid disease, and potentially, hyperprolactinemia and decreased ovarian reserve. Luteal-phase insufficiency or luteal-phase defects (LPDs) are characterized by inadequate luteal milestones and most likely relate to adverse pregnancy outcome through inadequate or improper timed endometrial development at potential implantation sites. LPD has many causes, some of which are associated with hypersecretion of luteinizing hormone. Although the mechanism underlying the association of elevated luteinizing hormone (LH) levels with recurrent pregnancy loss remains incompletely understood, abnormal LH secretion may have direct effects on the developing oocyte (premature aging), on the endometrium (dysynchronous maturation), or both. Many patients with elevated LH levels also display physical, endocrinologic, and metabolic characteristics of polycystic ovarian syndrome (PCOS). In fact, some studies report ovarian radiologic evidence of PCOS in as many as 80% of recurrent pregnancy loss patients (50). In addition to inappropriate elevated LH levels, PCOS patients are frequently obese and often have elevated circulating androgen levels. Although not undisputed (51), many studies have been linked to recurrent pregnancy loss (51,52) and elevated androgen levels have been shown to effect markers of uterine receptivity adversely in women with a history of recurrent pregnancy loss (53).

Many women with PCOS have metabolic alterations in glycerol control characterized by insulin resistance. This too may be directly or indirectly related to adverse pregnancy outcome, and it may be related to the mechanisms for spontaneous pregnancy loss among women with type II diabetes mellitus (54). Women with overt insulin-dependent diabetes mellitus (IDDM) appear to exhibit a threshold of pregestational glycemic control above which spontaneous pregnancy loss is increased (55,56). In fact, hyperglycemia has now been directly linked to embryonic damage (57). In cases of advanced IDDM with accompanying vascular complications, compromised blood flow to the uterus may be mechanistically involved in subsequent pregnancy loss.

Patients with thyroid disease often have concomitant reproductive abnormalities, including ovulatory dysfunction and LPDs. In addition, the metabolic demands of early pregnancy mandate an increased requirement for thyroid hormones. It is therefore not surprising that hypothyroidism has been associated with spontaneous pregnancy loss and with recurrent pregnancy loss (58). Although it continues to be debated, evidence suggests that, even in clinically euthyroid patients, the presence of antithyroid antibodies might be associated with recurrent pregnancy loss (59,60,61 and 62). The mechanism for this association remains unclear; however, these antibodies could mark women of more generalized autoimmunity or may predict an impaired ability of the thyroid gland to respond to the demands of pregnancy.

Two additional endocrinologic abnormalities have been linked to recurrent pregnancy loss, although support for these associations and their mechanistic pathways remains shrouded in controversy. The relationship of hyperprolactinemia with recurrent pregnancy loss continues to be debated. Animal models suggest that elevated prolactin levels may promote pregnancy wastage by direct effects on the endometrium or indirect immunomodulatory mechanisms (59). Most recently, attempts have been made to correlate markers of ovarian reserve (day 3 follicle-stimulating hormone, day 3 estradiol, response to the clomiphene challenge test) with recurrent pregnancy loss (51,66,67). At present, no consensus exists concerning this potential association.

Maternal Infection

The association of infection with recurrent abortion is among the most controversial and poorly explored of the potential causes of pregnancy loss. Reproductive tract infections with bacterial, viral, parasitic, zoonotic, and fungal organisms have all been linked theoretically to pregnancy loss; however, mycoplasma, ureaplasma, chlamydia, and b-streptococcus are the most commonly studied pathogens (68,69). Most recent data have directly addressed the roles of some of these proposed organisms in recurrent pregnancy loss. One prospective comparison trial involving 70 recurrent pregnancy loss patients reported no elevation in many markers for present or past infection with Chlamydia trachomatis when compared with controls (70). In contrast, a very large, prospective trial demonstrated a link between detection of bacterial vaginosis and history of second-trimester pregnancy loss among 500 recurrent pregnancy loss patients (71). The risk for bacterial vaginosis detection was also positively correlated with cigarette smoking in this study.

The etiologic mechanism linking specific organisms to either isolated or recurrent pregnancy loss remains unclear and must certainly differ among infectious organisms. Certain viral organisms, such as herpes simplex virus (72) and human cytomegalovirus (73), can directly infect the placenta and fetus (72,73). The resulting villitis and related tissue destruction may lead to pregnancy disruption. Another theoretical possibility warranting study is that infection-associated early pregnancy loss may result from immunologic activation in response to pathologic organisms. A large body of evidence supports the role of this mechanism in adverse
events later in gestation, such as intrauterine growth restriction (74), premature rupture of membranes, and preterm birth (75). Alternatively, mechanisms that protect the fetus from autoimmune rejection also may protect virally infected placental cells from recognition and clearance. This could potentially promote periods of unfeathered infectious growth for some of the pathogenic organisms gaining entry to the reproductive tract (76).

Immunologic Phenomena

In recent years, there has been extensive information published concerning the possible immunologic causes and treatments of recurrent pregnancy loss. However, there is a lack of consensus regarding the mechanisms and the impact of therapeutic intervention because the detection of a therapeutic effect is difficult in the absence of very large studies. This situation reflects the fact that many recurrent pregnancy loss patients present after their index pregnancy has expired but before being diagnosed. In these cases, the physiologic immune reaction to the presence of nonviable tissue may mask any alternative, underlying immune causes of the demise itself. Finally, it is very likely that there are a wide variety of immune alterations that may result in the same end result—isolated or recurrent pregnancy loss. This latter theory is certainly supported by a recent review article that lists 10 well-supported immune mechanisms that are each potentially important in pregnancy maintenance (77).

Before launching into the most commonly accepted causes of immune-mediated pregnancy loss, a brief review of some of the important concepts in basic immunology is warranted (Table 28.2). Although these descriptions are presented in general terms and are further defined in Chapter 8, they should serve as useful reference for the ensuing information.

Table 28.2. Concepts in Reproductive Immunology

<thead>
<tr>
<th>Immune responses classically are divided into innate and acquired responses. Innate responses represent the body’s first line of defense against pathogenic invasion. They are rapid and are not antigen specific. Cell types and mechanisms typically considered vital to innate immunity include complement activation, phagocytosis by macrophage, and lysis by natural killer (NK) cells and possibly by T-cell receptor-gd-positive (TCR-gd+) T cells (see later). Acquired immune responses, in contrast, are antigen specific and are largely mediated by T cells and B cells. Acquired responses can be further divided into primary (response associated with initial antigen contact) and secondary (rapid and powerful amnestic response associated with subsequent contact to the same antigen).</th>
</tr>
</thead>
<tbody>
<tr>
<td>Antigen specificity is generally regulated by two sets of genes in the major histocompatibility complex (MHC), located on chromosome 6 in humans. Class I MHC molecules (human leukocyte antigens [HLA] A, B, and C) are present on the surface of nearly every cell in the human body and are important in defense against intracellular pathogens, such as viral infection and oncogenic transformation. Class I MHC molecules act as important ligands for both the TCR on CD8+ cytotoxic and suppressor T cells and for a variety of receptors on NK cells (78). Class II MHC molecules (HLA-DR, HLA-DP, and HLA-DQ), in contrast, are present on the surface of a limited number of antigen-presenting cells, including dendritic cells, macrophage-monocytes, B cells, and tissue-specific cells, such as the Langerhans cells in the skin. These molecules are important in defense against extracellular pathogens, such as bacterial invaders. The major ligand for class II MHC is the TCR on CD4+ T-helper cells.</td>
</tr>
<tr>
<td>One very important concept in immunology that has particular application to pregnancy is that of immune tolerance. It has been well described that bone marrow–derived T cells pass through the fetal thymus during early development. During this developmental interval, the T cells encounter a process termed thymic education. During thymic education, T cells are chosen that express either the CD4 or the CD8 co-receptor, and autoreactive cells are effectively eliminated. In short, this education promotes T-cell tolerance, allowing selection and survival only of those T cells that can recognize oneself but will not react against self.</td>
</tr>
<tr>
<td>These immunologic characteristics have all been thoroughly described and investigated for the immune effector cells populating the peripheral immune system. The peripheral immune system consists of the spleen and peripheral blood, and it is generally responsible for protection against blood-borne pathogens. Pathogens that enter through the extensive surface areas of the lacrimal ducts, respiratory system, gastrointestinal tract, mammary ducts, and genitourinary tract encounter a very distinct and important immune environment—that of the mucosal immune system. Although the mucosal immune system may be primarily responsible for the initial protection against most exogenous pathogens, an understanding of its immune characteristics has lagged far behind that of the peripheral immune system. Insight into the specific characteristics of immunity within the reproductive tract is even further limited.</td>

Cellular Immune Mechanisms

Many of the immune theories surrounding the causes of isolated and recurrent spontaneous pregnancy losses have stemmed from attempts to define immunologic rules as they apply specifically to the mucosal reproductive tract. Four main questions summarize much of the theoretical thinking surrounding pregnancy maintenance and reproductive immunology:

1. Which immune cells populate the reproductive tract, particularly at implantation sites?
2. How do these cells arrive at this mucosal immune site, and are they educated in the same way as those populating the periphery?
3. How do the characteristics of antigen presentation differ at the maternal–fetal interface?
4. What regulatory mechanisms specifically affect reproductive tract immune cells?

Resident Cells

Immune cells populating the reproductive tract exhibit many characteristics that distinguish them from their peripheral counterparts. In particular, the human endometrium is populated by T cells, macrophage, and NK-like cells, but very few B cells are present (79,80). The relative proportions of these resident cells vary with the menstrual cycle and change dramatically during early pregnancy. In fact, surrounding the time of implantation, one particular cell type comprises between 70% to 80% of the total endometrial lymphocyte populations (79,80). This cell type is called a variety of names, including decidual granular lymphocytes, large granular lymphocytes, and decidual NK cells. This heterogeneity of names reflects the fact that this particular cell type differs from similar cells isolated from the periphery, although most believe it to be an NK cell variant. If we do consider them to be NK cells, the implantation site represents the largest accumulation of NK cells in any state of human health or disease. The true function of these cells remains unclear, but their remarkable abundance at the maternal–fetal interface makes their further study compelling (81,82). Other immune cells have been described in the periphery that have characteristics of both NK cells and T cells. These NK cells have recently been demonstrated to play a role in pregnancy loss in animal models (83), and their presence in the decidua in humans is now being investigated.

In the peripheral immune compartment, most T cells express a TCR composed of an ab heterodimer (TCR-ab+). In addition to TCR-ab+ T cells, the human reproductive tract also is populated by a subset of T cells with a distinctive TCR composed of the gd heterodimer (TCR-gd+), and the numbers of these cells increases in early pregnancy (84,85) and (86). TCR-gd+ T cells appear to fulfill functions quite distinct from their TCR-ab+ counterparts; functions that may include direct, non-MHC-restricted recognition of antigens within tissues (87). In fact, TCR-gd+ T cells may fill a protective niche missed or poorly covered by B cells and TCR-ab+ T cells. The role and importance of TCR-gd+ cells in the reproductive tract and, more particularly, in pregnancy maintenance deserves further attention.

Finally, it has been suggested that a subset of macrophage, termed suppressor macrophage, might be implicated in pregnancy maintenance. These specific cells differ from typical macrophage in their promotion of antinflammatory effects, and they have been detected in normal murine placenta (88). Their presence in human
decidual specimens requires further investigation.

The human decidua is populated by characteristic immune effector cells. To date, investigations into whether alterations in these cells (including T cells, decidual NK cells, and NKT cells) determine pregnancy outcome have been hampered by insufficient patient numbers to allow meaningful conclusions. Still, these immune cell populations have been repeatedly reported to be altered in recurrent pregnancy loss patients (89,90,145 and 96) but not in patients experiencing isolated spontaneous pregnancy losses (89).

**Immune Cell Education and Homing to the Reproductive Tract** The implanting fetus represents the most common model of allotraft acceptance. How the maternal immune system responds to the implantation of the fetus is a subject of intense investigation. The presence of an immune response that is not beneficial to the host, whether accidental or not, is often the root of an unsuccessful pregnancy. More specifically, the immune system must recognize the fetus as a foreign antigen without triggering a detrimental response to it. The current chapter begins the discussion of how the resident decidual immune effector cells are selected and educated, how they home to reproductive sites, and how they are maintained once they reach their destination. Animal studies have suggested that the rules for selection and maintenance of these cells, in terms of their requirement for MHC and their education within the thymus, may be distinct from those governing either peripheral immune cells or cells within other mucosal sites, including the intestine (90). Although the results of most studies are preliminary, it appears that the human reproductive tract displays similar characteristics—the immunophenotypes of immune cells populating the human reproductive tract are distinct from both the periphery and from other mucosal sites (95). The education of TCR-gd+ cells populating epithelial sites may occur outside the thymus and might involve mechanisms that substitute for or modify interaction with MHC (85,86). The development of MHC specificities is presently being investigated (97), with the hope that these investigations will shed light on similar processes in humans and, more specifically, on the selection and maintenance characteristics of decidual NK cells.

It is now becoming increasingly evident that the cells populating mucosal immune sites select these through interactions between cell surface molecules on the immune cell (integrins) and cell surface molecules on the endothelial cells of blood vessels within the mucosal tissues (e.g., selectins, vascular, vascular all adhesion molecule VCAM). This cellular recruitment process, called homing, has been most thoroughly described for the intestine (99,100). However, both murine (99,101) and human (102) reproductive tract tissues do express the integrin–vascular ligand pairs. The extension of these findings to pregnancy maintenance will surely prove fruitful. Solving the mechanisms of selection, education, and maintenance of reproductive tract immune effector cells is of paramount importance. Until we understand these vital processes in the normal state, we cannot define the effects that alterations will have on human disease, nor can we develop therapeutic interventions.

**Antigen Presentation at the Maternal–Fetal Interface** Historically, it was proposed that one method by which the implanting trophoblastic allorgraft could potentially avoid immune detection by the maternal host would be by making itself antigeneically invisible. It could downregulate its expression of the MHC-encoded transplantation antigens (some of which would be of paternal origin) and thereby avoid recognition as nonself. Although current knowledge of immunology now makes this theory somewhat obsolete (103), the implanting fetus does, in fact, use this strategy to some extent. It is certainly true that placental trophoblast cells do not express class II MHC molecules (104,105).

Unlike nearly every other cell in the human body, trophoblast cells do not express the classic class I MHC transplantation antigens HLA-A and -B. Rather, a subpopulation of placental cells, specifically the extravillous cytotrophoblast cells, express the classic class MHC I HLA-C products and the nonclassic HLA-E and -G products (75,106,107,108,109,110 and 111). These extravillous trophoblast cells are of particular interest because they are characterized by remarkable invasive properties. In fact, as these cells move from the tips of the anchoring villi of the human placenta and invade deeply into the maternal decidua, further, they can replace cells within the walls of decidual arterial vessels (112,113). Although the invasive characteristics of extravillous cytotrophoblast may reflect non-MHC-related mechanisms, including well-described integrin switching (114), the intimate contact of these fetal-derived cells with maternal immune effector cells certainly exposes the fetus to recognition as nonself.

It is not known why all placental cells downregulate expression of HLA-A and -B, whereas invasive extravillous cytotrophoblast cells express HLA-C, -E, and -G. However, this area of investigation is ripe with hypotheses and study. Because NK cells of the innate immune system recognize and kill cells that express no MHC (103), the complete downregulation of MHC would cause trophoblast cells to act as targets for those NK cells that are pavinous at sites of implantation. In addition to possible protection from direct NK cell–mediated killing, the expression of HLA-C, -E, and -G by trophoblast cells may serve a variety of alternative roles. NK cell receptor–mediated interactions with extravillous cytotrophoblast may modulate cytokine expression profiles at the maternal–fetal interface (91,92). MHC expression on extravillous trophoblast, an activity essential for proper placental development (115), whereas definitive correlations between placental class I MHC expression patterns and recurrent pregnancy loss have yet to be reported, trophoblast expression of HLA-G has been linked to other disorders of placentation, such as preeclampsia (115,116). Finally, soluble or secreted trophoblast MHC products may aid in the development of maternal immune tolerance toward the placenta (117).

To date, the study of newly described trophoblast class I MHC products in recurrent pregnancy loss remains limited. However, the results of two small studies investigating the possible association between polymorphisms in these MHC products and recurrent pregnancy loss have been negative (118,119). Aberrant expression of class II MHC determinants, or enhanced expression of class I MHC on syncytiotrophoblast occurring in response to interferon-g (IFN-g), could mediate apoptosis by inducing cytotoxic T-cell attack (120,121). This theory appears unlikely, however, because the expression of classic MHC antigens does not appear to be induced on aborted tissues from women experiencing one or more pregnancy losses (122). Finally, class II MHC genotypes appear to affect susceptibility to a variety of diseases, including diabetes and other autoimmune diseases. A similar link between maternal class II typing and adverse pregnancy outcome has been reported for recurrent pregnancy loss (123,124).

**Regulation of Decidual Immune Cells** The characteristics of the interactions between decidual immune effector cells and the implanting fetus may be determined by factors other than those already mentioned. Local regulation of the cells that populate the human decidua will further modify the effects of selection, maintenance, and homing on the unique characteristics of the maternal decidual interface. As might be predicted, these regulatory effects are often targets for investigative efforts because they may offer more direct insight into potential therapies for immune-mediated disorders of pregnancy maintenance. Three such regulatory mechanisms are discussed here: (a) alterations in T-helper cell phenotypes, (b) reproductive hormones and immunosuppression, and (c) trophoblastic metabolism.

As discussed in Chapter 6, antigen-stimulated immune responses involving CD4+ T cells can be divided into two major classes: T-helper cell subset 1 (Th1) responses and T-helper cell subset 2 (Th2) responses. This subclassification is based on the characteristics of the CD4+ cells present as well as on their associated cytokines. The production of these responses rests on the environment in which relatively undifferentiated CD4+ T cells become differentiated. Thus, Th0 cells exposed to IFN-g become Th1-type cells, and those exposed to interleukin-4 (IL-4) become Th2-type cells (125). Th1 responses are associated with inflammation and proliferation of IL-2 and tumor necrosis factor-β (TNF-β). Th2 cell responses are associated with antibody production and the cytokines IL-10, IL-4, IL-5, and IL-6 (126,127 and 128). Although TNF-α can be secreted by both Th1 and Th2 cells, it is most often characteristic of a Th1 response (129,130). A reciprocal regulating relationship exists between Th1 and Th2 cells and cytokines (131,132,133 and 134), with one response supporting its own persistence while averting conversion to the other.

Extending these immune regulatory phenomena to pregnancy, the type of CD4+ cellular response to the implanting fetus is controlled not only by the types of cells (e.g., T-helper cells) in the decidua but also by the cytokine environment at the maternal–fetal interface. As mentioned previously, the human endometrium and decidua are replete with immune and inflammatory cells capable of cytokine secretion (135,136,137,138 and 139). Cytokines may affect reproductive events either directly or indirectly, depending on the specific cytokines secreted, their concentrations, and the differentiation stage of potential reproductive target tissues. It is now well documented that Th1-type cytokines can be harmful to an implanting embryo (140,141 and 142). Further, most agree that some patients with recurrent pregnancy loss exhibit a dysregulation of their Th0 helper cell immune response to antigens at the site of implantation, with typical shifts toward Th1 inflammatory responses (143,144,145 and 146). Depending on the individual series, 50% to 80% of nonpregnant women with a history of otherwise unexplained recurrent spontaneous abortion have been found to have evidence of abnormal in vitro Th1 cellular immune responses. Fewer than 3% of women with normal reproductive histories demonstrate these responses (143,145,146 and 147). Rather, most women with normal pregnancies have a Th2 immune response to trophoblast antigens (146).

Methods for the documentation of cytokine dysregulation among recurrent pregnancy loss patients also vary among investigators, but groups have recently confirmed this abnormality within the endometrium (146,149 and 150) or among immune cells isolated from the decidua (151) of these patients. Others use peripheral lymphocytes as the source of cytokine profiles and find no evidence of a Th1 response (152,153). This discordance might be explained by the fact that cytokine profiles isolated from peripheral blood lymphocytes (PBLs) from recurrent pregnancy loss patients were stimulated in vitro by HLA-G bearing cells (154), whereas another study demonstrated that decidual and peripheral immune cells exhibit a shift toward the Th2 phenotype when exposed to HLA-G (155). Whether peripheral cytokine levels reflect T-helper cell dysregulation at the maternal–fetal interface or whether this dysregulation affects peripheral as well as local immune response during pregnancy remains controversial (156,157 and 158). Finally, as with all immune theories, there appears to be significant redundancy in the necessity
for particular cytokines and soluble immunoregulatory factors at the site of implantation. To date, animal models with directed gene deletions have shown only one of these factors to be absolutely essential to pregnancy maintenance—leukemia inhibitory factor (LIF) is required for blastocyst implantation (159), but not for subsequent embryogenesis (160). Interestingly, LIF induces the transcription of HLA-G in vitro in human placental cells (161).

Although many mechanisms are aimed at avoiding maternal immune recognition of the implanting fetus, research in both humans and animals indicates that immune responses to fetal antigens can be detected (162,163 and 164). Thus, the regulation of this response at the maternal–fetal interface may be critical. The concept that successful pregnancy requires some form of maternal immune suppression is supported by reports that failure to downregulate maternal responses to recall antigens, such as tetanus toxoid and influenza, is associated with poor pregnancy outcome among recurrent pregnancy loss patients (165). Reproductive hormones have dramatic effects on peripheral cell-mediated immunity, as demonstrated by well-documented and notable gender differences in immune responsiveness (166). The levels of these potentially immunosuppressive hormones are quite elevated in pregnant women. The fact that the levels of these hormones at the maternal–fetal interface may be far above those in the maternal circulation during pregnancy (167) may explain an apparent inconsistency: overall immune responsiveness during pregnancy appears to change little, whereas local suppression at the maternal–fetal interface may be vital.

It has been suggested for some time that the immunosuppressive effects of progesterone within the reproductive tract are at least partially responsible for the maintenance of the semiallogeneic implanting fetus (168). In vitro studies have shown that the progesterone mediates its suppression of T-cell effector function by alterations in membrane-resident potassium channels and cell membrane depolarization. This action, in turn, affects intracellular calcium signaling cascades and gene expression (169) and may be non-receptor mediated (170). Progesterone-mediated changes in T-cell gene expression have been associated with the development of T2-type responses and with increased LIF expression (151,171). Because a shift in the intrauterine immune environment from T2 to T1 has been linked to early spontaneous pregnancy loss (146,151), the recent intrauterine concentrations of progesterone characteristic of early pregnancy may promote an immune environment favoring pregnancy maintenance. To this point, recent in vitro evidence indicates that progesterone can inhibit both mitogen-induced proliferation of and cytokine secretion by CD8+ T cells (172).

Levels of estrogen also rise dramatically during pregnancy, and attention has focused on the role of estrogen in immune modulation. A group of animal studies has shown that estrogens improve immune responses in males after significant trauma and hemorrhage (173), suppress cell-mediated immunity after thermal injury (174), and protect against chronic renal allograft rejection (175). In vitro, estrogens appear to downregulate delayed-type hypersensitivity reactions and promote the development of T2-type immune responses, particularly at the elevated estrogen concentrations typical of pregnancy (176,177).

One additional regulatory mechanism proposed for the induction of maternal tolerance to the fetal allograft involves the amino acid tryptophan and its catabolizing enzyme indoleamine 2,3-dioxygenase (IDO). The IDO hypothesis of tolerance in pregnancy rests on data that T cells need tryptophan for activation and proliferation (178) and that local alterations in tryptophan metabolism at the maternal–fetal interface could either activate or fail to suppress maternal antifetal immunoreactivity (179). Recent studies in mice have shown that the inhibition of IDO leads to loss of allogeneic, but not syngeneic, fetuses and that this effect is mediated by lymphocytes (180). Further support lies in studies demonstrating that hamsters fed diets high in tryptophan have increased rates of fetal wastage (181). Extending this theory to humans requires further investigation. However, the demonstration of IDO expression in human uterine decidual (182) and the documentation of alterations in serum tryptophan levels with increasing gestational age during human pregnancy (183) both support further interest in this potential local immunoregulatory mechanism.

Endometriosis is the growth of both endometrial glands and stroma outside of the intrauterine cavity. Although associations between the development of endometriosis and immunologic abnormalities are now being defined (184), the link between endometriosis and recurrent pregnancy loss remains contentious. Recurrent pregnancy loss in the presence of endometriosis certainly would involve the interaction of complex mechanisms, some of which may involve cellular or humoral dysfunction (185,186).

Humoral Immune Mechanisms

Humoral responses to pregnancy-specific antigens exist, and patients with recurrent pregnancy loss can display altered humoral responses to endometrial antigens (187) (Table 2.2). Nevertheless, most of literature surrounding humoral immune responses and recurrent pregnancy loss focus on organ-nonspecific autoantibodies associated with APAS. Historically, these immunoglobulin G (IgG) and IgM antibodies were thought to be directed against negatively charged phospholipids. Those phospholipids most often implicated in recurrent pregnancy loss are cardiolipin and phosphatidylserine. Most recently, however, it has been shown that antiphospholipid antibodies often are directed against a protein cofactor, called β2 glycoprotein 1, that assists antibody association with the phospholipid (188,189). Antiphospholipid antibodies were originally characterized by prolonged phospholipid-dependent coagulation tests in vitro [activated partial thromboplastin time (aPTT), Russell viper venom time] and by thrombosis in vivo. The association of these antiphospholipid antibodies with thrombotic complications has been termed the antiphospholipid syndrome, and although many of these complications are systemic, some are pregnancy specific—spontaneous abortion, preterm labor, premature rupture of membranes, stillbirth, intrauterine growth retardation, and pre eclampsia (190). A recent reassessment of the criteria used to diagnose APAS was undertaken during a postconference workshop after the Eighth International Symposium on Antiphospholipid Antibodies held in 1998 in Sapporo, Japan (191). This reassessment resulted in the Sapporo criteria for diagnosis of APAS, which include adverse pregnancy outcomes. These criteria, which have been validated clinically (192), are as follows:

For a patient to be diagnosed with antiphospholipid syndrome, one or more clinical and one or more laboratory criteria must be present:

**Clinical**

1. One or more confirmed episodes of vascular thrombosis of any type
2. Pregnancy complications
   - Three or more consecutive spontaneous pregnancy losses at less than 10 weeks of gestation
   - One or more fetal deaths at greater than 10 weeks of gestation
   - One or more preterm births at less than 34 weeks of gestation secondary to severe preeclampsia or placental insufficiency

**Laboratory**

1. Positive plasma levels of anticardiolipin antibodies of the IgG or IgM isotype at medium to high levels
2. Positive plasma levels of lupus anticoagulant

The presence of antiphospholipid antibodies (antiphospholipid or lupus anticoagulant) during pregnancy is a major risk factor for adverse pregnancy outcome (193). In large series of couples with recurrent abortion, the incidence of the antiphospholipid syndrome was between 3% and 5% (194). The presence of anticardiolipin antibodies among patients with known systemic lupus erythematosus portends less favorable pregnancy outcome (195).

A number of mechanisms have been proposed by which antiphospholipid antibodies might mediate pregnancy loss. Antibodies against phospholipids could increase thromboxane and decrease prostacyclin synthesis within placental vessels. The resultant prothrombotic environment could promote vascular constriction, platelet adhesion, and placental infarction (195,196) and 197). Alternatively, in vitro evidence from trophoblast cell lines indicates that IgM action against phosphatidylserine inhibits formation of syncytiotrophoblast (198). Syncytialization is, of course, required for proper placental function. One study demonstrated that both extravillous cytotrophoblast and syncytiotrophoblast cells synthesize β 2 glycoprotein 1, the essential cofactor for antiphospholipid antibody binding (199). Although it has been investigated, data surrounding the prognostic value of serum antibodies against β 2 glycoprotein 1 with respect to pregnancy outcome among recurrent pregnancy loss patients remain inconsistent (200,201). Some have proposed that sera from antibody-positive recurrent pregnancy loss patients is particularly adept at inhibiting trophoblast adhesion to endothelial cells in vitro (202). Others have noted rapid development of atheroocrosis in the decidual spiral arteries of patients who test positive for antiphospholipid antibodies (203). Finally, still others have suggested that levels of the placental antithrombotic molecule—annexin V—are reduced within the placental villa from those women with recurrent pregnancy loss who are antiphospholipid antibody positive (204). It must be mentioned, however, that placental pathologic evidence supporting causal involvement of the antiphospholipid antibody syndrome in pregnancy loss is often equivocal. The characteristic lesions for this syndrome (placental infarction, abruption, and hemorrhage) are often missing in women with antiphospholipid antibodies
One additional group of autoantibodies that have been linked to recurrent pregnancy loss is the antithyroid antibodies (ATAs). Although the data remain somewhat controversial (207,208), one large retrospective study has demonstrated an increased prevalence of these antibodies among women with a history of recurrent pregnancy loss, even in the absence of thyroid endocrinologic abnormalities (62). The overall significance of ATAs, however, is unclear. In fact, one study recently reported that the presence of serum ATA had no effect on pregnancy outcome in euthyroid pregnant patients with a history of recurrent pregnancy loss (60).

Other antibody-mediated mechanisms for recurrent abortion have been proposed, including antisperm and antiphospholipid antibodies, as well as blocking antibody deficiency. Although each hypothesis has been shown to have minimal relevance to recurrent pregnancy loss (68,121), their discussion is warranted because therapies aimed at these disorders persist. Historically, the blocking antibody deficiency hypothesis has received the most attention. This hypothesis is based on a supposition that blocking factors (presumably antibodies) were required to prevent a maternal, cell-mediated, antifetal immune response that was believed to occur in all pregnancies. It was therefore proposed that, in the absence of these blocking antibodies, abortion occurred (209,210). This supposition has never been consistently substantiated (211,212). For instance, maternal hyporesponsiveness in mixed lymphocyte culture with paternal stimulator cells was originally proposed to identify women with deficient blocking activity (210). Investigations based on this type of testing were continued by others (213,214), who proposed that parental HLA sharing may protect the fetus in a predisposition to blocking antibody deficiency. These reports were based on limited sample size, were retrospective in nature, and were population-based controls. One prospective, population-based control study conclusively demonstrated that HLA heterogeneity was not essential for successful pregnancy (215). However, follow-up studies have now shown that, in the exceedingly rare case of complete sharing of the entire HLA region, spontaneous pregnancy losses do increase (216). This particular 10-year prospective trial concluded, however, that HLA typing is of no use in outbred populations because only isolated and significantly inbred populations have such HLA homogeneity. Further evidence refuting the blocking antibody hypothesis for recurrent abortion comes from reports of successful pregnancies both among women who do not produce serum factors capable of mixed lymphocyte culture inhibition (210) and among women who do not produce antipaternal cytotoxic antibodies (211). Those mixed lymphocyte culture results that demonstrate hyporesponsiveness in some recurrent pregnancy loss patients are now believed to represent the effect of the pregnancy loss rather than the cause of recurrent abortion (364,410,211, and 212).

One last theory that arose out of the blocking antibody investigations involved a novel HLA-linked alloantigen system. The finding that polyclonal rabbit antisera could recognize both lymphocytes and trophoblast cells suggested to some the presence of trophoblast–lymphocyte cross-reactive alloantigens (called TLXes) (217). These TLXes were, in turn, linked to maternal blocking antibody deficiency and recurrent pregnancy loss. The TLX hypothesis is now of historical relevance only because this theory was invalidated when TLX was found to be identical to CD64, a complement receptor that is thought to protect the placenta from complement-mediated attack (216). CD64 was not a novel alloantigen. It can be found on a wide variety of cells, thus explaining the cross-reactive nature of the original rabbit antisera.

It is important to conclude this in-depth discussion of the immune-mediated mechanisms of isolated and recurrent pregnancy loss by suggesting that pregnancy may not require an intact maternal immune system. Supporting this concept are data showing that agammaglobulinemic animals and women can successfully reproduce (219). Further, viable births also occur among women with severe immune deficiencies and in murine models that lack T and B cells (SCID mice) and those that display a congenital absence of their thymus (nude mice). Still, immune factors may play important roles in a significant proportion of patients with recurrent pregnancy loss, and their presence is the subject of immense amounts of research. Until this role is better defined, an understanding of the contemporary immunologic hypotheses allows for the informed consideration of novel findings.

Other Factors

It is now becoming increasingly evident that the implantation of the blastocyst within the uterine decidua represents an exquisitely scripted cross-talk between embryo and mother. Alterations in this dialogue often result in improper implantation and placental development. For instance, recurrent pregnancy loss has been linked to a dysregulation in the expression patterns of vascular endothelial growth factors on the developing placenta and their requisite receptors within the maternal decidua (220). Cellular and extracellular matrix adhesion properties may also be involved in this dialogue. Lessey recently reviewed the concept of uterine receptivity, with particular emphasis on the importance of integrins and the timing of integrin switching in implantation (221). Others have reported decreased levels of endometrial mucin secretion (222) and reductions in the endometrial release of soluble intercellular adhesion molecule 1 (223) among women with a history of recurrent pregnancy loss. Programmed cell death (apoptosis) may also play an essential role in normal placental development. Alterations in two important apoptotic pathways—Fas-Fas ligand and bcl-2—have both been linked to recurrent pregnancy loss and poor pregnancy outcome (77,224).

A variety of environmental factors have been linked to sporadic and recurrent early spontaneous pregnancy loss. These are difficult studies to perform because, in humans, they must all be retrospective and are all confounded by alternative or additional environmental exposures. Nevertheless, the following factors have been linked to pregnancy loss: exposure to medications (e.g., antiprogestogens, antineoplastic agents, and inhalation anesthetics), exposure to ionizing radiation, prolonged exposure to organic solvents, and exposure to environmental toxins, especially heavy metals (224,225,226). The latter have recently been documented to have both maternal and immune effects that could lead to poor placentalation and subsequent pregnancy loss (227). Associations between spontaneous pregnancy loss and exposures to video display terminals, microwave ovens, high-energy electric power lines, and high altitudes (e.g., flight attendants) were not without controversy (228). Cigarette smoking has also been linked to early spontaneous pregnancy loss (229). One additional group of autoantibodies that have been linked to recurrent pregnancy loss is the antithyroid antibodies (ATAs). Although the data remain somewhat controversial (207,208), one large retrospective study has demonstrated an increased prevalence of these antibodies among women with a history of recurrent pregnancy loss, even in the absence of thyroid endocrinologic abnormalities (62). The overall significance of ATAs, however, is unclear. In fact, one study recently reported that the presence of serum ATA had no effect on pregnancy outcome in euthyroid pregnant patients with a history of recurrent pregnancy loss (60).
X (45X), especially among anembryonic conceptuses (244). Although somewhat controversial, the detection of aneuploidy in miscarriage specimens may be less than when the couple experiencing recurrent abortions is euploid. Alternatively, some investigators have suggested that, because aneuploidy is common among miscarriage specimens from patients experiencing both isolated and recurrent spontaneous pregnancy losses, the documentation of aneuploidy among tissues from recurrent pregnancy loss patients does not affect their prognosis for future pregnancy maintenance (9).

Most women with recurrent pregnancy losses tend to experience spontaneous abortion at about the same gestational age in sequential pregnancies. Unfortunately, the gestational age when pregnancy loss occurred, as determined by last menstrual period, may not be informative, because there is often a 2- to 3-week delay between fetal demise and signs of pregnancy expulsion (244). The designation of couples experiencing recurrent abortion into either primary or secondary categories is also problematic, since this is dependent on the diagnosis or management of women with recurrent abortion. About 10% to 15% of couples cannot even be classified into either the primary or secondary categories because, although their first pregnancy resulted in a loss, this was followed by a term delivery before subsequent losses.

It is important to evoke any history of subfertility or infertility among couples with recurrent pregnancy loss. This is defined by the inability to conceive after 12 months of unprotected intercourse. By definition, 15% of all couples meet this criteria; this number increases to 33% among couples with recurrent pregnancy losses. In fact, because many pregnancies are lost before or near the time of missed menses, subfertility among recurrent pregnancy loss patients may in some cases reflect preclinical losses. Menstrual cycle history also may provide information about the possibility of oligoovulation or other relevant endocrine abnormalities in recurrent pregnancy loss patients. An assessment of the timing of intercourse relative to ovulation should be reviewed with couples in an effort to detect dysynchronous fertilization that could contribute to pregnancy loss (246). A personal and family history of thrombotic events or renal abnormalities may provide vital information. A family history of pregnancy losses and obstetric complications should be addressed specifically. Detailed information about drug and environmental exposure should also be obtained.

**Physical Examination**

A general physical examination should be performed to detect signs of metabolic illness, including PCOS, diabetes, hyperandrogenism, and thyroid or prolactin disorders. During the pelvic examination, signs of infection, DES exposure, and previous trauma should be ascertained. Estrogenization of mucosal tissues, cervical and vaginal anatomy, and the size and shape of the uterus should also be determined.

**Laboratory Assessment**

Laboratory assessment of couples with recurrent pregnancy losses should include the following:

1. Parental peripheral blood karyotyping with banding techniques
2. Assessment of the intraluminal cavity with either office hysteroscopy or hysterosalpingography, followed by operative hysteroscopy if a potentially correctable anomaly is found
3. A well-timed luteal-phase endometrial biopsy, ideally 10 days after the LH surge or after cycle day 24 of an idealized 28-day cycle. If the cycle is abnormal by 3 or more days, the assessment should be repeated in a subsequent cycle. If endometrial histology is out of phase, the biopsy should be repeated in the subsequent cycle. Confirmed out-of-phase biopsies warrant further testing with serum prolactin and androgen profiles.
4. Thyroid function testing, including serum thyroid-stimulating hormone levels
5. Platelet assessment
6. Anti-cardiolipin and a lupus anticoagulant testing (aPTT or Russell viper venom testing)

A number of laboratory assessment tools are under investigation for use in patients with a history of recurrent pregnancy loss. At present, results are either too preliminary to warrant recommendation or studies of their use have been too contradictory to allow final determination of their value. Tests with proven or unknown utility include the following:

1. Evaluation of ovarian reserve using day 3 serum follicle-stimulating hormone levels or the clomiphene challenge test. It appears that decreased ovarian reserve may portend poor outcome in all patients, including those with recurrent pregnancy loss (247,248).
2. Testing for serologic evidence of PCOS using LH or androgen values may be useful (50,51,52, and 53,249).
3. Testing for peripheral evidence of T1,2 and T1,3 cytokine dysregulation. Although large studies have failed to demonstrate an association between peripheral cytokine alterations and pregnancy outcome among patients with recurrent pregnancy loss (156), smaller studies have reported peripheral shifts toward T1,1 profiles only in those recurrent pregnancy loss patients who subsequently lose their pregnancy (158). One study documented a shift toward T1,1 profiles at the time of fetal demise in these patients; however, it is particularly difficult to determine cause and effect in this situation (157).
4. Testing for hypercoagulability using the aPTT (14) or for the presence of a hereditary thrombophilia (250) in patients with otherwise unexplained recurrent pregnancy loss has been suggested.
5. Preconceptional testing for the prevalence and activity of peripheral NK cells has been reported in small studies to reflect prognosis and to assist in patient counseling (251,252).
6. Testing for antiphospholipid antibodies, even among women with recurrent pregnancy loss who are euthyroid, remains controversial. Although some have shown no association between their presence and recurrent loss (207), others have demonstrated an increased prevalence among patients with a history of recurrent pregnancy loss (62,208). However, even if the prevalence of antiphospholipid antibodies is increased among these patients, the significance of their presence has been questioned (259).
7. Testing for the presence of a variety of autoantibodies (other than lupus anticoagulant and anti-cardiolipin antibody) has been hotly debated, but without consensus (253,254). Testing for some antiphospholipid antibodies, such as antiphosphatidylerine and anti-b2 glycoprotein 1 (anti-b2,G1), are particularly attractive because mechanistic connections between their presence and placentental pathology have been made (198,199,200, and 201). One recent, large series has demonstrated anti-b2,G1 to be associated with risk for recurrent pregnancy loss (255). Among patients with known autoimmune diseases and recurrent pregnancy loss, additional antiphospholipid testing may be warranted (256).
8. Testing for congenital or acquired defects in hemostasis metabolism may play a role in the evaluation of some patients with recurrent pregnancy loss. The most common methods involve the measurement of blood levels of homocysteine, either fasting or after methionine loading (13). Methionine loading may increase the usefulness of results; however, it has been associated with acute endothelial dysfunction (257), which could pose potential problems if testing is performed during early pregnancy.
9. Cervical cultures for mycoplasma, ureaplasma, and chlamydia may be considered.

The following investigations have no place in modern clinical care of patients with recurrent spontaneous pregnancy loss:

1. Evaluations that involve extensive testing for serum or site-specific autoantibodies or alloantibodies (including antinuclear antibodies and anti-paternal cytotoxic antibodies) are both expensive and unproven. Their use or continued use serves only to verify the statistical tenet that if the number of tests performed reaches a critical limit, the results of at least one will be positive in every patient.
2. Testing for parental HLA profiles is never indicated in outbred populations. Findings that HLA sharing is associated with poor pregnancy outcomes are strictly limited to those specific populations studied, which have very high and sustained levels of marriage within a limited community (214).
3. Mixed lymphocyte cultures have not proved useful. Use of other immunologic tests also is unnecessary unless these studies are performed, with informed consent, under a specific study protocol in which the costs of these experimental tests are not borne by the couple or their third-party payers.
4. Further work is necessary before suppressor cell and factor determinations; cytokine, oncogene, and growth factor measurements; or embryotoxic factor assessment can be clinically justified.

**Postconception Evaluation**

After conception, close monitoring of patients with a history of recurrent pregnancy loss is advised to provide psychological support and to confirm intrauterine pregnancy and its viability. The incidence of ectopic pregnancy (258,259) and complete molar gestation (259,260) is increased in women with a history of recurrent spontaneous pregnancy loss. Although somewhat controversial (259), some data suggest that the risk for pregnancy complications other than spontaneous abortion are not significantly different between women with and without a history of recurrent losses (261,262). Two exceptions to this observation are those women who have...
Determining serum levels of h-BGH may be helpful in monitoring early pregnancy until an ultrasonographic examination can be performed; however, not all investigators have found inadequate h-BGH levels in pregnancies that ultimately abort (263). Other hormonal determinations are rarely of benefit because levels are often normal until fetal death or abortion occurs (264).

The best method for monitoring in early pregnancy is ultrasonography. If used, serum h-BGH levels should be serially monitored from the time of a missed menstrual period until the level is about 1,500 mIU/mL, at which time an ultrasonographic scan is performed and blood sampling is discontinued. Ultrasonographic assessment is then performed every 2 weeks until the gestational age at which previous pregnancies were aborted. The prognostic value of serial ultrasonography and a variety of hormonal and biochemical measurements during early pregnancy in women with a history of recurrent losses has been recently investigated (265).

If a pregnancy has been confirmed, but fetal cardiac activity cannot be documented by about 6 to 7 weeks of gestation (by sure menstrual or ultrasonographic dating), intervention is recommended to expedite pregnancy termination and to obtain tissue for karyotype analysis. Maternal serum is obtained for a-fetoprotein assessment at 16 to 18 weeks of gestation. Amnioncentesis is recommended to assess the fetal karyotype after the pregnancy has progressed past the time of prior losses.

The importance of obtaining karyotypic analysis from tissues obtained after pregnancy demise in a woman experiencing recurrent losses cannot be overemphasized. Results may suggest karyotypic anomalies in the parents. The documentation of aneuploidy may have important prognostic implications and may direct future interventions. A cost analysis has even demonstrated that karyotypic analysis is financially prudent among patients with histories of recurrent pregnancy loss (266). Of course, obtaining karyotypic data from aborted specimens has many hindrances, including difficulties in culturing cells from tissues that may have significant inflammation or necrosis and contamination of specimens with maternal cells. Efforts to develop methods that avoid such difficulties include the application of comparative genomic hybridization technology to recurrent pregnancy loss (267). This technology has even been used successfully on archived and paraffin-embedded pregnancy tissues (268). In the future, fetal karyotype assessment may also be performed using DNA isolated from nucleated fetal erythrocytes in maternal blood (269).

Therapy
Advances in the treatment of patients with recurrent pregnancy loss have been regrettably slow. Although we have experienced a rapid expansion in our understanding of the molecular and subcellular mechanisms involved in implantation and early pregnancy maintenance, extension of these concepts to prevention of recurrent early pregnancy loss has lagged. In addition to these limitations, progress toward treatment of most causes of recurrent pregnancy loss has been hampered by a variety of factors. The condition itself has been inconsistently defined. The results of clinical trials involving recurrent pregnancy loss patients are therefore often nearly impossible to compare and evaluate. Trial design is frequently substandard, with lack of rationale, lack of appropriate controls, and poor statistical analysis, limiting the ability to draw rational conclusions from reported results. Finally, epidemiologic data indicate that most patients with a history of recurrent pregnancy loss will, in fact, have a successful pregnancy the next time they conceive (9). For these reasons, with few exceptions, most therapies for recurrent pregnancy loss must be considered experimental. Until further study is completed these treatment protocols should be undertaken only with informed consent and in the setting of a well-designed, double-blind, placebo-controlled clinical trial.

Common therapeutic options that currently exist for patients with recurrent pregnancy loss include the use of donor oocytes or sperm, the use of preimplantation genetic diagnosis (PGD), the use of antithrombotic interventions, the repair of anatomic anomalies, the correction of any endocrine abnormalities, the treatment of infections, and a variety of immunologic interventions and drug treatments. Psychological counseling and support should be recommended for all patients.

Genetic Abnormalities
No therapies are presently available to address directly those parental chromosomal anomalies that potentially contribute to recurrent abortion. Three alternative approaches exist when genetic factors are linked to recurrent pregnancy loss. Some, such as antithrombotic therapy for patients with inherited thrombophilias, address the effects of the genetic abnormality. Others attempt to identify those particular embryos that are affected by chromosomal disorders and select against them. This approach involves the technique of PGD. Recent evidence suggests that, in women with a history of two or more spontaneous pregnancy losses, a subsequent pregnancy loss has a 60% chance of chromosomal abnormality. This raises the genetic etiology of recurrent pregnancy loss to new prominence. If the incidence of chromosomal abnormalities among the conceptuses of recurrent pregnancy loss patients is indeed this high, it could be argued that the use of assisted reproductive technologies, including PGD, might be indicated for all patients with unexplained recurrent pregnancy loss.

PGD involves the removal of a single cell from an in vitro–matured embryo. Genetic testing can be performed on this cell to rule out gross chromosomal abnormalities or the presence of specific genetic diseases (e.g., cystic fibrosis). Embryos that are diagnosed with genetic abnormalities would not be chosen for replacement into the uterine cavity. Those demonstrated to be normal would be considered appropriate for transfer into the uterus. Use of preimplantation genetic diagnosis, therefore, has the potential to reduce dramatically the incidence of pregnancy loss arising from a genetic etiology. Use of PGD in patients with known heritable genetic disorders (e.g., cystic fibrosis, X-linked disorders) is presently in widespread use in internationally recognized assisted reproductive technology centers. Efficacy of PGD in the treatment of patients with recurrent pregnancy loss is now under investigation (270-272). The third approach to patients with genetic factors and recurrent pregnancy loss is particularly relevant to those with Robertsonian translocations involving homologous chromosomes. In these patients, their genetic anomaly always results in embryonic aneuploidy. Therefore, use of either donor oocyte or donor sperm, depending on the affected partner, is recommended. Use of donor gametes among patients with a history of recurrent pregnancy loss has been demonstrated to be as effective as its use in matched partners (273). Synchronization of intercourse with ovulation may benefit some patients with genetic factor recurrent pregnancy loss (248). In all cases, genetic counseling is warranted.

Anatomic Anomalies
Hysteroscopic resection represents state-of-the-art therapy for submucous leiomyomas, intrauterine adhesions, and intrauterine septa. This approach appears to limit postoperative sequelae while maintaining efficacy for reproductive outcome (43). Use may be even be safely extended to patients with DES exposure, hypoplastic uter, and complicating septal anomalies (274). Attempts to improve on standard hysteroscopic metroplasty, which is typically performed in the operating room using general anesthesia, are presently under investigation. Ultrasonographically guided transcervical metroplasty has been reported to be safe and effective (275). Ambulatory, office-based procedures (276), including septum resection under fluoroscopic guidance (277), are also becoming attractive options.

For patients with a history of loss secondary to cervical incompetence, placement of a cervical cerclage is indicated. This is usually performed early in the second trimester, and certainly after documentation of fetal viability. Cervical cerclage should be considered as a primary intervention for women with DES-associated uterine anomalies. If endometriosis is encountered during a diagnostic evaluation, it should be resected laparoscopically.

Endocrine Abnormalities
Some investigators have proposed the use of ovulation induction for the treatment of recurrent pregnancy loss (278,279). The theory behind its use in these patients rests on hypotheses that ovulation induction is associated with healthier oocytes. Healthier oocytes, in turn, may decrease the incidence of luteal-phase insufficiency, which should result in improved pregnancy maintenance. This approach grossly oversimplifies the mechanisms involved in implantation and early pregnancy maintenance. Until appropriately studied, use of empiric ovulation induction for treatment of unexplained recurrent pregnancy loss should be viewed with caution. Recent evidence from small studies indicates that such use is not effective (279). Use of ovulation induction in some subsets of patients with recurrent pregnancy loss could be of benefit. For instance, stimulating folliculogenesis with ovulation induction or luteal-phase support with progesterone should be considered for women with luteal-phase insufficiency. The efficacy of these therapies, however, has never been substantiated (280). Ovulation induction might also be beneficial for women with hyperandrogenism and LH hypersecretion disorders, especially following pillary desensitization with gonadotropin-releasing hormone agonist therapy (58). This treatment also remains controversial because the only large, prospective, randomized controlled trial to date reports no therapeutic efficacy, either for prepregnancy pituitary suppression or for luteal-phase progesterone supplementation (281).

Recent links between PCOS, hyperandrogenism, hyperinsulinemia, and recurrent pregnancy loss (50,51,52 and 53) make use of insulin-sensitizing agents in the
treatment of recurrent pregnancy loss associated with PCOS attractive. At present, their use for this application is limited to case reports (282). Prepregnancy glycemic control may be particularly important for women with overt diabetes mellitus (54,55). Thyroid hormone replacement with synthroid may be helpful in cases of hypothyroidism. There is no place in the medical management of recurrent abortion for either thyroid medication or bromocriptine for women who do not have a thyroid or prolactin disorder.

Infections
Empiric antibiotic treatment has been used for couples with recurrent abortion. Its efficacy is unknown. Thus, elaborate testing for infectious factors among women with recurrent pregnancy loss and treatment of therapeutic interventions are not justified unless a patient is immunocompromised or a specific infection has been documented (43). Treatment of an infection in which an infectious organism has been identified, appropriate antibiotics should be administered to both partners, followed by posttreatment culture to verify eradication of the infectious agent before attempting conception.

Immunologic Factors
Immune-mediated recurrent pregnancy loss has received more attention than any other single etiologic classification of recurrent pregnancy loss. Nevertheless, the diagnosis and subsequent treatment of most cases remain unclear (121,283,284 and 285). Most therapies for proposed immune-related recurrent pregnancy loss must be considered experimental. As stated earlier, it is known that the developing conceptus contains paternal inherited gene products and tissue-specific differentiation antigens and that there is maternal recognition of these antigens (162,163 and 164). Historically, it has been speculated that both inappropriate weak immune responses to these antigens and unusually strong responses could result in early pregnancy loss. As a consequence, both immunostimulating and immunosuppressive therapies have been proposed.

Immunostimulating Therapies—Leukocyte Immunization
Stimulation of the maternal immune system using alloantigens on either paternal or pooled donor leukocytes has been promoted for patients with immune recurrent pregnancy loss, and a number of reports support possible mechanisms for potential therapeutic value (286,287 and 288). Both individual clinical trials and metaanalyses, however, continue to report conflicting results concerning the efficacy of leukocyte alloimmunization in patients with recurrent pregnancy loss (289,290,291,292,293 and 294). This most certainly reflects the remarkable heterogeneity in study design, patient selection, and therapeutic protocols, as well as the typically small numbers of enrolled subjects in these investigations. One published analysis reported that about 11 women with unexplained recurrent abortion would need to be immunized with alloantigens before one additional live birth was achieved (292). About 92% of successful pregnancy outcomes in these studies were not attributable to leukocyte immunization. Whether the 8% successful pregnancy rate achieved in leukocyte-immunized women is clinically relevant remains uncertain. One of the most recent and largest trials evaluating the efficacy of leukocyte immunization in patients with unexplained recurrent pregnancy loss is a part of the Recurrent Miscarriage (REMS) study (294). This investigation was large (more than 90 patients per treatment arm), prospective, placebo controlled, randomized, and double blinded. It demonstrated no efficacy for paternal leukocyte immunization in couples with unexplained recurrent pregnancy loss. Despite the unsubstantiated rationale for this therapy and the controversial reports concerning its efficacy, paternal leukocyte transfusion has been widely used, often in response to patient demand that some form of therapy be initiated. Unfortunately, entrepreneurial interests have also clouded the rational assessment of couples experiencing recurrent abortion, resulting in a growing number of financially lucrative leukocyte immunization clinics. However, there is no credible clinical or laboratory method to identify a specific individual who may benefit from such therapy. Furthermore, leukocyte immunization also poses significant risk to both the mother and her fetus (295,296). Several cases of graft-versus-host disease, severe intrauterine growth retardation, and stillbirth and immunocyte control system (301). Third-party seminal plasma hormone replacement for recurrent abortion have no scientifically credible rationale and should not be used.

Immunosuppressive Therapies
Immunosuppressive and other immunoregulating therapies have been advocated for cases in which abortion was believed to be due to antiphospholipid antibodies or to inappropriate cellular immunity toward the implanting fetus. Again, study design problems, including small numbers of recruited patients, lack of prestratification by maternal age and number of prior losses before randomization, and other methodologic and statistical inaccuracies preclude definitive statements regarding therapeutic efficacy for most of the proposed immunosuppressive approaches.

Intravenous Immunoglobulin
Intravenous immunoglobulins (IVIGs) are composed of pooled samples of immunoglobulins harvested from a large number of blood donors. Studies on the use of IVlg therapy in the treatment of recurrent pregnancy loss are based on the theory that some recurrent pregnancy loss patients have an overseasue immune reaction to their implanting fetal lymphocytes. These mechanisms may include decreased autoantibody production and increased autoantibody clearance, T-cell and Fc receptor regulation (302), complement inactivation (303), enhanced T-cell suppressor function, decreased T-cell adhesion to the extracellular matrix (304), and downregulation of T 1 cell immunoglobulin and T cell receptor family and an enlarged Fc receptor cell population (305). These mechanisms may be involved in a relatively small subgroup of patients with recurrent pregnancy loss. Other studies have suggested that use of IVlg in the treatment of patients with unexplained (and presumed immunologic) recurrent pregnancy loss has no benefit (306,307,308,309,310,311,312 and 313). However, improved posttreatment pregnancy rates may be seen when IVlg is used in those specific patients with autoimmune-mediated pregnancy loss associated with antiphospholipid syndrome (APS) (314,315). Therapy with IVlg for recurrent pregnancy loss is expensive, invasive, and time-consuming, requiring multiple intravenous infusions over the course of pregnancy. Side effects of IVlg therapy include nausea, headache, myalgias, and hypotension. More serious adverse effects include anaphylaxis (particularly in patients with IgA deficiency) (316).

Progesterone
As mentioned earlier, progesterone also has known immunosuppressive effects (166,167 and 168). A number of studies using in vitro cellular systems relevant to the maternal–fetal interface have now demonstrated that progesterone either inhibits T 1 cell immunity or causes a shift from T 1 to T 2-type responses (151,171,172,317,318). Progesterone has been administered both intramuscularly and intravaginally for the treatment of recurrent pregnancy loss. It is thought that vaginal administration may increase local, intrauterine concentrations of progesterone better than systemic administration. Vaginal formulations may therefore provide a safer method of maintaining local immunosuppressive levels of progesterone while averting any adverse systemic side effects. Although both vaginal and intramuscular progesterone therapy are associated with few minor side effects, their efficacy in the treatment of early unexplained recurrent pregnancy loss or recurrent pregnancy loss associated with T-helper cell dysregulation has never been appropriately investigated.

Other immunoregulating therapies theoretically useful in treating recurrent pregnancy loss include the use of cyclosporine, pentoxifylline, and rifledipine, although maternal and fetal risks with these agents preclude their clinical use. Plasmapheresis has also been used to treat women with recurrent abortion suspected to be caused by antiphospholipid antibodies (319). Generalized immunosuppressive therapy with corticosteroids, such as prednisone, has been advocated during pregnancy for women with recurrent losses and APS. Although corticosteroids have shown some treatment promise in these patients (320), maternal and fetal side effects and the availability of alternative therapies have limited their use. The effects of prednisone plus low-dose aspirin were examined in a recent, large, randomized, placebo-controlled trial treating patients with autoimmune and recurrent pregnancy losses. Pregnancy outcomes for treated and control patients were similar; however, the incidence of maternal diabetes and hypertension and the risk for premature delivery were all increased among those treated with prednisone and aspirin (321).

Antithrombotic Therapy
Therapy for patients with recurrent pregnancy losses associated with either the APS or other thrombophilic disorders has now shifted toward the use of antithrombotic medications. Unlike immunosuppressive treatments, this approach mainly addresses the effect (hypercoagulability), but not the underlying cause (e.g., genetic, APS), of recurrent pregnancy loss. However, there are reports that heparin, one typical antiagulant, may exert direct immunomodulatory effects by binding
to antiphospholipid antibodies (322). The combined use of low-dose aspirin (75 to 80 mg/d) and subcutaneous unfractionated heparin (5,000 units twice daily) during pregnancy has been best studied among women with APAS and appears to be efficacious (323,324 and 325). A typical regimen for women with antiphospholipid antibody syndrome would include use of aspirin (80 mg every day) beginning with any attempts to conceive. After pregnancy has been confirmed, 5,000 IU unfractionated sodium heparin is administered subcutaneously twice daily, throughout gestation. An aPTT should be obtained weekly, and dosages of heparin should be adjusted until anticoagulation is achieved. Patients using this therapy should be treated in conjunction with a perinatologist because of their increased risk for preterm labor, premature rupture of the membranes, intrauterine growth restriction, intrauterine fetal demise, and preeclampsia. Other potential risks include gastric bleeding, osteopenia, and abruptio placenta.

Attempts have recently been made to extend the finding that antithrombotic therapy is efficacious when used to treat patients with APAS and recurrent pregnancy loss in a number of directions. These directions include the use of low-molecular weight heparin (LMWH) and the use of antithrombotic therapy in non-APAS patients with thrombophilia and recurrent pregnancy loss and even among recurrent pregnancy loss patients without thrombophilia (unexplained recurrent losses).

New formulations of heparin (LMWH) have been demonstrated to be superior to unfractionated heparin in the treatment of many clotting disorders (326,327). LMWH has the advantage of an increased antithrombotic ratio when compared with unfractionated heparin. This results in improved treatment of inappropriate clotting but fewer bleeding side effects. In addition, LMWH has been associated with a decreased incidence of thrombocytopenia and osteoporosis when compared with its unfractionated counterpart. Finally, LMWH has a long half-life and requires less frequent dosing and monitoring, thereby improving patient compliance. Although its safe use in pregnancy is only now being fully evaluated, LMWH has shown promise when combined with low-dose aspirin in the treatment of recurrent pregnancy loss associated with APAS (324). Efficacy has also been suggested for similar treatment of recurrent pregnancy loss associated with other thrombophilias, including activated protein C resistance associated with factor V Leiden (326,327 and 328).

The prophylactic use of daily low-dose aspirin has become common practice within the lay public based on its perceived cardiovascular effects combined with its low incidence of side effects. Its sole use in the treatment of recurrent pregnancy loss has likewise gained momentum, and many patients with a history of recurrent loss will either be self-prescribing this therapy or will inquire about its usefulness. At present, there are no good data supporting its use either in patients with thrombophilia or in the general recurrent pregnancy loss population. In fact, although studies are small, the use of low-dose aspirin alone has not been shown to be effective in the treatment of recurrent pregnancy loss associated with APAS (323,331). One large study recently addressed the therapeutic efficacy of empiric low-dose aspirin among 805 patients with unexplained recurrent pregnancy losses. The authors conclude that such therapy cannot be justified (329).

More directed antithrombotic therapies have also been described for the treatment of recurrent pregnancy loss among patients with thrombophilias. For instance, the use of protein C concentrates has been reported to be associated with favorable pregnancy outcome in a patient with a history of thrombosis, recurrent fetal losses, and protein C deficiency (330).

As mentioned previously, vitamins B<sub>6</sub>, B<sub>12</sub>, and folate are important in homocysteine metabolism (17,18), and hyperhomocysteinemia is linked to recurrent pregnancy loss (15,16,26). Use of folate or B vitamin supplementation in patients with heritable or acquired disorders in homocysteine metabolism has been suggested (34).

Psychological Support

Despite commonly held biases that anxiety, stress, depression, and other psychological variables might be related to the occurrence of miscarriage, a number of recent studies have reported no causal association (334,335). It is important to discuss this misconception, which may otherwise promote inappropriate feelings of guilt among patients with recurrent losses. There is no doubt, however, that experiencing both isolated and recurrent losses can be emotionally devastating. The risk for major depression is increased greater than twofold among women with spontaneous pregnancy loss; in most women, it arises in the first weeks after delivery (336). A caring and empathetic attitude is prerequisite to all healing. The acknowledgment of the pain and suffering couples have experienced as a result of recurrent abortion can be a cathartic catalyst enabling them to incorporate their experience of loss into their lives rather than their lives into their experience of loss (69). Referrals to support groups and counselors should be offered. Self-help measures, such as meditation, yoga, exercise, and biofeedback, may also be useful.

Prognosis

The prognosis for successful pregnancy depends both on the potential underlying cause of pregnancy loss and (epidemiologically) on the number of prior losses (Table 28.4). As previously discussed, epidemiologic surveys indicate that the chance of a viable birth even after four prior losses may be as high as 60%. Depending on the study, the prognosis for successful pregnancy in couples with a cytogenetic etiology for reproductive loss varies from 20% to 80% (337,338 and 339). Women with corrected anatomic anomalies may expect a successful pregnancy in 60% to 90% of cases (337,338,340,341). A success rate higher than 90% has been reported for women with corrected endocrinologic abnormalities (337). Between 70% and 90% of pregnancies reported among women receiving therapy for antiphospholipid antibodies have been viable (342,343).

Many forms of preconceptional and postconceptional tests have been proposed to help predict pregnancy outcome (147,165,250,252,344); none has been fully substantiated in large, prospective trials. The documentation of fetal cardiac activity on ultrasound may offer prognostic value. However, it appears that its predictions may be greatly affected by any underlying diagnosis. In one study, the live birth rate following documentation of fetal cardiac activity between 5 and 6 weeks from the last menstrual period was about 77% in women with two or more unexplained spontaneous abortions (345). It may be important to note that most of the patients in this study had evidence of inappropriate antithrophoblast cellular immunity. Others have shown that 86% of patients with antiphospholipid antibodies and recurrent pregnancy loss had fetal cardiac activity detected before subsequent demise (346). Most recently, however, a prospective, longitudinal, observational study of 325 patients with unexplained recurrent pregnancy losses demonstrated that only 3% of 55 miscarriages occurred after the detection of fetal cardiac activity using transvaginal ultrasonography (347).

References

More than 30% of the female population of the United States is postmenopausal, and this percentage is increasing (1). Despite the universality of “the change of life,” the importance of its medical and psychological implications has only recently been appreciated. Each woman’s response to menopause may be different; as a result, management must be individualized to each woman’s needs.

Menopause is defined as the permanent cessation of menses for 1 year and is physiologically correlated with the decline in estrogen secretion resulting from the loss of follicular function. It is the most identifiable event of the perimenopausal period. The years immediately preceding and the decades afterward, however, are of far greater clinical significance. The perimenopausal period encompasses the time before, during, and after menopause. This period of hormonal transition is sometimes known as the menopausal transition period. Perimenopause usually begins in the mid- to late 40s; it often is insidious and uneventful but may be abrupt and symptomatic. Symptoms that begin with the menopausal transition usually continue into the postmenopausal period.

The postmenopausal period is associated with a significant increase in the incidence of age-related medical conditions. Some of these conditions, specifically osteoporosis and cardiovascular disease, are related to estrogen deficiency as well. For this reason, hormone replacement therapy should be a part of gynecologic care of postmenopausal women.

Perimenopausal Phases

- Menopausal Transition
- Menopause
- Premenopause
- Ovarian Failure
- Hormonal Changes
- Menopausal Transition
- Menopause

Menopausal Transition is the period that precedes menopause. Early recognition of the symptoms and the use of appropriate screening tests can minimize the impact of this potentially disruptive period. In many cases, however, it is difficult to differentiate stress-related symptoms from those associated with decreasing levels of estrogen. For this reason, both stress and relative estrogen deficiency should be considered when managing problems associated with the menopausal transition.

In some women, menstrual irregularity is the most significant symptom of the menopausal transition (2). Because abnormal bleeding is one of the most common symptoms of uterine problems, menstrual irregularity during the perimenopause should be evaluated carefully. Often uterine bleeding associated with this transition period is secondary to normal physiologic estrogen fluctuations rather than underlying pathology and may be treated medically (3).

Menopause

The period that precedes menopause is characterized by a varying degree of somatic changes that reflect alterations in the normal functioning of the ovary. Early recognition of the symptoms and the use of appropriate screening tests can minimize the impact of this potentially disruptive period. In many cases, however, it is difficult to differentiate stress-related symptoms from those associated with decreasing levels of estrogen. For this reason, both stress and relative estrogen deficiency should be considered when managing problems associated with the menopausal transition.

In some women, menstrual irregularity is the most significant symptom of the menopausal transition (2). Because abnormal bleeding is one of the most common symptoms of uterine problems, menstrual irregularity during the perimenopause should be evaluated carefully. Often uterine bleeding associated with this transition period is secondary to normal physiologic estrogen fluctuations rather than underlying pathology and may be treated medically (3).

Menopause

The cessation of menses resulting from the loss of ovarian function is a natural event, a part of the normal process of aging. Menopause is associated with the cessation of menses resulting from the loss of ovarian follicular function, and should be characterized as an event rather than a period of time. The time of menopause is determined genetically and occurs at a median age of 51 years (2, 3 and 4). It is related neither to race nor nutritional status. However, menopause occurs earlier in nulliparous women, in those who smoke tobacco, and in some women who have had hysterectomies (4, 5).

With the depletion of ovarian follicles that are able to respond to gonadotropins, follicular development and cyclic estrogen production cease. The ovaries, however, continue indefinitely to produce small amounts of androgens postmenopausally. Traditionally, menopause has been diagnosed retrospectively based on the lack of menstrual periods. With the advent of modern laboratory testing, menopause may now be more precisely defined as amenorrhea, with signs of hypoestrogenemia,
and an elevated serum follicle-stimulating hormone (FSH) level of greater than 40 IU/L. Menopause can also be diagnosed on the basis of subjective symptoms, such as hot flashes, or on the basis of provocative studies such as the progesterone withdrawal test. Hot flashes and other acute symptoms associated with the perimenopausal period often become more intense near menopause when the levels of circulating estrogen suddenly drop. These symptoms are especially intense in patients who experience premature ovarian failure or surgical menopause, which are accompanied by gradual drops in circulating estrogens.

**Postmenopausal Period**

The perimenopausal period is one of relative ovarian quiescence following menopause. Given the current lifespan of women in the United States, this period can comprise more than one-third of the average woman’s life. During this prolonged period, women are vulnerable to conditions caused by estrogen deficiency. Even though the long-term health impact of estrogen deficiency may be similar to that of thyroid or adrenal disorders, relatively little attention has been paid to this problem until recently. For this reason hormone replacement therapy is one of the primary concerns of many postmenopausal women’s health care.

Reasons for this lack of attention are many. Health problems associated with estrogen deficiency tend to be chronic rather than acute. For example, osteoporosis is not clinically apparent until decades after menopause, when unfortunately it becomes harder to treat. Second, the impact of estrogen deficiency on cardiovascular disease is often confused with age-related changes. Third, because of the peripheral conversion of both ovarian and adrenal androgens to estrogen, the loss of ovarian function does not result in an absolute estrogen deficiency. As a result, some women are less affected by estrogen deficiency than others.

**Premature Ovarian Failure**

As previously stated, loss of ovarian function is usually a gradual process that occurs over a number of years and culminates in menopause. Ovarian function is lost earlier and more suddenly than expected in some women as a result of natural causes, chemotherapy, or surgery.

Premature ovarian failure is defined as menopause occurring spontaneously before 40 years of age (3,4). Because of the relatively young age and the unexpected nature of the event, both psychological and hormonal support may be necessary. Although most practitioners are not adequately prepared to offer comprehensive psychological support, asking appropriate questions and making support services available can be helpful. The possibility of associated endocrine abnormalities should also be considered in women who develop premature ovarian failure. This is further addressed in Chapter 25.

In more than 40% of women who have hysterectomies, both ovaries are removed (3). As a result, many of these women undergo surgical menopause at a significantly younger age than do their counterparts who undergo natural menopause. The relatively young age of these women and the abrupt onset of associated symptoms create special problems (7).

The most obvious problem with surgical menopause is the acute onset of hot flashes (8). After several months, these hot flashes may be followed by signs of vaginal atrophy. In addition, long-term surgical menopause has been associated with significantly higher risk for both osteoporosis and cardiovascular disease than has natural menopause (9,10). The risk of osteoporosis can be decreased with estrogen replacement therapy. Because long-term hormone replacement may expose women to other types of risks, the relative risks and benefits of oophorectomy in conjunction with estrogen replacement therapy should be thoroughly discussed with any woman considering bilateral oophorectomy at the time of hysterectomy.

**Hormonal Changes**

Changes in hormone production and metabolism occur gradually during the menopausal transition. After almost 4 decades of cyclic production of estrogen and progesterone, the ovaries decrease their production of estrogen and will eventually cease any cyclic activity.

**Menopause Transition**

During the menopausal transition, ovulatory follicles become increasingly resistant to FSH stimulation even though levels of estradiol remain relatively constant. This process is most clearly demonstrated even before the onset of clinically apparent perimenopause by the relative resistance to gonadotropins in women undergoing ovulation stimulation for *in vitro* fertilization. In the average woman younger than 30 years, levels of estradiol higher than 1,000 pg/ml are easily attainable using stimulation of approximately 225 IU of FSH per day. In contrast, most women older than 40 years rarely attain estradiol levels this high, despite stimulation with up to 3 times as much gonadotropin per day. This degree of ovarian resistance to stimulation may explain the hot flashes experienced by some women, despite what appear to be normal levels of estradiol. It suggests that hot flashes may be the result of gonadotropin surges related to fluctuating estradiol levels or low levels of other ovarian hormones such as inhibin.

Progesterone is produced almost exclusively by granulosa cells and is highest in the midluteal phase. During the menopausal transition, ovulation becomes less frequent, with a decrease in overall progesterone production (11). In some women ovulation continues to occur, but the luteal levels of progesterone are lower than those observed in younger women (12).

**Menopause**

Near the time of the menopause, the levels of hormones, the way they are produced, and their roles change. Hormones most affected are those produced by the ovaries and include estrogen, progesterone, and androgens.

**Estrogen**

Even though the amount of estrogen secreted by the postmenopausal ovary is negligible, postmenopausal women continue to have measurable amounts of both estrone and estradiol (13). Prior to menopause, estradiol levels range from 50 to 300 pg/ml. However, even with cessation of ovarian function levels of estradiol may remain as high as 150 pg/ml (14). The answer to this apparent paradox lies in the ability of peripheral tissue to aromatize adrenal and ovarian androgens.

Androstenedione is produced by the adrenal and ovary and is aromatized to estrogen primarily by muscle and adipose tissue (15,16). Obese women have an increased level of circulating estrogens, and the unopposed estrogen places them at an increased risk for endometrial cancer (17). In contrast, thin women have a decreased level of circulating estrogens and are at an increased risk for developing osteoporosis (18). Surprisingly, the increased levels of estrogen often seen in obese women do not appear to protect them from acute menopausal symptoms; however, the higher levels do provide some skeletal protection (19).

**Progesterone**

After menopause, progesterone production ceases (20). The absence of cyclic changes in progesterone is usually associated with the absence of premenstrual symptoms (21). Decreased progesterone levels affect organs that are responsive to gonadal hormones, such as endometrium and breasts. During the reproductive years, progesterone protects the endometrium from excess estrogen stimulation by directly regulating estrogen receptors. It also exerts a direct intrinsic effect by inhibiting the trophic effects of estrogen on the endometrium (22).

Because circulating levels of estrogen can remain high enough to stimulate the endometrium both pre- and postmenopausally, unopposed stimulation of the endometrium may be a relatively common problem just prior to and after menopause (12). This probably explains the higher risk of endometrial hyperplasia and cancer found during this time (23).

Breast tissue also is known to be extremely sensitive to gonadal hormones. Although the relationship is less clear with breast than with endometrial tissue, unopposed stimulation of the breast ductal epithelium by estrogen in the absence of progesterone may play a role in the development of breast cancer (24). There are data that suggest that the use of combined estrogen and progestin replacement therapy may decrease the risk of breast cancer; however, a more recent large study does not
Menopausal Transition

Prior to menopause, the ovaries produce approximately 50% of the circulating androstenedione and 25% of the testosterone produced by a woman's body. Circulating concentration of testosterone in women is less than one-tenth that in men (0.50 ng/ml versus 6 ng/ml) and the amount of biologically active testosterone in women is only one-third that in men. In part, this is accounted for by the amount of sex hormone–binding globulin, which is relatively higher in women (30 to 90 nmol/L) than men (10 to 50 nmol/L) (26). After menopause, total androgen production decreases, mainly because ovarian production decreases but also because adrenal production decreases (11). The circulating levels of androstenedione and testosterone after menopause are approximately 0.53 and 0.23 ng/ml, respectively (27). After ovulation has ceased, the ovaries are responsible for 20% of the androstenedione and 40% of the testosterone as a result of continued gonadotropin stimulation of ovarian stromal cells (28). Although oophorectomy also results in a marked reduction in androgen production, the significance of these decreases will remain uncertain until the physiologic role of these hormones becomes more fully elucidated (12).

Patient Concerns about Menopause

A broad spectrum of emotions often is associated with hormonal and bodily changes characteristic of this period (29,30). A patient's response to menopause may be affected by factors such as lifestyle and regulation of the aging process. The loss of fertility and menstrual function that accompany natural or surgical menopause may have an impact on a woman's sense of well-being. The physician should be sensitive to the potentially significant emotional distress faced by women entering menopause and be prepared to offer psychological support. Subtle signs of the menopausal transition may be overlooked, because a woman may be hesitant to report unusual and potential hormonally related symptoms. Unless asked about directly, these symptoms often go undetected and result in a delay in diagnosis and treatment.

Loss of Childbearing Capacity

The effect of the loss of the ability to have children may depend on many factors, including the role childbearing has played in a woman's life. For some women in whom childbearing and childrearing have been a major source of status and self-esteem, the loss of fertility may cause great distress (30). For other women who have delayed childbearing for various reasons and are now unable to become pregnant, menopausal symptoms may represent tangible evidence of their inability to have children. One study suggests, however, that single and childless women are less likely to be depressed than their parous counterparts (31).

Loss of Youth

Regardless of the effect of the loss of childbearing capacity, the distress produced by the loss of youth symbolized by menopause may be subtle yet disturbing (29). In our society, youth is highly prized whereas maturity often is not; thus, tangible evidence of aging may be traumatic. The degree to which this may affect a woman may be related to the value she places on personal appearance. Aging may not be important to many women, but the possibility that this may cause anxiety or depression should be considered.

Skin Changes

The apparent acceleration of the skin changes associated with aging, especially after menopause, is a concern for many women. Evidence suggests that estrogen deficiency may play a role in these changes and that estrogen therapy may help to maintain skin thickness (32). Mechanisms underlying this effect are not completely understood but appear related to the ability of estrogen to both prevent and restore age-related skin collagen (33,34). Certainly, estrogen therapy cannot completely prevent the effects of aging on skin, nor can it counteract the effects of environmental stresses on skin, such as sun exposure and cigarette smoking.

Changes in Mood and Behavior

Depression

Depression is a particularly common problem for women and older patients. It accounts for more than 20% of visits of those who seek medical care (35). Although it is a widely held belief that depression is increased during the perimenopausal period, studies have failed to show a relationship between clinical depression and hormonal status (36). This finding would suggest that many psychiatric symptoms occurring during this period may be more related to psychosocial events such as changes in relationships with children, marital status, and other life events than to changes in hormonal status (37).

Anxiety and Irritability

Many women report an increased level of anxiety and irritability during the perimenopausal period; thus, these symptoms have become a prominent part of what is sometimes termed the climacteric syndrome (38). These feelings can be exacerbated by sleep deprivation as a result of vasomotor symptoms. Although the incidence of overt psychiatric disorders may not be increased, these complaints become more frequent following menopause. A popular notion is that anxiety and irritability associated with menopause are the result of estrogen deficiency (30). Multiple studies, however, have found no evidence to suggest that psychological symptoms experienced during the menopausal transition are related to estrogen changes (39,40). Increased anxiety and irritability associated with the perimenopausal period are more clearly associated with psychosocial factors than with estrogen status (41). It is important not only to investigate and treat the constellation of symptoms associated with the menopausal transition, but also to realize that psychological intervention may be helpful for some women.

Decreased Libido

A major concern for some women is a decrease in libido or sexual satisfaction that may occur with natural or surgical menopause. Sexual activity, however, remains relatively stable in menopausal women (42). However, only one-half of menopausal women report being sexually active (43). This may be related to a decrease in the number of available male partners in an aging population (1).

Vaginal changes associated with menopause may also contribute to decreased sexual satisfaction. Approximately one-third of postmenopausal woman not taking estrogen supplements will experience vaginal atrophy (44). Discomforts resulting from a lack of vaginal lubrication can also lead to dyspareunia. Atrophy can be treated easily with oral or vaginal estrogen therapy. Vaginal lubricants, especially those that are water soluble, are specifically useful for vaginal dryness.

The role androgens play in libido before and after menopause is uncertain. Although testosterone levels have been reported to be lower in postmenopausal than in premenopausal women, circulating concentrations do not change at menopause, and free testosterone levels might actually increase for several months before they decrease to levels lower than those of premenopausal women (45). In contrast, there is a marked drop in androgen levels following oophorectomy (11). In men, the relationship of androgens to libido is well established. For this reason, some clinicians have advocated androgen therapy in women experiencing decreased libido (46). In women, however, the decrease in circulating androgens following menopause has not been shown to consistently alter libido. Available evidence suggests that sexual satisfaction among postmenopausal women is not decreased over time, making treatment with androgens controversial (47).

Menopausal Transition
Abnormal Bleeding

Menstrual irregularity occurs in more than one-half of all women during the menopausal transition (48). Uterine bleeding can be irregular, heavy, or prolonged. In most cases, this bleeding is related to anovulatory cycles. This disruption of normal menstrual flow has been attributed to a gradual decrease in the number of normally functioning follicles and is reflected by a gradual increase in early follicular-phase FSH levels (49).

Although anovulation is one of the more common causes of abnormal uterine bleeding, pregnancy must always be considered. There are numerous reports of pregnancies in women in their late 40s who did not consider themselves fertile. In these women, abnormal bleeding may be the first indicator of an unexpected pregnancy.

Endometrial cancer should be suspected in any perimenopausal women with abnormal uterine bleeding. After menopause, the overall incidence of endometrial cancer is approximately 0.1% of women per year, but in women with abnormal uterine bleeding, it is about 10% (50,51,52 and 53). This risk is increased at least fivefold in women with a history of unopposed estrogen use (52,53) and decreased by more than two-thirds in women taking a combination of estrogen and a progestin (50).

Malignant precursors such as complex endometrial hyperplasia become more common during the menopausal transition. Because early diagnosis is the most effective way to improve a woman's prognosis, perimenopausal women with abnormal uterine bleeding should undergo an endometrial biopsy to exclude a malignant condition. Other causes that should be considered when a woman experiences abnormal uterine bleeding include cervical cancer, polyps, or leiomyomata.

Evaluation

The goal of evaluation of abnormal uterine bleeding is to achieve the greatest accuracy with the least risk and expense for the patient. In the past, when few diagnostic options were available, this condition was routinely managed with inpatient uterine curettage (54). However, with the development of less invasive office procedures and more accurate outpatient surgical approaches, uterine curettage without hysteroscopy is seldom done (Fig. 29.1).

Vaginal Ultrasonography

With the advent of newer diagnostic modalities, vaginal ultrasonography has become an established first step in the evaluation of perimenopausal bleeding. In premenopausal women, vaginal ultrasonography is extremely useful for identifying leiomyomata and endometrial asymmetry suggestive of endometrial polyps. When combined with saline injection, sonohysterography can accurately visualize polyps and other focal intrauterine lesions (55).

In postmenopausal women, vaginal ultrasonography, with or without saline injection, is even more helpful than in premenopausal women. An endometrial stripe <5 mm thick has been shown to be associated with an extremely low risk of endometrial hyperplasia or cancer (55,56 and 57). A thickened or asymmetric endometrial lining or an obvious intrauterine lesion is an indication for more thorough evaluation (Fig. 29.1) (55). Likewise, refractory abnormal uterine bleeding in a high-risk patient is an indication for endometrial biopsy even in the presence of reassuring ultrasonographic findings.

Endometrial Sampling

The importance of the endometrial biopsy cannot be overemphasized for the pre- or postmenopausal woman with abnormal uterine bleeding. It is well accepted that endometrial biopsy performed in the office is just as accurate as dilation and curettage and certainly more economical (54). Although vaginal ultrasonography has changed the way patients with abnormal uterine bleeding are evaluated, endometrial biopsy continues to be the most accurate screening method available for these patients. Dilation and curettage in the operating room with adequate anesthesia should be reserved for patients with abnormal endometrial biopsies or for conditions that preclude performing an office biopsy, such as cervical stenosis.

Hysteroscopy with Uterine Curettage

The addition of hysteroscopy to uterine curettage has greatly improved diagnostic accuracy in the evaluation of focal intrauterine lesions (58,59). It allows for visual inspection of the endometrial cavity and gives the physician the opportunity to perform directed biopsies (59). Endometrial polyps or submucosal leiomyomas can easily be identified by hysteroscopy. As with many high-technology approaches, however, hysteroscopy requires appropriate training and equipment to ensure patient safety. If hysteroscopy is unavailable, dilation and curettage remains an accepted method for evaluation of the endometrium (54) (see Chapter 13).

Treatment

Treatment of perimenopausal abnormal uterine bleeding may be either hormonal or surgical, depending on the patient's symptoms and diagnosis. Because anovulation is one of the most common causes of abnormal uterine bleeding during menopause, hormonal therapy is the first approach after the presence of intrauterine pathology has been excluded.

Hormonal Therapy

Oral Contraceptives In low-risk perimenopausal women with hormone-related symptoms, modern low-dose (0.35 mg ethinyl estradiol) oral contraceptives offer many advantages with minimal risk (60). New formulations contain as little as 20 mg of ethinyl estradiol and 1 mg of desogestrel. In addition to preventing undesired pregnancies, these formulations are associated with a high degree of menstrual regularity and can be used to treat symptoms associated with relative estrogen deficiency. The use of oral contraceptives until menopause has been found to be safe in women with no risk factors for cardiovascular disease (61).

Before starting the administration of oral contraceptives in this age group, patients should be free of the following risk factors: hypertension, hypercholesterolemia, cigarette smoking, previous thromboembolic disorders, cerebral vascular disease, or coronary artery disease. Because the estrogen dose in these pills is approximately 4 times the dose used after the menopause, women taking this therapy should be switched to traditional estrogen therapy by 50 years of age or sooner if symptoms occur. If the estradiol level is <20 pg/ml on day 7 of the pill-free interval, it may be appropriate to...
switch from oral contraceptives to estrogen replacement therapy (62).

**Cyclic Progesterone** Some women may not be candidates for oral contraceptives, because their use is contraindicated or unacceptable based on the presence of other symptoms or because of fear of complications. In these patients, alternative methods of hormonal therapy can be used. A standard approach is cyclic progesteron therapy (medroxyprogesterone 10 mg daily for 10 days each month) to induce withdrawal bleeding and to decrease the risk of endometrial hyperplasia. It may be difficult to control abnormal uterine bleeding with cyclic progesterin during the menopausal transition, because the ovaries continue to cycle intermittently. Progesterin administration may be difficult to synchronize with spontaneous ovulation.

**Surgical Therapy**

During the menopausal transition, surgery may be required for treatment of conditions causing abnormal uterine bleeding.

**Dilation and Curettage** When endometrial polyps are determined to be the cause of abnormal uterine bleeding, curettage can be both therapeutic and diagnostic. Because polyps can be missed by curettage alone, it has been recommended that diagnostic hysteroscopy be performed prior to uterine curettage for abnormal uterine bleeding (58). With the exception of endometrial polyps, uterine curettage has not been shown to have any long-term benefit in the treatment of abnormal uterine bleeding.

**Hysterectomy** Although removal of the uterus is the most common and effective surgical treatment for abnormal uterine bleeding (63), hysterectomy is associated with a certain degree of morbidity and cost. Prior to recommending hysterectomy, an adequate preoperative evaluation must include endometrial sampling and an adequate trial of hormonal therapy to control the bleeding.

A special consideration is whether normal ovaries should be removed (see Chapter 22). It is now standard practice for postmenopausal women undergoing hysterectomy to have their ovaries removed to avoid the subsequent risk of ovarian cancer (84). Oophorectomy has been recommended in women older than 40 to 45 years for the same reason. In perimenopausal women, however, there are some disadvantages to oophorectomy. First, immediate hormone replacement is necessary and may be somewhat more difficult to manage because of the sudden and precipitous drop in estrogen levels. In addition, oophorectomy results in a decrease in androgen production, which may have as yet unknown long-term effects (11). After 40 years of age, the decision to remove normal ovaries during hysterectomy should be discussed carefully and the patient should be made aware of the potential known advantages and disadvantages.

**Endometrial Ablation** A relatively new and potentially advantageous approach to dysfunctional uterine bleeding during the menopausal transition is endometrial ablation. This relatively minor surgical procedure involves destroying the functioning endometrium with electrical energy using a hysteroscuresectoscope, as discussed in Chapter 21. The risks of uterine perforation, bowel injury, and fluid overload related to the nonconducting distention media are low if the technique is used correctly (69).

In response to these problems, a nonsurgical thermal balloon endometrial ablation technique has been developed that requires a substantially lower level of technical skill (65). First reported in 1994, this method is performed by blind placement in the uterus of a single-use saline-filled balloon catheter that is warmed rapidly to cause thermal damage to the endometrium. Most patients report either decreased bleeding or amenorrhea, and both intraoperative and postoperative complications are uncommon.

The risk of uterine malignancy after any type of endometrial ablation procedure remains uncertain. The concern is that as the injured endometrial lining remodels, glandular tissue may be buried under scar tissue. Theoretically, this situation could delay uterine bleeding, which is the earliest sign of endometrial cancer. However, subsequent endometrial cancer after endometrial ablation has been reported only in women who had preexisting endometrial hyperplasia (86). For this reason, a thorough fractional curettage should be performed prior to the procedure. Monthly progesterin therapy could be used thereafter in an attempt to decrease the risk in these potentially anovulatory women. Until long-term data become available, women considering this therapy should be informed about the potential risk of endometrial ablation.

**Menopause**

Most women experience some effects of estrogen deficiency during menopause. Other symptoms often associated with menopause may not be directly related to estrogen deficiency but rather are multifactorial or the results of aging. Effects can range from short-term discomfort to long-term changes that can have a profound effect on a woman's health. Both short-term and chronic effects respond to hormone replacement therapy.

**Diagnosis of Estrogen Deficiency**

The determination of ovarian function is based primarily on clinical criteria. If a woman's body is producing enough hormones to sustain regular menstruation, her estrogen level is presumed to be sufficient to protect against osteoporosis and heart disease. In the years prior to menopause, many women experience symptoms of estrogen deficiency due to declining ovarian function even while they are having relatively regular menses. These symptoms typically begin with a break in the regular pattern of ovulatory cycles and often include irregular vaginal bleeding, hot flashes, night sweats, mood swings, vaginal dryness, insomnia, heart palpitations, headache, and fatigue. Even though measurable levels of circulating hormones are still present, hormone replacement therapy in these women can be extremely helpful in controlling symptoms (87). If a woman who is almost 50 years old stops menstruating completely, a presumptive diagnosis of estrogen insufficiency can be made. However, because chronic anovulation is common during this time and can also cause amenorrhea, a progestin challenge test is frequently used as a bioassay of estrogen status (69). If a nonpregnant woman has amenorrhea but no other symptom of estrogen deficiency, administration of medroxyprogesterone (10 mg orally for 10 days) will produce withdrawal bleeding in women who have levels of circulating estrogen adequate to produce endometrial proliferation.

**Estradiol**

In women who have amenorrhea along with symptoms of estrogen deficiency or in whom progesterin withdrawal bleeding does not occur, measurement of serum estradiol levels can be helpful. In a menstruating woman, normal estradiol levels range from 40 to 300 pg/ml. In an oligoovulatory woman, an estradiol level of 30 pg/ml usually indicates some degree of residual ovarian function. Women over 70 years of age occasionally have levels this high, presumably as a result of peripheral conversion (39). For this reason, the absolute estradiol level should not be the deciding factor when considering hormone replacement therapy.

During the menopausal transition, relative ovarian resistance with fluctuating estrogen secretion may result in hot flashes and related symptoms despite relatively normal serum estradiol levels. Because many of the symptoms of the menopausal transition are central nervous system in origin, treatment is sometimes indicated for symptoms alone and should not be withheld simply because the serum estradiol levels are in the normal range.

**Follicle-stimulating Hormone**

The most consistent finding in the menopausal transition is an elevation of serum FSH levels. In fertile menstruating women, FSH on cycle day 3 should be 5 to 10 IU/L with normally functioning ovaries (69). Elevated FSH levels (10 to 25 IU/L) suggest ovarian resistance consistent with the menopausal transition, even if estradiol levels are in the normal range. Physiologically, this is believed to be the result of decreased inhibin production by the ovarian follicles during the last decade of menstrual function. FSH levels >40 IU/L, are consistent with complete cessation of ovarian function. However, ovarian function can wax and wane over several years, and levels can fluctuate accordingly. Therefore, women with amenorrhea and FSH >40 IU/L may resume menstruating for a short time in the future and occasionally may achieve pregnancy (79).

**Luteinizing Hormone**

Evaluation of luteinizing hormone (LH) levels appears to be of somewhat less value than other hormone assessments during the menopausal transition. Prior to menopause, LH levels are usually in the range of 5 to 20 IU/L. Although LH levels increase during the menopausal transition in a manner similar to those of FSH, LH is also significantly elevated during the midcycle surge and in cases of chronic anovulation. Because individuals rarely may have amenorrhea as a result of
risk of developing Alzheimer’s disease can be decreased by estrogen therapy (71).

One of the most intriguing areas of research is the potential role of estrogen therapy in the prevention or treatment of Alzheimer’s disease. Evidence suggests that the long-term memory in postmenopausal women (72).

Estrogen deficiency appears to have effects on the central nervous system that have only recently been appreciated. Perimenopausal women often experience stress urinary incontinence in more than 50% of treated women, presumably by exerting a direct effect on urethral mucosa (73,74).

Urinary symptoms may include dysuria, urgency, and recurrent urinary tract infections (75). Vaginal symptoms include dryness, dyspareunia, and recurrent vaginal infections (76).

In women for whom hormone replacement is contraindicated, multiple alternative treatments for hot flashes have been developed. Somewhat effective alternatives may be progestins such as medroxyprogesterone (10 to 30 mg daily orally) (76) or medrogestrol acetate (20 to 40 mg daily orally) (79). If either of these progestins results in intolerable side effects, the use of alternative progestins may be considered, although few data exist regarding their efficacy.

In the past, right sweats were treated with a formulation that contained a combination of phenobarbital, ergotamine, and belladonna. However, this combination has a marked sedative effect and potentially can be habit forming. In addition, controlled studies show little long-term effectiveness of this treatment (91). For these reasons, this formulation is not currently recommended as a treatment for hot flashes.

Many women have mild hot flashes that they do not feel require therapy. The patients can be advised that, without treatment, the symptoms usually subside slowly over 3 to 5 years (73).

Sleep Disturbances

Changes in sleep patterns occur in both sexes with age. However, during the menopausal transition, many women experience increasing sleep difficulties and insomnia that appear to be related to estrogen deficiency (38). Hot flashes may disrupt sleep and sleep patterns, a problem that may be markedly improved by hormone therapy (82).

Low estrogen levels have a cumulative effect on many tissues. Prolonged estrogen deficiency may contribute to the development of potentially reversible conditions, such as genitourinary atrophy, or more life-threatening and irreversible conditions, such as cardiovascular disease and osteoporosis. Prevention and early detection remain the cornerstones of health maintenance in this age group.

Vaginal and Urinary Tract Changes

Vaginal tissue and the tissues of the urethra and bladder base are known to be estrogen sensitive. Within 4 to 5 years of menopause, approximately one-third of women who are not taking hormone therapy develop symptomatic atrophy (83). Vaginal symptoms include dryness, dyspareunia, and recurrent vaginal infections. Fortunately, these symptoms are reversible with estrogen therapy (84).

Urinary symptoms may include dysuria, urgency, and recurrent urinary tract infections (44). In addition, genuine stress urinary incontinence may be related to estrogen deficiency. Urethral shortening associated with postmenopausal atrophic changes may result in urinary incontinence. Estrogen therapy may improve or cure stress urinary incontinence in more than 50% of treated women, presumably by exerting a direct effect on urethral mucosa (85). A trial of hormone therapy should be undertaken prior to a surgical approach in any woman with vaginal atrophy.

Central Nervous System

Estrogen deficiency appears to have effects on the central nervous system that have only recently been appreciated. Perimenopausal women often experience difficulty concentrating and loss of short-term memory. These symptoms have been attributed to either the effects of aging alone or subtle sleep deprivation associated with hot flashes (86). Estrogen appears to have direct effects on mental function, and replacement therapy has been shown to improve both short-term and long-term memory in postmenopausal women (87,88).

One of the most intriguing areas of research is the potential role of estrogen therapy in the prevention or treatment of Alzheimer’s disease. Evidence suggests that the risk of developing Alzheimer’s disease can be decreased by estrogen therapy (89,90), but prospective trials to verify this are lacking. Although the precise role of
Cardiovascular disease, including coronary artery disease and cerebrovascular disease, continues to be the leading public health problem in this country. Combined, these diseases account for more than 50% of all deaths in women over 50 years of age (91).

Cardiovascular disease has been associated with multiple causes, the most important of which may be age. The risk of cardiovascular disease increases for men and women throughout their lifetimes (91). Although the risk of death from coronary artery disease is at least 3 times as great for men as for women before menopause, the relative risk for women increases significantly after menopause. It is essential to be aware of preventable risk factors for cardiovascular disease and to encourage women to minimize these risk factors.

One of the most pervasive and treatable risk factors after the menopause is hypoestrogenemia. In the past, it was believed that age alone explained the increased risk of cardiovascular disease observed after menopause (92). Recent data have indicated that estrogen deficiency significantly increases the risk of cardiovascular disease and that this risk may be reduced by hormone replacement therapy (93). Postmenopausal women taking estrogen replacement therapy have less than one-half the risk of either myocardial infarction or stroke as women who are not taking estrogen therapy (77,91,94). However, long-term prospective trials of the cardiovascular benefits and risks of estrogen replacement therapy are lacking. This potentially substantial but controversial benefit of estrogen therapy should be made known to patients, especially those who may be reluctant to take estrogens for other reasons. On the other hand, a short-term trial suggested no overall decrease in mortality and an increase in early venous thrombotic events in women with preexisting cardiovascular disease (95).

Although hypoestrogenemia is apparently a major contributing factor to cardiovascular disease in women, other risk factors that are amenable to change may be equally important. Probably the most significant risk factors are hypertension and cigarette smoking (55). Studies suggest that hypertension increases the risk of cardiovascular disease by 10-fold and cigarette smoking increases the risk by at least threefold (96). Other risk factors include diabetes mellitus, hypercholesterolemia, and a sedentary lifestyle. To decrease cardiovascular disease in postmenopausal women, screening for these risk factors must be performed and lifestyle changes must be recommended.

Osteoporosis

The association between both natural and surgical menopause and osteoporosis has been clearly established. By definition, osteoporosis is the reduction in the quantity of bone. Because this definition may be too broad to be clinically useful, some authors have narrowed the definition to include only bone loss that has progressed to a point that specific parts of the skeleton are so thin that they have an enhanced susceptibility to fractures or that fractures are actually present (80). The degree of cortical and trabecular bone loss necessary to meet this criterion is uncertain in those who have not yet had a bone fracture. The numbers of elderly women who have osteoporosis-related crush fractures of spinal vertebrae or fractures of either the radius or the neck of the femur have reached epidemic proportions (98). With the aging of the population, the problem is likely to increase.

Although the rate of bone loss significantly increases at the time of menopause, the maximal incidence of osteoporosis-related fractures appears to occur several decades later. It is estimated that more than 30% of all women older than 90 years will experience hip fractures (99), and approximately 20% of these women will die within 3 months, most commonly from complications related to prolonged immobilization (100). By the time signs of osteoporosis become apparent, treatment is difficult.

Pathophysiology

The cause of osteoporosis is multifactorial. The primary factors associated with osteoporosis include heredity, age, estrogen status, and dietary calcium intake.

Age is the most important factor associated with bone loss (101). All women begin losing bone mass in their early 30s, and this loss continues throughout their lives. Before menopause, the rate of loss is less than 1% of total bone tissue per year. After menopause, the rate of bone loss increases to as high as 5% per year in estrogen-deficient women. Evidence suggests that this may be related to the gradual decrease in growth hormone levels associated with age (102).

Heredity plays a role primarily by determining the peak bone mass that a woman will attain during her life and the subsequent rate of bone loss. On average, African American women have a higher bone mass than white women, and this may explain the low risk of osteoporosis-related fractures observed in African Americans (103). A family history of osteoporosis is a strong risk factor (104).

A third factor associated with bone loss is estrogen status. For women not taking hormone replacement, bone loss after menopause is accelerated to a rate of 3% to 5% per year (105). This loss is most rapid during the first 5 years after menopause, when up to 20% of the expected lifetime loss from the femoral neck may occur (106). Depending on the age at surgery, surgical menopause poses a higher risk than natural menopause because a woman experiences a longer period with low estrogen levels (107). Hypoestrogenemia has a direct effect on osteoblast function and appears to exert its adverse effects by altering calcium balance (108,109).

A fourth factor affecting bone loss is dietary calcium. Dietary intake of calcium, primarily in the form of dairy products, has been shown to be associated with decreased bone loss in premenopausal women (110). In postmenopausal women taking estrogen therapy, calcium supplementation of 1,000 mg/day appears to be sufficient to decrease bone loss (111). Combined with the average dietary intake of calcium in the United States of only 500 mg/day for adults (110), the total requirement of 1,500 mg/day is provided by diet plus supplementation. Calcium therapy can be given as calcium carbonate (oyster shell) tablets or as calcium citrate. Fortunately, this amount of calcium supplementation does not appear to increase the risk of kidney stones (112). However, it may be associated with gastrointestinal complaints such as constipation or increased flatulence.

Other factors that preserve bone density and decrease the risk of osteoporosis include physical activity (113) and avoidance of cigarette smoking (114). There have been no controlled studies of these factors to determine their impact on osteoporosis-related fractures in later life.

Methods for Detection

After a prolonged period of hypoestrogenemia, bone loss is only partially reversible. For these reasons, it is more practical and effective in most women to implement therapy to prevent bone loss at the time of menopause than to screen for early signs of osteoporosis.

In some women, hormone replacement therapy may be contraindicated or not desired by the patient. In these women, an alternative approach would be to screen for bone loss at set intervals and institute therapy if a defined threshold of osteopenia is reached (Table 29.1). No standard guideline for significant osteopenia has been established, but recommendations for screening have been published (115).

esteorgen deficiency in Alzheimer's disease has yet to be defined, the implications of this finding for the aging population are readily apparent.
Hormone Replacement Therapy

Estrogen deficiency has been considered by many to be a physiologic rather than a pathologic condition, probably because ovarian failure is genetically programmed. With the increased life expectancy of women, however, the negative impact of prolonged estrogen deficiency becomes more significant. Although estrogen deficiency is treatable, fewer than 20% of postmenopausal women take estrogen (116). Although hormone replacement therapy is not completely risk free, the health benefits appear to outweigh the risks for most women.

Benefits

Hormone replacement therapy is indicated for any woman with signs or symptoms of hypoestrogenemia (Table 29.2). Because of the health risks associated with estrogen deficiency, replacement therapy should be offered to all postmenopausal women who have no contraindications. Women with known risk factors for osteoporosis should be encouraged to consider taking estrogen to minimize their risks. Some of the benefits of estrogen are felt immediately, but the long-term benefits may not be apparent for several decades.

Table 29.2. Indications and Contraindications for Estrogen Replacement Therapy

Hot Flashes

Relief of hot flashes is the most common reason motivating women to start and continue hormone replacement. Hot flashes may interfere with the normal sleep cycle resulting in insomnia (68) and, in severe cases, they may also interfere with concentration (73). Although oral estrogen therapy usually is effective in reducing the severity and frequency of hot flashes within a few days, patients should be advised that it might be several weeks before maximal relief is achieved.

Osteoporosis

Hormone replacement therapy helps maintain bone mass and skeletal integrity, thereby protecting against osteoporosis (117). Estrogen conserves calcium by both enhancing the efficiency of intestinal absorption and by improving renal calcium conservation (108). In addition, estrogen appears to have a direct effect on osteoclast function (109). Estrogen can effectively slow bone loss and, to a limited degree, it can reverse the bone loss associated with osteoporosis (118). For this reason, hormone replacement therapy should be initiated at menopause and should be given for a long term, although the optimal duration is unclear.

Recent evidence has suggested that progesterone also has a role in maintaining bone density (119). Progesterone appears to promote bone formation by increasing osteoblast activity, either directly or indirectly, by inhibiting the corticosteroid effect on osteoblasts. This finding supports the use of a progestin alone in women who are unable to take estrogen therapy.

Cardiovascular Disease

Estrogen replacement therapy may protect against cardiovascular disease, including coronary artery disease and stroke, although the issue has not been settled. Multiple cohort and case-control studies have suggested that estrogen decreases the risk of both myocardial infarction and stroke by 50% (76,90,93). Even when there is angiographic evidence of coronary artery disease, estrogen enhances survival (120). However, carefully controlled prospective trials to rule out the possibility of selection bias and other confounding factors must be completed to fully understand the cardiovascular benefits and risks of hormone replacement therapy.

There are several mechanisms by which estrogen could protect the heart. The most important mechanism appears to be the effect of estrogen on serum lipids and lipoproteins. Estrogen decreases circulating levels of low-density lipoproteins (121,122) and increases levels of high-density lipoproteins. Both the absolute decrease in total cholesterol and the increase in the high-density to low-density lipoprotein ratio appear to retard progression of coronary artery disease. Although these effects are attenuated by concomitant progestin use, this effect appears to decrease over time (123). It has been estimated that estrogen accounts for 20% to 50% of the total protective effect for cardiovascular disease. The degree to which progestins may diminish this effect, if any, is unknown.

Estrogen also exerts an antiatherosclerotic effect on blood vessels (124). This appears to result, in part, from a direct effect on blood vessels that is not reversed by progestin. Estrogen appears to be an antioxidant that decreases the formation of lipid peroxides, which may prevent arteriosclerosis by minimizing the oxidation of low-density lipoprotein cholesterol, a potent inducer of plaque formation in vessels (125). A third beneficial effect is that of vasodilation (128). There appears to be a direct effect on blood vessel endothelial cells that results in immediate vasodilation, perhaps mediated by estrogen receptors (127).

A final beneficial effect is on coagulation. Low-dose estrogen therapy (i.e., 0.625 mg daily of conjugated estrogens) results in a subclinical decrease in coagulability by decreasing platelet aggregation and fibrinogen and by inhibiting plasminogen formation (128). This effect appears to be lost with higher doses of estrogen (i.e., 1.25 mg of conjugated estrogens). At even higher doses, equivalent to those used in oral contraceptives, there is an increase in coagulability. Therefore, doses of estrogen equivalent to 0.625 mg of conjugated estrogens should be used for long-term therapy.

Potential Health Risks

The risks of estrogen therapy appear to be dose related. Many of the side effects of high-dose oral contraceptives have not occurred with the lower doses of estrogen used for hormone replacement therapy. Because of the sensitivity of some tissues to estrogen, the potential risks of estrogen for postmenopausal women must be considered.

Breast Cancer

Numerous retrospective and prospective observational studies have evaluated whether exogenous estrogens in the form of either oral contraceptives or estrogen replacement therapy have an impact on the incidence of breast cancer. Although some recent meta-analyses have concluded that there is no increased risk of this malignancy among women who receive hormone replacement (129,130), others have demonstrated a significant increase in breast cancer risk that may be related to the duration of estrogen use (24,131,132). One of these studies showed a relative risk for the development of breast cancer of 1.46 in women who took postmenopausal estrogens for 5 years or longer (24). However, large prospective clinical trials are incomplete and the benefits of hormone replacement may outweigh
Endometrial Cancer

A well-established risk of estrogen replacement therapy is endometrial hyperplasia and endometrial cancer. Early observational studies found that women who used estrogen alone were over 7 times more likely to develop endometrial cancer than women who did not (53). The simultaneous use of progestins effectively prevents this problem in most cases (133,134). However, it should be kept in mind that even women taking progestin therapy can develop endometrial cancer, especially if they have used unopposed estrogens in the past (136). Therefore, endometrial evaluation remains an important part of management for all women with irregular vaginal bleeding.

Gallbladder Disease

The risk of symptomatic gallbladder disease is increased by the use of oral contraceptives (135). In a recent questionnaire study of postmenopausal women, hormone replacement therapy doubled the risk of gallbladder disease compared with women taking no hormones (136). However, in two case-control studies, no increased risk could be appreciated (135,136).

Thrombophlebitis

There is no increased risk of thrombophlebitis associated with hormone replacement therapy, despite the well-established association with the use of oral contraceptives. With the standard doses of conjugated estrogens normally used, there is no increased risk of either venous thrombosis or pulmonary embolism in healthy women (138), although there appears to be some increased risk in women with preexisting cardiovascular disease (95). Hormone replacement therapy does not significantly alter clotting factors (139).

No study has specifically addressed the risk of recurrent thrombophlebitis for women taking estrogen. Therefore, women who have a history of thrombophlebitis should be offered hormone replacement therapy with the understanding that it is unlikely, but uncertain, that this therapy alters the risk of recurrent thrombophlebitis (140).

Hypertension

Hypertension has been one of the relative contraindications to oral contraceptives because the higher-dose formulations were found to further increase blood pressure (141). In contrast, at the dosages used for hormone replacement therapy, conjugated estrogens appear to have little effect on blood pressure (142). Because chronic hypertension is a well-established risk factor for myocardial infarction and stroke, women with this disorder should be encouraged to maintain low blood pressure levels and to consider the potential protective effect of hormone replacement therapy for cardiovascular disease.

Side Effects

Vaginal Bleeding

Any vaginal bleeding may be distressing; therefore, hormone replacement regimens associated with amenorrhea are preferable. Daily use of estrogen and cyclic use of progestins produces cyclic bleeding in most women. In an effort to avoid cyclic bleeding, the daily use of estrogen and progestin has been advocated. After several months, daily progestin therapy may result in amenorrhea in one-half of women with minimal risk of hyperplasia (72).

Irregular bleeding may be an early warning sign of endometrial hyperplasia or malignancy. More commonly, it is a sign of endometrial atrophy or asynchronous shedding. Because of the known association of estrogen replacement therapy with endometrial cancer, endometrial biopsy is indicated when irregular uterine bleeding occurs postmenopausally.

Breast Tenderness

Breast tenderness can occur with hormone replacement therapy (143). This effect may be related to both estrogen and progesterone stimulation of breast tissue. The symptoms of fibrocystic breast changes may be increased (143,144). The initial approach to relieving breast symptoms is to decrease the daily estrogen dose to the equivalent of 0.625 mg of conjugated equine estrogen, and reduce progestin to the equivalent of 2.5 mg of medroxyprogesterone. If this is ineffective, the type of estrogen may be changed.

Mood Changes

Progestins are known to cause mood disturbances similar to those of premenstrual syndrome, including anxiety, irritability, or depression (145,146). Because of the significant protective effect of progestins against endometrial cancer, a dose or formulation of progestin that has the fewest side effects should be sought.

Weight Gain and Water Retention

Some women are extremely sensitive to exogenous estrogens and experience symptoms such as weight gain or water retention (147). Although few data are available regarding these problems, alternative doses and formulations of both estrogen and progestins should be used to find the combination with the fewest side effects.

Special Cases

In some women, the standard approach to hormone replacement therapy may not be appropriate or sufficient. Despite the benefits of estrogen administration after menopause, for some this therapy is contraindicated (Table 29.2).

History of Breast Cancer

One of the most controversial subjects concerning hormone replacement therapy is whether a woman with a history of successfully treated breast cancer can receive estrogen. Because it appears that estrogen replacement therapy may increase the risk of breast cancer, there has been a fear that estrogen may increase the risk of recurrent breast cancer. The limited data available suggest no increased risk of recurrent breast cancer among postmenopausal estrogen users (148,149). Until more long-term data are available, estrogen should be used with caution in women with a history of breast cancer. In a woman with nonmetastatic (node-negative) estrogen receptor-negative breast cancer, particularly one who has a strong family history of osteoporosis and heart disease, the benefits of estrogen may outweigh the low theoretic risk that the hormone will predispose her to the development of recurrent cancer.

History of Endometrial Cancer

Although, theoretically, estrogen and progestin therapy should not increase the risk of recurrent endometrial cancer, there are few data regarding estrogen or progestin therapy in women who have been treated for endometrial cancer (150). Progestins have been used to treat recurrent endometrial cancer (151). One study of women successfully treated for stage I endometrial cancer revealed that a combination of estrogen and progestin therapy does not increase the risk of recurrence (152). Because of the limited information available, any woman with a history of endometrial cancer should be informed of the unknown risk of recurrence with hormone therapy.

Endometriosis
There have been anecdotal reports of recurrent endometriosis (153,154) or malignant transformation of endometriosis in women with endometriosis who take hormone replacement therapy following bilateral oophorectomy (155). Therefore, such women should be treated with continuous estrogen and progestin. In women with severe endometriosis, especially when the bowel, bladder, or ureter is involved, a hormone-free period for up to 6 months immediately after surgery may also be advisable prior to instituting combined estrogen and progestin therapy.

Liver Disease

Hormone replacement therapy has not been associated with the development of liver disease. However, estrogens are metabolized in the liver, and women with normal ovarian function and chronic liver disease are known to have significantly elevated levels of circulating estrogens (156). Likewise, normal doses of conjugated estrogens could lead to a substantially higher level of circulating estrogens than expected in these women. Therefore, hormone replacement therapy should be avoided in women with active or chronic liver disease.

Replacement Hormones and Regimens

The mainstay of hormone replacement in the absence of ovarian function is estrogen, usually with the addition of a progestin. Standard replacement therapy has consisted of concurrent estrogen and progestin in anyone with an intact uterus. Estrogen only was given to women who had had hysterectomies. Better understanding of the effects hormones have on the body has altered these classic approaches to therapy.

Types of Estrogen and Progesterone

Estrogens are available in oral and parenteral forms (Table 29.3). The most commonly prescribed oral estrogen preparation is conjugated equine estrogen, a combination of estrone (50%), equilenin (23%), 17a-dihydroequilenin (13%), and various other estrogens extracted from the urine of pregnant mares (157). This formulation has been available in the United States for more than 50 years; thus, most of the data regarding the safety and efficacy of estrogen replacement therapy have been gathered from women taking conjugated estrogens. Several other estrogen preparations have been developed, and data are accumulating regarding their comparative effectiveness. There is, at present, no compelling reason to recommend one preparation over others based on risks or side effects. If side effects become a problem with one formulation, a woman should be encouraged to try a different dose or estrogen formulation rather than abandon estrogen replacement altogether.

Table 29.3. Standard Dosages Used for Hormone Replacement Therapy

Estrogens are used orally as the first line of therapy in most women. Transdermal estradiol patches have also been found to be an effective method for hormone administration. However, there are several potential drawbacks to this approach. On a physiologic level, it is uncertain whether the same benefit is achieved in terms of reduction of cardiovascular disease risks, because changes in lipoprotein profiles do not occur as rapidly as with oral therapy (158). Transdermal patches are more expensive than oral preparations and result in some skin irritation at the site of placement in one-third of users (159). In women in whom oral estrogen therapy does not alleviate symptoms or is poorly tolerated or in whom oral preparations create a problem with hypertriglyceridemia, estrogen patches may offer some advantage (121).

A special situation is the vaginal use of conjugated estrogens. Apparently, the rate of vaginal absorption of estrogen is similar to that of oral absorption (160). This has two important implications. First, when women who have contraindications to oral estrogen therapy use vaginal estrogen for atrophic vaginitis, the amount of systemically absorbed estrogen must be considered. In these women, it is recommended that the smallest dose needed to maintain the vaginal tissue effect be used. This is usually approximately one-third of an applicator (0.2 mg) used 2 to 3 times weekly. Second, women who desire estrogen therapy but are unable to take oral estrogen can try vaginal administration. This route of administration appears to be less effective in resolving symptoms of estrogen deficiency (161) and may not alter serum lipids to the same degree as oral estrogens (162).

Progestins are also available in several different formulations (Table 29.3). The most common progestin used is medroxyprogesterone given orally. In the doses prescribed to protect the endometrium (2.5 to 10 mg daily), some women experience psychological effects such as anxiety, irritability, or depression (142,143). Although these problems may be associated to some degree with all progestins, few studies have evaluated them. Many progestin formulations have been evaluated for the treatment of irregular bleeding and have been found to be effective. No single progestin is clearly superior to another. If a woman has significant side effects with one progestin dose, a lower dose or a different progestin formulation should be given.

Estrogen Alone

Whenever possible, unopposed estrogen therapy should be avoided in a woman with a uterus (163). However, some women experience intolerable side effects from progestin therapy. If no dose or formulation of progestin can be found that has acceptable side effects, estrogen alone may be given. A reasonable approach is the use of the lowest effective dose of estrogen daily coupled with yearly surveillance of the endometrium by endometrial biopsy. The use of vaginal ultrasonography for endometrial surveillance may prove ultimately to be effective for this use.

Daily estrogen alone has been recommended for women after hysterecomy. Progestins have been avoided because they may partially reverse the beneficial effects of oral estrogens on serum lipids. However, the effects of progestins on lipids appear to be short term (122), and only part of the protective effect of estrogens on the cardiovascular system are derived from lipid effects. Therefore, it is controversial whether progestins should be used in combination with estrogen for these women (64).

Estrogen plus Cyclic Progesterone

Methods have been sought to avoid the risks of estrogen therapy while retaining the benefits. The addition of a progestin to estradiol minimizes the risk of endometrial hyperplasia and cancer (164). The use of 12 to 14 days per month of medroxyprogesterone results in a risk of endometrial cancer less than that for the population at large.

Initially, in the United States, estrogen was given for only 21 to 25 days per month and progestins were given for the last 7 to 10 days of the estrogen therapy (164), followed by a monthly period of 6 to 8 days when no hormones were given. Although this had the theoretic advantage of giving all hormonally responsive tissue a rest, no study has ever shown a benefit to this hormone-free period. However, data from Great Britain suggest that 10 days of progestin therapy per month may not be enough to prevent endometrial hyperplasia in some women (165). Therefore, when cyclic progestins are used, they should be given for 12 to 14 days per year. With 14 days of therapy (10 mg medroxyprogesterone or equivalent), endometrial hyperplasia is uncommon (156).
Estrogen plus Continuous Progesterone

Although cyclic progestins given at appropriate doses can protect the endometrium from hyperplasia, this approach also results in cyclic endometrial shedding and menstruation in most women (167). Vaginal bleeding is one of the most common reasons that women discontinue hormone replacement therapy (158). In addition, the relatively high dose of progestin used may result in significant symptoms in some women (142). These may include physical symptoms such as breast tenderness, fluid retention, and edema and psychological symptoms such as anxiety, irritability, or depression. Therefore, regimens using lower daily doses of progestins have been developed (164,169). Daily progestin therapy (2.5 to 5.0 mg medroxyprogesterone acetate or equivalent) protects against endometrial hyperplasia to a degree similar to that of cyclic administration at higher doses (Fig. 29.2) (166).

Figure 29.2 Administration of hormone replacement therapy.

More than 50% of women who take a daily combination of estrogen and progestin will experience irregular bleeding, even after 1 year of therapy (72). This group of women may be better served by continuous estrogen accompanied by cyclic progesterone. For many women, regular bleeding may be preferable to unpredictable bleeding.

Selective Estrogen Receptor Modulators

In 1995, an estrogen receptor, ER-b, was cloned (170). This receptor displayed similar but distinct ligand-binding specificities to that of ER-a but had a different tissue distribution. With this discovery came the search for the optimal long-term female hormone replacement for women. It resulted in the development of selective estrogen-receptor modulators known as SERMS.

Raloxifene, a benzothiopene compound is of particular interest (171). This SERM binds with higher affinity to the estrogen receptor a than b. Clinically, raloxifene produces an effect similar to estrogen on the skeletal and cardiovascular system while behaving as an estrogen antagonist in the uterus and the breast. Raloxifene maintains a favorable lipid profile and does not exert a proliferative effect on the endometrium. More importantly, effects on bone remodeling are similar to those of estrogen. Unfortunately, raloxifene does not relieve hot flushes. Raloxifene may be particularly useful for decreasing the risk of osteoporosis in women who are unwilling or unable to take hormone replacement therapy because of persistent benign bleeding, a history of severe endometriosis, or a high risk for primary or recurrent breast cancer (172).

Testosterone

Testosterone has been used in women, especially after surgical menopause, to alleviate specific symptoms (173). In the United States, testosterone is available in an injectable form (testosterone enanthate 75 to 150 mg intramuscular every month), and as a combined oral formulation (methyltestosterone 2.5 to 5 mg, plus conjugated or esterified estrogens 0.625 to 1.25 mg). In Great Britain, a subcutaneous testosterone implant is also available.

The most common indication for androgens is loss of libido (174). Studies of testosterone administration have shown mixed results in terms of libido improvement (173,174,175,176,177 and 178). One 6-month study of the oral preparation showed an adverse effect on the estrogen-induced changes in lipoproteins (176). Because of a lack of long-term studies of any of these agents, the effects on heart disease and other organ systems are unknown. Until studies establish a benefit for this type of therapy, androgens should be prescribed with caution. For women who experience decreased sexual responsiveness, appropriate counseling appears to be the most effective therapy (177,180).

Patient Monitoring

Continued monitoring of patients taking hormone replacement therapy relies heavily on self-reporting of symptoms and bleeding patterns. Postmenopausal women also should undergo routine assessments that should include evaluation and counseling regarding risk factors.

Symptoms

In women for whom the standard doses of estrogen do not seem to be sufficient to control hot flashes, doses as high as 2.5 mg of conjugated estrogens per day can be used. In premenopausal women who have undergone oophorectomy, oral contraceptives may offer relief in difficult cases (65), but they have more side effects than hormone replacement therapy (61).

Vaginal dryness responds somewhat slower than hot flashes to hormone replacement therapy. Even at the lowest therapeutic doses, however, complete resolution of vaginal dryness is usually seen after 3 to 6 weeks (181). Any symptoms of atrophic vaginitis will decrease over the same period.

Vaginal Bleeding

The bleeding patterns associated with estrogen therapy depend on the type of hormone protocol used. The most common pattern with unopposed estrogen is amenorrhea (72). If breakthrough bleeding occurs, endometrial biopsy should be performed. Even with no vaginal bleeding, yearly endometrial evaluation is recommended for women taking unopposed estrogen because of the risk of endometrial cancer.

With continuous estrogen and cyclic medroxyprogesterone, cyclic estrogen withdrawal bleeding almost always occurs monthly (167). If irregular or intermenstrual bleeding occurs, endometrial biopsy should be performed (Fig. 29.2). Although endometrial hyperplasia or cancer occurs only rarely, risk is not completely eliminated with progestin therapy.

When continuous estrogen and continuous progestins are used, the bleeding pattern is more variable. Many women taking this therapy will develop amenorrhea (72). One-half of women will have some degree of irregular bleeding even after 1 year. The best method for evaluation of the endometrium has not been determined. Although the bleeding is almost always light, the significance of it cannot be determined without endometrial evaluation. It is reasonable to consider a baseline endometrial biopsy for anyone taking this agent who has irregular bleeding. If irregular bleeding persists for 6 months, further evaluation with ultrasonography and possibly hysterectomy may be of benefit.

Nonhormonal Drugs

In addition to estrogen, calcium, vitamin D, calcitonin, and bisphosphonates (especially etidronate and alendronate) have been used for the treatment of
postmenopausal osteoporosis. Calcium can slow bone loss but does not increase bone mass (152), and calcium intake of 1,500 mg daily is considered a mainstay of both prevention and treatment of osteoporosis in postmenopausal women. Fluoride is the only agonist agent that can stimulate bone formation and substantially increase bone density (183), but the bone formed is actually more fracture prone, and fluoride is not recommended therapy. Calcitonin is probably as effective as estrogen in reducing fracture risk and is a consideration for women who cannot take oral medication (154). Calcitriol, a vitamin D analog, can increase lumbar bone mass and decrease the rate of vertebral fractures (1470 IU vitamin D3 daily). Although calcitriol does not appear to slow bone loss as effectively as conventional hormone replacement therapy, it does appear to be effective in reducing fracture risk (185).

Of the bisphosphonates, alendronate is approximately 1,000 times more potent than etidronate in terms of the inhibition of bone resorption. Newer bisphosphonates, pamidronate and risedronate, are being evaluated and appear to be equally effective in increasing bone mineral density and reducing fracture risk (186). In a randomized study, alendronate was given orally 5 to 20 mg/day for 3 years, or 20 mg/day for 2 years followed by 5 mg/day for the third year, along with 500 mg/day of calcium (148). Compared with placebo, the rate of vertebral fracture was approximately one-half. 3.2% for those receiving alendronate versus 6.2% for the placebo group.

In general, women with documented osteoporosis, either by densitometry or previous fracture, are candidates for aggressive antiresorptive therapy in addition to calcium and vitamin D replacement.
Endometrial carcinoma is the most common malignancy of the female genital tract, accounting for almost half of all gynecologic cancers in the United States. About 39,300 new cases are diagnosed annually, resulting in more than 6,600 deaths. Endometrial carcinoma is the fourth most common cancer, ranking behind breast, lung, and bowel cancers, and the seventh leading cause of death from malignancy in women. Overall, about 2% to 3% of women develop endometrial cancer during their lifetime (1).

In recent years, certain factors have led to an increasing awareness of and emphasis on diagnosis and treatment of endometrial cancer. These factors include the declining incidence of cervical cancer and related deaths in the United States, prolonged life expectancy, postmenopausal use of hormone replacement therapy, and earlier diagnosis. The availability of easily applied diagnostic tools and a clearer understanding of premalignant lesions of the endometrium have led to an increase in the number of women diagnosed with endometrial cancer. Although endometrial carcinoma usually presents as early-stage disease and can generally be managed without radical surgery or radiotherapy, deaths from endometrial carcinoma now exceed those from cervical carcinoma in the United States. Endometrial cancer is a disease that occurs primarily in postmenopausal women and is increasingly virulent with advancing age. The role of estrogen in the development of most endometrial cancers has clearly been established; any factor that increases exposure to unopposed estrogen increases the risk for endometrial cancer.

During the past several decades, the histopathology, spread patterns, and prognostic factors that affect the prognosis of endometrial cancers have been better defined. Management of endometrial cancer has evolved from a program of preoperative intrauterine radium packing or external pelvic irradiation followed in 6 weeks by hysterectomy, to a single brachytherapy session using an intrauterine tandem and colpostats followed immediately by hysterectomy, to an individualized approach using hysterectomy as primary therapy and employing additional postoperative treatment depending on surgical and pathologic findings. Further analysis and investigation are needed to determine whether this initial operative approach to treatment and staging, followed by targeted postoperative therapy, will translate into improved survival rates and lower morbidity.

**Epidemiology and Risk Factors**

There appear to be two different pathogenetic types of endometrial cancer (2). The most common type occurs in younger, perimenopausal women with a history of exposure to unopposed estrogen, either endogenous or exogenous. In these women, tumors begin as hyperplastic endometrium and progress to carcinoma. These “estrogen-dependent” tumors tend to be better differentiated and have a more favorable prognosis than tumors that are not associated with hyperestrogenism. The other type of endometrial carcinoma occurs in women with no source of estrogen stimulation of the endometrium. These spontaneously occurring cancers are not associated pathologically with endometrial hyperplasia, but may arise in a background of atrophic endometrium. They are less differentiated and associated with a poorer prognosis than estrogen-dependent tumors. These “estrogen-independent” tumors tend to occur in older, postmenopausal, thin women and are present disproportionately in African American and Asian women.

Several risk factors for the development of endometrial cancer have been identified (3,4,5,6,7 and 8) (Table 30.1). Most of these risk factors are related to prolonged, unopposed estrogen stimulation of the endometrium. Nulliparous women have 2 to 3 times the risk of parous women. Infertility and a history of irregular menses as a result of anovulatory cycles (prolonged exposure to estrogen without sufficient progesterone) increase the risk. Natural menopause occurring after 52 increases the risk for endometrial cancer 2.4 times compared with that in women whose menopause occurred before 49 years of age, probably as a result of prolonged exposure of the uterus to progesterone-deficient menstrual cycles. The risk for endometrial cancer is increased 3 times in women who are 21 to 50 pounds overweight and 10 times in those more than 50 pounds overweight (excess estrone as a result of peripheral conversion of adrenally derived androstenedione by aromatization in fat).
Progestin therapy is very effective in reversing endometrial hyperplasia without atypia but is less effective for endometrial hyperplasia with atypia. Relapse occurred in all 7 patients who discontinued progestin therapy (another study, hyperplasia resolved in 94% of 32 patients with atypical endometrial hyperplasia who were treated with medroxyprogesterone acetate (10 to 20 mg per day), 84% of 65 who did not have cytoxic atypia, only 50% responded to progestin, 25% developed recurrent hyperplasia, and 25% developed adenocarcinoma. In another study, hyperplasia resolved in 94% of 32 patients with atypical endometrial hyperplasia who were treated with megestrol acetate (20 to 40 mg/d); however, relapse occurred in all 7 patients who discontinued progestin therapy. For

Figure 30.1 Atypical hyperplasia (complex hyperplasia with severe nuclear atypia) of endometrium. A: The proliferative endometrial glands reveal considerable crowding and papillary infoldings. The endometrial stroma, although markedly diminished, can still be recognized between the glands. B: Higher magnification demonstrates disorderly nuclear arrangement and nuclear enlargement and irregularity. Some contain small nuclei. (Reproduced or modified from Berek JS, Hacker NF. Practical gynecologic oncology, 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

The risk of endometrial hyperplasia progressing to carcinoma is related to the presence and severity of cytologic atypia. Kurman and colleagues retrospectively studied endometrial curettages from 170 patients with untreated endometrial hyperplasia followed a mean of 13.4 years (13). They found that progression to carcinoma occurred in 1% of patients with simple hyperplasia, 3% of patients with complex hyperplasia, 8% of patients with atypical simple hyperplasia, and 29% of patients with atypical complex hyperplasia. Most of the hyperplasias seemed to remain stable (18%) or regress (74%). The premalignant potential of hyperplasia is influenced by age, underlying ovarian disease, endocrinopathy, obesity, and exogenous hormone exposure (12,13).

Of patients with atypical hyperplasia detected in an endometrial biopsy or curettage specimen, about 25% have an associated, usually well-differentiated, endometrial carcinoma seen at hysterectomy. Marked cytologic atypia, a high mitotic rate, and marked cellular stratification are features of atypical endometrial hyperplasia most often associated with the finding of an undiagnosed carcinoma at hysterectomy.

In a report of 85 menopausal women with endometrial hyperplasia treated with medroxyprogesterone acetate (10 to 20 mg per day), 84% of 65 who did not have cytoxic atypia had complete reversal of the lesions, 6% developed recurrent hyperplasia, but none developed cancer, at a mean follow-up of 7 years (14). By contrast, of 20 patients with cytoxic atypia, only 50% responded to progestin, 25% developed recurrent hyperplasia, and 25% developed adenocarcinoma. In another study, hyperplasia resolved in 94% of 32 patients with atypical endometrial hyperplasia who were treated with megestrol acetate (20 to 40 mg/d); however, relapse occurred in all 7 patients who discontinued progestin therapy (15).

Progestin therapy is very effective in reversing endometrial hyperplasia without atypia but is less effective for endometrial hyperplasia with atypia. For
women with endometrial hyperplasia without atypia, ovulation induction, cyclical progestin therapy (e.g., medroxyprogesterone acetate, 10 to 20 mg/d for 14 days per month), or continuous progestin therapy (e.g., megestrol acetate, 20 to 40 mg/d) all appear to be effective. Continuous progestin therapy with megestrol acetate (40 mg/d) is probably the most reliable treatment for reversing complex or atypical hyperplasia. Therapy should be continued for 2 to 3 months, and endometrial biopsy should be performed 3 to 4 weeks after completion of therapy to assess response.

Periodic endometrial biopsy or transvaginal ultrasound is advisable in patients being followed after progestin therapy for atypical hyperplasia, because of the presence of undiagnosed cancer in 25% of cases, the 29% progression rate to cancer, and the high recurrence rate after treatment with progestins.

**Endometrial Cancer Screening**

Screening for endometrial cancer should currently not be undertaken because of the lack of an appropriate, cost-effective, and acceptable test that reduces mortality (16,17 and 18). Routine Papanicolaou's (Pap) test is inadequate and endometrial cytology is too insensitive and nonspecific to be useful in screening for endometrial cancer even in a high-risk population. A progesterone challenge test reveals whether the endometrium has been primed by estrogen, but it does not identify abnormal endometrial pathology. Transvaginal ultrasound examination of the uterus and endometrial biopsy are too expensive to be employed as screening tests.

Although many risk factors for endometrial cancer have been identified, screening of high-risk individuals could at best detect only half of all cases of endometrial cancer. Furthermore, no controlled trials have been carried out to evaluate the effectiveness of screening for endometrial cancer. Screening for endometrial cancer or its precursors may be justified for certain high-risk women, such as those receiving postmenopausal estrogen replacement therapy without progestins and members of families with hereditary nonpolyposis colorectal cancer. Conversely, women taking tamoxifen receive no benefit from routine screening with transvaginal ultrasound or endometrial biopsy (19,20).

Fortunately, most patients who have endometrial cancer present with abnormal perimenopausal or postmenopausal uterine bleeding early in the development of the disease, when the tumor is still confined to the uterus. Application of an appropriate and accurate diagnostic test in this situation usually results in early diagnosis, timely treatment, and a high cure rate.

**Endometrial Cancer**

**Clinical Features**

**Symptoms**

Endometrial carcinoma most often occurs in women in the sixth and seventh decades of life, at an average age of 60 years; 75% of cases occur in women older than 50 years of age. About 90% of women with endometrial carcinoma have vaginal bleeding or discharge as their only presenting complaint. Most women recognize the importance of this symptom and seek medical consultation within 3 months. Some women experience pelvic pressure or discomfort indicative of uterine enlargement or extraterine disease spread. Bleeding may not have occurred because of cervical stenosis, especially in older patients, and may be associated with hematometra or pyometra, causing a purulent vaginal discharge. This finding is often associated with a poor prognosis (21). Less than 5% of women diagnosed with endometrial cancer are asymptomatic. In the absence of symptoms, endometrial cancer is usually detected as the result of investigation of abnormal Pap test results, discovery of cancer in a uterus removed for some other reason, or evaluation of an abnormal finding on a pelvic ultrasound or computed tomography (CT) scan obtained for an unrelated reason. Women who are found to have malignant cells on Pap test are more likely to have a more advanced stage of disease (22).

Abnormal perimenopausal and postmenopausal bleeding should always be taken seriously and be properly investigated, no matter how minimal or nonpersistent. Causes may be nongenital, genital extrauterine, or uterine (23). Nongenital tract sites should be considered based on the history or examination, including testing for blood in the urine and stool.

Invasive tumors of the cervix, vagina, and vulva are usually evident on examination, and any tumors discovered should be biopsied. Traumatic bleeding from an atrophic vagina may account for up to 15% of all causes of postmenopausal vaginal bleeding. This diagnosis can be considered if inspection reveals a thin, friable vaginal wall, but the possibility of a uterine source of bleeding must first be eliminated.

Possible uterine causes of perimenopausal or postmenopausal bleeding include endometrial atrophy, endometrial polyps, estrogen replacement therapy, hyperplasia, and cancer or sarcoma (24,25,26) and 27) (Table 30.3). Uterine leiomyomas should never be accepted as a cause of postmenopausal vaginal bleeding. This diagnosis can be considered if inspection reveals a thin, friable vaginal wall, but the possibility of a uterine source of bleeding must first be eliminated.

Estrogen therapy is an established risk factor for endometrial hyperplasia and cancer. The risk for endometrial cancer is 4 to 8 times greater in postmenopausal women receiving unopposed estrogen replacement, and the risk increases with time and higher estrogen doses. This risk can be decreased by the addition of a progestin to the estrogen, either cyclically or continuously. Endometrial biopsy should be performed as indicated to assess unexplained bleeding or annually in women not taking a progestin. Endometrial hyperplasia occurs in 5% to 10% of patients with postmenopausal uterine bleeding.

The source of excess estrogen should be considered, including obesity, exogenous estrogen, or an estrogen-secreting ovarian tumor. Only about 10% of patients with postmenopausal bleeding have endometrial cancer.

Premenopausal women with endometrial cancer invariably have abnormal uterine bleeding, which is often characterized as menometrorrhagia or oligomenorrhea, or cyclic bleeding that continues past the usual age of menopause. The diagnosis of endometrial cancer must be considered in premenopausal women when abnormal bleeding is persistent or recurrent or if obesity or chronic anovulation is present.

**Signs**

Physical examination seldom reveals any evidence of endometrial carcinoma, although obesity and hypertension are commonly associated constitutional factors. Special attention should be given to the more common sites of metastasis. Peripheral lymph nodes and breasts should be assessed carefully. Abdominal examination...
is usually unremarkable except in advanced cases in which ascites or hepatic or omental metastases may be palpable. On gynecologic examination, the vaginal introitus and suburethral area, as well as the entire vagina and cervix, should be carefully inspected and palpated. Bimanual rectovaginal examination should be performed specifically to evaluate the uterus for size and mobility, the adnexa for masses, the parametria for induration, and the cul-de-sac for nodularity.

**Diagnosis**

Office endometrial aspiration biopsy is the accepted first step in evaluating a patient with abnormal uterine bleeding or suspected endometrial pathology (28). The diagnostic accuracy of office-based endometrial biopsy is 90% to 98% when compared with subsequent findings at dilation and curettage (D & C) or hysterectomy (29,30 and 31).

The narrow plastic cannulas are relatively inexpensive, can often be used without a tenaculum, cause less uterine cramping, resulting in increased patient acceptance, and are successful in obtaining adequate tissue samples in more than 95% of cases. If cervical stenosis is encountered, a paracervical block can be performed, and the cervix can be dilated. Premedication with an antiprostaglandin agent can reduce uterine cramping. Complications following endometrial biopsy are exceedingly rare; uterine perforation occurs in only 1 to 2 cases per 1,000. Endocervical curettage may also be performed at the time of endometrial biopsy if cervical pathology is suspected. A Pap test is an unreliable diagnostic test because only 30% to 50% of patients with endometrial cancer have abnormal Pap test results (32).

Hysteroscopy and D & C should be reserved for situations in which cervical stenosis or patient tolerance does not permit adequate evaluation by aspiration biopsy, bleeding recurs after a negative endometrial biopsy, or the specimen obtained is inadequate to explain the abnormal bleeding. Hysteroscopy is more accurate in identifying polyps and submucous myomas than endometrial biopsy or D & C alone (33,34).

Transvaginal ultrasound may be a useful adjunct to endometrial biopsy for evaluating abnormal uterine bleeding and selecting patients for additional testing (35,36 and 37). Transvaginal ultrasound, with or without endometrial fluid instillation (ultrasonohysterography), may be helpful in distinguishing between patients with minimal endometrial tissue whose bleeding is due to perimenopausal anovulation or postmenopausal atrophy and patients with significant amounts of endometrial tissue or polyps who are in need of further evaluation. The finding of an endometrial thickness greater than 4 mm, a polypoid endometrial mass, or a collection of fluid within the uterus requires further evaluation. Although most studies agree that an endometrial thickness of 5 mm or less in a postmenopausal woman is consistent with atrophy, more data are needed before ultrasound findings can be considered to eliminate the need for endometrial biopsy in a patient who has symptoms.

**Pathology**

The histologic classification of carcinoma arising in the endometrium is shown in Table 30.4 (10,38).

**Table 30.4. Classification of Endometrial Carcinomas**

Endometrioid Adenocarcinoma

The endometrioid type accounts for about 80% of endometrial carcinomas. These tumors are composed of glands that resemble normal endometrial glands; they have columnar cells with basally oriented nuclei, little or no intracytoplasmic mucin, and smooth intraluminal surfaces (Fig. 30.2). As tumors become less differentiated, they contain vadjust solid areas, less glandular formation, and more cytologic atypia. The well-differentiated lesions may be difficult to separate from atypical hyperplasia.

Criteria that indicate the presence of invasion and are used to diagnose carcinoma are desmoplastic stroma, glands back-to-back without intervening stroma, extensive papillary pattern, and squamous epithelial differentiation. These changes, with the exception of the infiltrating pattern with desmoplastic reaction, require an area of involvement equal to or exceeding half of a low-power microscopic field (LPF) (>1 LPF; 4.2 mm in diameter) (39,40).

The differentiation of a carcinoma, expressed as its grade, is determined by architectural growth pattern and nuclear features (Table 30.5). In the International Federation of Gynecology and Obstetrics (FIGO) grading system proposed in 1989, tumors are grouped into three grades: grade 1, 5% or less of the tumor shows a solid growth pattern; grade 2, 6% to 50% of the tumor shows a solid growth pattern; and grade 3, more than 50% of the tumor shows a solid growth pattern. In addition, notable nuclear atypia that is inappropriate for the architectural grade increases the tumor grade by one.
Table 30.5. FIGO Definition for Grading of Endometrial Carcinoma

Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component. This FIGO system is applicable to all endometrioid carcinomas, including its variants, and to mucinous carcinomas. In serous and clear cell carcinomas, nuclear grading takes precedence; however, most investigators believe that these two carcinomas should always be considered high-grade lesions, making grading unnecessary.

About 15% to 25% of endometrioid carcinomas have areas of squamous differentiation (Fig. 30.3). In the past, tumors with benign-appearing squamous areas were called adenoacanthomas, and tumors with malignant-looking squamous elements were called adenosquamous carcinomas. It is now recommended that the term endometrial carcinoma with squamous differentiation be used to replace these two designations because the degree of differentiation of the squamous component parallels that of the glandular component and the behavior of the tumor is largely dependent on the grade of the glandular component (41,42).

A villoglandular configuration is present in about 2% of endometrioid carcinomas (43,44). In these tumors, the cells are arranged along fibrovascular stalks, giving a papillary appearance but maintaining the characteristics of endometrioid cells. The villoglandular variants of endometrioid carcinomas are always well-differentiated lesions that behave like the regular endometrioid carcinomas, and they should be distinguished from papillary serous carcinomas.

Secretory carcinoma is a rare variant of endometrioid carcinoma that accounts for about 1% of cases (45,46). Occurs mostly in women in their early postmenopausal years. The tumors are composed of well-differentiated glands with intracytoplasmic vacuoles similar to early secretory endometrium. These tumors behave as regular well-differentiated endometrioid carcinomas and generally have an excellent prognosis. Secretory carcinoma may be an endometrioid carcinoma that exhibits postgestational changes, but a history of postgestational therapy is rarely elicited. Secretory carcinoma must be distinguished from clear cell carcinoma because both tumors have predominately clear cells. These two tumors can be distinguished by their structure: secretory carcinomas have uniform glandular architecture, uniform cytology, and low nuclear grade, whereas clear cell carcinomas have more than one architectural pattern and a high nuclear grade.

Mucinous Carcinoma

About 5% of endometrial carcinomas have a predominant mucinous pattern in which more than half of the tumor is composed of cells with intracytoplasmic mucin (47,48). Most of these tumors have a well-differentiated glandular architecture; their behavior is similar to that of common endometrioid carcinomas, and the prognosis is good. It is important to recognize mucinous carcinoma of the endometrium as an entity and to differentiate it from endocervical adenocarcinoma. Features that favor a primary endometrial carcinoma are the merging of the tumor with areas of normal endometrial tissue, presence of foamy endometrial stromal cells, presence of squamous metaplasia, or presence of areas of typical endometrioid carcinoma. Positive perinuclear immunohistochemical staining with vimentin suggests an endometrial origin (49).

Papillary Serous Carcinoma

About 3% to 4% of endometrial carcinomas resemble serous carcinoma of the ovary and fallopian tube (50,51,52 and 53). Most often, these tumors are composed of fibrovascular stalks lined by highly atypical cells with tufted stratification (Fig. 30.4). Psammoma bodies are frequently observed.

Uterine papillary serous carcinomas (UPSCs) are all considered high-grade lesions. They are commonly admixed with other histologic patterns, but mixed tumors behave as aggressively as pure serous carcinomas. Serous carcinomas are often associated with lymph–vascular space and deep myometrial invasion. Even when
these tumors appear to be confined to the endometrium or endometrial polyps without myometrial or vascular invasion, they behave more aggressively than endometrioid carcinomas and have a propensity for intraperitoneal spread, simulating the behavior of ovarian carcinoma. Of patients with clinical stage I disease, more than half are found to have deep myometrial invasion, three fourths manifest lymph–vascular space invasion (LVSI), and about half have extratubal disease detected at surgery.

The first description of UPSC, in 1982, noted that this entity usually occurred in elderly, hypoestrogenic women who presented with advanced-stage disease and accounted for up to half of deaths from endometrial carcinoma (50). Since then, several reports have documented the aggressive nature and poor prognosis of UPSC. Even when the disease was confined to an endometroid polyp without other evidence of spread, recurrence developed in more than half of patients (51–53). More recently, in a report on 50 surgically staged patients with UPSC, extratubal disease was found in 72% (53). Presence of lymph node metastases, positive peritoneal cytology, and intraperitoneal tumor did not correlate with increasing myometrial invasion (53).

### Clear Cell Carcinoma

Clear cell carcinoma accounts for less than 5% of all endometrial carcinomas (45,54). Clear cell carcinoma usually has a mixed histologic pattern, including papillary, tubulocystic, glandular, and solid types.

The cells have highly atypical nuclei and abundant clear or eosinophilic cytoplasm. Often, the cells have a hobnail configuration arranged in papillae with hyalinized stalks (Fig. 30.5). Clear cell carcinoma characteristically occurs in older women and is a very aggressive type of endometrial cancer; the prognosis is similar to or worse than that of papillary serous carcinoma. Overall survival rates of 33% to 64% have been reported. Myometrial invasion and LVSI are important prognostic indicators.

![Figure 30.5 Clear cell adenocarcinoma of the endometrium. Back-to-back glands lined by polygonal to columnar cells with distinct cell membrane, abundant granular to clear cytoplasm, and variably sized nuclei (including binucleated and multinucleated forms) with prominent nucleoli (magnification ×400).](image)

### Squamous Carcinoma

Squamous carcinoma of the endometrium is rare. Some tumors are pure, but most have a few glands. To establish primary origin within the endometrium, there must be no connection with or spread from cervical squamous epithelium. Squamous carcinoma often is associated with cervical stenosis, chronic inflammation, and pyometra at the time of diagnosis. This tumor has a poor prognosis, with an estimated 36% survival rate in patients with clinical stage I disease (55).

### Simultaneous Tumors of the Endometrium and Ovary

Synchronous endometrial and ovarian cancers are the most frequent simultaneously occurring genital malignancies, with a reported incidence of 1.4% to 3.8% (56,57,58,59 and 60). Most commonly, both the ovarian and endometrial tumor are well-differentiated endometrioid adenocarcinomas of low stage, resulting in an excellent prognosis. Patients often are premenopausal and present with abnormal uterine bleeding. The ovarian cancer usually is discovered as an incidental finding and is diagnosed at an earlier stage because of the symptomatic endometrial tumor, leading to a more favorable outcome. As many as 29% of patients with endometrioid ovarian adenocarcinomas have associated endometrial cancer. If more poorly differentiated, nonendometrioid histologic subtypes are present or if the uterine and ovarian tumors are histologically dissimilar, the prognosis is less favorable. Immunohistochemical studies, flow cytometry, and assessment of molecular DNA patterns to detect loss of heterozygosity may be helpful in distinguishing between metastatic and independent tumors, but the differential diagnosis can usually be determined by conventional clinical and pathologic criteria.

### Pretreatment Evaluation

After establishing the diagnosis of endometrial carcinoma, the next step is to evaluate the patient thoroughly in order to determine the best and safest approach to management of the disease. A complete history and physical examination is of utmost importance. Patients with endometrial carcinoma are often elderly and obese and have a variety of medical problems, such as diabetes mellitus and hypertension, that affect surgical management. Any abnormal symptoms, such as bladder or intestinal complaints, should be evaluated.

On physical examination, attention should be directed to enlarged or suspicious-feeling lymph nodes, abdominal masses, and possible areas of cancer spread within the pelvis. Evidence of distant metastasis or locally advanced disease in the pelvis, such as gross cervical involvement or parametrial spread, may alter the treatment approach. Stool should be tested for occult blood.

A chest x-ray should be performed to exclude pulmonary metastasis and to evaluate the cardiorespiratory status of the patient. Other routine preoperative studies should include electrocardiography, complete blood and platelet counts, serum chemistries (including renal and liver function tests), blood type and screen, and urinalysis. Other preoperative or staging studies are neither required nor necessary for most patients with endometrial cancer. Studies such as cystoscopy, colonoscopy, intravenous pyelography, barium enema, and CT scanning of the abdomen and pelvis are not indicated unless dictated by patient symptoms, physical findings, or other laboratory tests (61). Ultrasonography and magnetic resonance imaging (MRI) can be used to assess myometrial invasion preoperatively with a fairly high degree of accuracy (62). This information may be of use in planning the surgical procedure with regard to whether lymph node sampling should be undertaken.

Serum CA125, an antigenic determinant that is elevated in 80% of patients with advanced epithelial ovarian cancers, also is elevated in most patients with advanced or metastatic endometrial cancer (63). In one study, 23 of 81 patients with apparently localized disease preoperatively had elevated CA125 levels (64). At surgery, 20 (87%) of these 23 patients with an elevated CA125 were found to have extratubal disease, whereas only 1 of 58 patients with a normal CA125 had disease spread outside the uterus (64). Preoperative measurement of serum CA125 may, therefore, help determine the extent of surgical staging and, if elevated, may be useful as a tumor marker in assessing response to subsequent therapy (65).

### Clinical Staging

Clinical staging, according to the 1971 FIGO system (Table 30.6), should be performed in patients who are deemed not to be surgical candidates, because of their poor medical condition or the spread of their disease (66). With improvements in preoperative and postoperative care, anesthesia administration, and surgical techniques, almost all patients are medically suitable for operative therapy. One study reported an operability rate of 87% in a series of 595 consecutive patients with clinical early-stage endometrial cancer (67). A small percentage of patients will not be candidates for surgical staging because of gross cervical involvement, parametrial spread, invasion of the bladder or rectum, or distant metastasis.
Most patients with endometrial cancer should undergo surgical staging based on the 1988 FIGO system (68,69 and 70) (Table 30.7). At a minimum, the surgical procedure should include sampling of peritoneal fluid for cytologic evaluation, exploration of the abdomen and pelvis with biopsy or excision of any extratereine lesions suggestive of metastatic cancer, extrafascial hysterectomy, and bilateral salpingo-oophorectomy. The uterine specimen should be opened and tumor size (71), depth of myometrial involvement (72,73 and 74), and cervical extension assessed. Any suspicious pelvic and paraaortic lymph nodes should be removed for pathologic examination.

Additionally, clinically negative retroperitoneal lymph nodes should be sampled in all patients with one or more of the risk factors noted in Table 30.8. Tumor histology and depth of myometrial invasion appear to be the two most important factors in determining the risk for lymph node metastasis (69,70). The overall incidence of lymph node metastasis in clinical stage I endometrial cancer is about 3% in grade 1, 9% in grade 2, and 18% in grade 3 tumors (Table 30.9). Less than 5% of patients with no myometrial invasion or with superficial (<50%) myometrial invasion have lymph node metastasis, compared with about 20% of patients with deep (>50%) myometrial invasion (Table 30.10). Pelvic lymph node metastases are present in less than 5% of grade 1 and 2 tumors with superficial myometrial invasion, in about 15% of grade 1 and 2 tumors with deep myometrial invasion or grade 3 tumors with superficial invasion, and in more than 40% of grade 3 tumors with deep myometrial invasion (Fig. 30.6). About one half to two thirds of patients with positive pelvic lymph nodes also have paraaortic lymph node metastases, but the aortic nodal nodes are seldom involved in the absence of pelvic nodal disease. Cervical involvement is associated with about a 15% risk for pelvic or paraaortic node metastasis (70). The incidence of lymph node metastasis also correlates with tumor size (<2 cm, 4%; >2 cm, 15%; entire cavity, 35%) (71). Extragernine spread of disease increases the risk for pelvic and paraaortic nodal metastasis. Adnexal metastasis increases the risk for pelvic and paraaortic nodal metastasis to 32% and 20%, respectively. Of patients with positive peritoneal cytology, 25% have positive pelvic nodes, and 19% have positive paraaortic nodes (70).
Although stage of disease is the most significant variable affecting survival, a number of other individual prognostic factors for disease recurrence or survival have...
been identified, including tumor grade, histopathology, depth of myometrial invasion, patient age, and surgical-pathologic evidence of extraterine disease spread (Table 30.12). Other factors, such as tumor size, peritoneal cytology, hormone receptor status, flow cytometric analysis, and oncogene perturbations, have also been implicated as having prognostic importance.

### Table 30.12. Prognostic Variables in Endometrial Carcinoma

<table>
<thead>
<tr>
<th>Variable</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Age</td>
<td>In general, younger women with endometrial cancer have a better prognosis than older women. Two authors observed no deaths related to disease in patients with endometrial cancer diagnosed before 50 years of age (86,94). Others have demonstrated a 60.9% 5-year survival rate for patients older than 70 years of age, compared with 82.1% survival rate for patients younger than 50 years of age (85). Decreased survival was associated with an increased risk for extraterine spread (38% versus 21%) and deep myometrial invasion (57% versus 24%) for these two groups. The GOG reported 5-year survival rates of 96.3% for patients 50 years of age or younger, 87.3% for patients 51 to 60 years, 78% for patients 61 to 70 years, 70.7% for patients 71 to 80 years, and 53.6% for patients older than 80 years of age (85). Increased risk for recurrence in older patients has also been related to a higher incidence of grade 3 tumors or unfavorable histologic subtypes; however, age appears to be an independent prognostic variable. Increasing patient age is independently associated with disease recurrence in endometrial cancer (91). The mean age at diagnosis of patients who had recurrence or died of disease was 68.6 years, compared with 60.3 years for patients without recurrence. For every 1-year increase in age, the estimated rate of recurrence increased 7%. None of the patients younger than 50 years of age developed recurrent cancer, compared with 12% of patients aged 50 to 75 years and 33% of patients older than 75 years of age.</td>
</tr>
<tr>
<td><strong>Histologic Type</strong></td>
<td>Nonendometrioid histologic subtypes account for about 10% of endometrial cancers and carry an increased risk for recurrence and distant spread (87,88). In a retrospective review of 388 patients treated at the Mayo Clinic for endometrial cancer, 52 (13%) had an uncommon histologic subtype, including 20 adenosquamous, 14 papillary serous, 11 clear cell, and 7 undifferentiated carcinomas. In contrast to the 92% survival rate among patients with endometrioid tumors, the overall survival for patients with one of these more aggressive subtypes was only 33%. At the time of surgical staging, 62% of the patients with an unfavorable histologic subtype had extraterine spread of disease (97).</td>
</tr>
<tr>
<td><strong>Histologic Grade</strong></td>
<td>Histologic grade of the endometrial tumor is strongly associated with prognosis (70,76,88,90,91,92 and 93). In one study, recurrences developed in 7.7% of grade 1 tumors, 10.5% of grade 2 tumors, and 36.1% of grade 3 tumors. Patients with grade 3 tumors were more than 5 times more likely to have a recurrence than were patients with grade 1 and 2 tumors. The 5-year disease-free survival rates for patients with grades 1 and 2 tumors were 92% and 88%, respectively, compared with 64% for patients with grade 3 tumors (91). Another study reported similar results, noting recurrences in 9% of patients with grade 1 and 2 tumors compared with 39% of patients with grade 3 lesions (89). Increasing tumor anaplasia is associated with deep myometrial invasion, cervical extension, lymph node metastasis, and both local recurrence and distant metastasis.</td>
</tr>
<tr>
<td>Myometrial Invasion</td>
<td>Because access to the lymphatic system increases as cancer invades into the outer one half of the myometrium, increasing depth of invasion has been associated with increasing likelihood of extraterine spread and recurrence (69,90,93). The association of depth of myometrial invasion with extraterine disease and lymph node metastases has been confirmed (69). Of patients without demonstrable myometrial invasion, only 1% had pelvic lymph node metastasis, compared with patients with outer one-third myometrial invasion who had 25% pelvic and 17% aortic lymph node metastases. Survival also decreases with increasing depth of myometrial invasion. In general, patients with noninvasive or superficially invasive tumors have an 80% to 90% 5-year survival rate, whereas those with deeply invasive tumors have a 60% survival rate. The most sensitive indicator of the effect of myometrial invasion on survival is distance from the tumor–myometrial junction to the uterine serosa. Patients with tumors that are less than 5 mm from the serosal surface are at much higher risk for recurrence and death than those with tumors greater than 5 mm from the serosal surface (98,100).</td>
</tr>
<tr>
<td>Lymph–Vascular Space Invasion</td>
<td>LVS, appears to be an independent risk factor for recurrence and death from all types of endometrial cancer (93,101,102 and 103). The overall incidence of LVS in early endometrial cancer is about 15%, although it increases with increasing tumor grade and depth of myometrial invasion. One author reported LVS in 2% of grade 1 tumors and 5% of superficially invasive tumors, compared with 42% of grade 3 tumors and 70% of deeply invasive tumors (101). Another reported deaths in 26.7% of patients with clinical stage I disease who had LVS, compared with 9.1% of those without LVS (93). Likewise, an 83% 5-year survival rate has been reported for patients without demonstrable LVS, compared with a 64.5% survival rate for those in whom LVS was present (102). Using multivariate analysis, only depth of myometrial invasion, DNA ploidy, and vascular invasion–associated changes correlated significantly with survival of patients with stage II endometrial adenocarcinomas (103).</td>
</tr>
<tr>
<td>Isthmus and Cervix Extension</td>
<td>The location of the tumor within the uterus is important. Involvement of the uterine isthmus, cervix, or both is associated with an increased risk for extraterine disease and lymph node metastases as well as recurrence. One study reported that if the fundus of the uterus alone was involved with tumor, there was a 13% recurrence rate, whereas if the lower uterine segment or cervix was involved with occult tumor, there was a 44% recurrence rate (88). A subsequent GOG study found that tumor involvement of the isthmus or cervix without evidence of extraterine disease was associated with a 16% recurrence rate and a relative risk of 1.6 (76). Patients with cervical involvement also tended to have higher-grade, larger, and more deeply invasive tumors, undoubtedly contributing to the increased risk for recurrence.</td>
</tr>
<tr>
<td>Adnexal Involvement</td>
<td>Most patients with adnexal spread have other poor prognostic factors that place them at high risk for recurrence. For the 20% of patients with adnexal spread as their only high-risk factor, however, the survival rate has been reported to be as high as 85% (70).</td>
</tr>
<tr>
<td>Peritoneal Cytology</td>
<td></td>
</tr>
</tbody>
</table>
The significance of malignant peritoneal cytology in endometrial cancer is a controversial issue [104]. Several reports in the literature have noted increased recurrence rates and decreased survival rates and, on this basis, have recommended treatment for positive cytology. In an early report, positive peritoneal cytology was noted in 26 (16%) of 167 patients with clinical stage I adenocarcinoma of the endometrium [105]. Recurrent cancer developed in 10 (38%) of these 26 patients, compared with 14 (10%) of 141 patients with negative cytology. Positive peritoneal cytology was found to be associated with deep myometrial invasion, cervical involvement, adnexal spread, and lymph node metastasis as well as a propensity for intraabdominal disease recurrence. Several subsequent reports supported the observation that positive peritoneal cytology was associated with an increased risk for cancer recurrence. Most of the studies included patients with other evidence of extraterine disease spread and were performed without appropriate multivariate analysis and with patients who were incompletely staged. The GOG study, however, critically analyzed 1,180 clinical stage I and II endometrial cancer patients in whom appropriate surgical and pathologic staging was performed [76]. Considering only the 697 patients for whom peritoneal cytology status and adequate follow-up were available, 25 (29%) of 86 patients with positive cytology developed recurrence, compared with 64 (10.5%) of 611 patients with negative cytology. They noted, however, that 17 of the 25 recurrences in the positive cytology group were outside the peritoneal cavity.

In contrast to these reports, an equal number of studies have found no significant relationship between malignant peritoneal cytology and an increased incidence of disease recurrence in early endometrial cancer. In a prospective evaluation of peritoneal cytology in 157 patients with clinical stage I endometrial cancer who underwent primary surgical therapy [106], no therapy was directed specifically to positive cytology. Positive cytology was not significantly associated with disease recurrence. Recurrence developed in 5 (17%) of 30 patients with positive cytology and in 11 (9%) of 127 patients with negative cytology. Of the 5 patients with positive peritoneal cytology who had disease recurrence, only one recurrence arose within the peritoneal cavity. Patients with malignant washings often had other poor prognostic factors such as deep myometrial invasion, lymph nodes, grade 3 tumors, and positive lymph nodes. Disease recurred in none of the patients with positive cytology but no other poor prognostic factors. A subsequent study confirmed by multivariate analysis that positive peritoneal cytology was not an independent prognostic factor for endometrial cancer recurrence. Only 6 (22%) of the 27 patients with positive cytology as their only evidence of extraterine disease spread suffered a recurrence despite no therapy directed toward this finding [93]. Positive peritoneal cytology seems to have an adverse effect on survival only if the endometrial cancer has spread to the adnexa, peritoneum, or lymph nodes—not if the disease is otherwise confined to the uterus [107]. More grade 3 tumors (41% versus 19%), vascular invasion (18% versus 6%), adnexal spread (18% versus 4%), lymph node metastasis (29% versus 8%), and intraperitoneal spread (18% versus 2%) occurred in patients with positive peritoneal cytology, which contributed to the overall recurrence rate of 47% in these patients [107]. The 5-year survival rate for patients with positive peritoneal cytology with disease otherwise confined to the uterus exceeded 90%.

The following conclusions may be reached regarding the prognostic implications of positive peritoneal cytology:

1. Positive peritoneal cytology is associated with other known poor prognostic factors.
2. Positive peritoneal cytology in the absence of other evidence of extraterine disease or poor prognostic factors probably has no significant effect on recurrence and survival.
3. Positive peritoneal cytology, when associated with other poor prognostic factors or extraterine disease, increases the likelihood for distant as well as local disease recurrence and has a significant adverse effect on survival.
4. Use of several different therapeutic modalities has not resulted in any proven benefit to patients with endometrial cancer and positive peritoneal cytology.

Lymph Node Metastasis

Lymph node metastasis is the most important prognostic factor in clinical early-stage endometrial cancer. Of patients with clinical stage I disease, about 10% will have pelvic and 6% paraaortic lymph node metastases. Patients with lymph node metastases have almost a sixfold higher likelihood of developing recurrent cancer than patients without lymph node metastases. One study reported a recurrence rate of 48% with positive lymph nodes, including 45% with positive pelvic nodes and 64% with positive aortic nodes, compared with 8% with negative nodes. The 5-year disease-free survival rate for patients with lymph node metastases was 54%, compared with 90% for patients without positive lymph node metastases [91]. The GOG found that the presence or absence of paraaortic lymph node metastases was of paramount importance in determining prognosis. Of 48 paraaortic node-positive patients, 28 (58%) developed progressive or recurrent cancer, and only 36% of these patients were alive at 5 years, compared with 85% of patients without paraaortic node involvement [76].

Intraperitoneal Tumor

Extraterine metastasis, excluding peritoneal cytology and lymph node metastasis, occurs in about 4% to 6% of patients with clinical stage I endometrial cancer. Gross intraperitoneal spread has been highly correlated with lymph node metastases; one study noted that 51% of patients with intraperitoneal tumor had positive lymph nodes, whereas only 7% of patients without gross peritoneal spread had positive nodes [76]. Extraperitoneal spread other than lymph node metastasis is also significantly associated with tumor recurrence. Another study found that 50% of patients with extraterine disease developed recurrence, compared with 11% of patients without extraterine disease, making recurrence almost 5 times more likely in patients with extraterine disease spread. The 5-year disease-free survival rate for patients with nonlymphatic extraterine disease was 50%, compared with 88% in the other patients [93].

Tumor Size

Tumor size is a significant prognostic factor for lymph node metastasis and survival in patients with endometrial cancer [71,108]. One report determined tumor size in 142 patients with clinical stage I endometrial cancer and found lymph node metastasis in 4% of patients with tumors 2 cm or smaller, in 15% of patients with tumors larger than 2 cm, and in 35% of patients with tumors involving the entire uterine cavity [71]. Tumor size better defined an intermediate-risk group for lymph nodes metastasis (i.e., patients with grade 2 tumors with less than 50% myometrial invasion). Overall, these patients had a 10% risk for lymph node metastasis, but there was no nodal metastasis associated with tumors 2 cm or smaller, compared with 18% when tumors were larger than 2 cm. Five-year survival rates were 98% for patients with tumors 2 cm or smaller, 84% for patients with tumors 2 to 4 cm, and 64% for patients with tumors involving the whole uterine cavity [108].

Hormone Receptor Status

Estrogen receptor and progesterone receptor levels have been shown to be prognostic indicators for endometrial cancer independent of grade in several studies (109,110,111,112,113,114 and 115). Patients whose tumors are positive for one or both receptors have longer survival times than patients whose carcinomas lack the corresponding receptors. Even patients with metastasis have an improved prognosis with receptor-positive tumors [112]. Progesterone receptor levels appear to be stronger predictors of survival than estrogen receptor levels, and the higher the absolute level of the receptors, the better the prognosis.

DNC Ploidy and Proliferative Index

About two thirds of endometrial adenocarcinomas have a diploid DNA content as determined by flow cytometric analysis [103,113,118,117,118,119,120,121,122,123 and 124]. Analysis of these patients by DNA content has been shown to correspond to the clinical stage of the disease, with diploidy generally reported to be higher in women whose tumors contained aneuploid populations of cells. The proliferative index also is related to prognosis.

Genetic and Molecular Markers

Mutations in codons 12 or 13 of the K-ras oncogene have been reported in 10% to 20% of endometrial adenocarcinomas [125]. In one study, the presence of mutations of K-ras appeared to be an independent unfavorable prognostic factor [126]. Overexpression of the HER-2/neu oncogene, which encodes for a cell surface glycoprotein that is similar to the human epidermal growth factor receptor, has been identified in 10% to 15% of endometrial adenocarcinomas. It is more frequently found in women with metastatic disease, and overexpression has been related to diminished progression-free survival [127,128]. Alteration of the tumor suppressor gene p53 has been demonstrated in about 20% of endometrial carcinomas and has been associated with papillary serous cell type, advanced stage, and poor prognosis [123,129,130]. Expression of MiB-1 (Ki-67), a proliferation marker, has been associated with extraterine disease spread and decreased survival [131]. Analysis of expression of ras oncogenes has demonstrated that the ras oncogene is overexpressed in 30% to 50% of endometrial cancers, which tend to be endometroid, well differentiated, and minimally invasive [132]. Microsatellite instability, present in about 20% of endometrial cancers, appears to be restricted to endometroid adenocarcinomas and is associated with other molecular features that predict a
favorable outcome, including PTEN mutation and absence of p53 overexpression (133,134).

Treatment

An algorithm for the management of patients with clinical stage I and II endometrial cancer is presented in Fig. 30.7.

Surgery

Abdominal Hysterectomy

Total abdominal hysterectomy and bilateral salpingo-oophorectomy are the primary operative procedures for carcinoma of endometrium. The adnexa should be removed because they may be the site of microscopic metastasis, and patients with endometrial carcinoma are at increased risk for ovarian cancer occurring either simultaneously or developing later. Removal of a segment of vagina below the cervix is not necessary.

Laparotomy is performed through an abdominal incision that is adequate to allow thorough intraabdominal exploration and retroperitoneal lymph node dissection, if necessary. A lower abdominal midline vertical incision is most commonly employed, although a lower abdominal transverse, muscle-dividing incision (e.g., Maylard incision) or muscle-detaching incision (e.g., Cherney incision) usually provides adequate exposure. After opening the abdomen, peritoneal washings are taken from the subdiaphragmatic area, paraotic gutters, and pelvis using 50 mL of saline for each. These washings are sent to the cytology laboratory for examination. Exploration of the abdomen and pelvis is then performed, noting particularly the diaphragm, liver, omentum, and pelvic and aortic lymph nodes. The uterus should be observed for tumor on the serosal surface. Any suspicious-looking lesions or lymph nodes should be excised for biopsy or removed for histologic examination. The uterus is opened in the operating room, and tumor size, depth of myometrial invasion, and cervical extension are assessed. This information, along with the surgical findings and knowledge of the preoperative histology, influences whether pelvic and aortic lymph node dissection is indicated. The uterus is sent to the pathology laboratory, where tissue can be obtained for measurement of steroid hormone receptors and flow cytometry.

For patients in whom lymph node sampling is indicated, lower paraaortic lymph node resection can be accomplished by extending the pelvic peritoneal incisions over the common iliac arteries and lower aorta. A sample of lymph nodes along the common iliac vessels from either side and the fat pad overlying the vena cava are removed. Pelvic lymph node samples are obtained by removing nodes overlying the midportion of the external iliac artery and vein and within the obturator fossa above and along the obturator nerve. An omental biopsy or partial omentectomy may also be performed.

Vaginal Hysterectomy

Vaginal hysterectomy may be considered for selected patients who are extremely obese and have a poor medical status, or for patients with extensive uterovaginal prolapse. The disadvantages to this approach are that: bilateral salpingo-oophorectomy is often technically difficult and abdominal exploration and lymph node sampling cannot be performed. Vaginal hysterectomy is, therefore, particularly suitable for patients who are at low risk for extrauterine spread of disease (i.e., those with clinical stage I, well-differentiated tumors). A 94% survival rate has been found in 56 patients with clinical stage I endometrial cancer treated vaginal hysterectomy, with or without postoperative radiotherapy (mostly brachytherapy). Three fourths of these patients had grade 1 lesions (135). Others have reported similar good results (136,137 and 138). Vaginal hysterectomy clearly is preferable to radiation therapy alone, but generally should be reserved for specific patients.

Laparoscopic Management

Recent advances in endoscopic surgery have allowed application of a laparoscopic approach to the management of endometrial cancer. Since 1992, there have been several reports that have documented the feasibility of laparoscopically-assisted vaginal hysterectomy with bilateral salpingo-oophorectomy and laparoscopic retroperitoneal lymph node sampling for staging and treatment of patients with endometrial cancer (139,140 and 141). In an early study of 59 patients with endometrial cancer managed laparoscopically, 29 had retroperitoneal lymph node sampling (139). In a comparison study of the results of laparoscopic versus traditional laparotomy management of 44 patients with endometrial cancer, 20 patients underwent successful laparoscopic management; 15 had both pelvic and paraaortic lymph node sampling, and 4 had pelvic node sampling only (140). There was no difference in the number of lymph nodes (19 versus 17) removed in the laparoscopy and laparotomy groups, respectively. Patients undergoing laparoscopic management had shorter hospital stays (2.5 versus 5.0 days) and a lower overall complication rate, although all three patients who had serious complications (one ureteral injury and two small bowel herniations through 12-mm trocar sites) were in the laparoscopy group. A subsequent retrospective analysis compared the clinical outcomes and hospital charges for 69 women with early-stage endometrial cancer who underwent laparoscopically-assisted vaginal hysterectomy, compared with 251 women who had traditional laparotomy. The patients managed laparoscopically had fewer complications, shorter hospital stays, and lower overall hospital charges than those who underwent laparotomy. Furthermore, there was no difference in recurrence rates between the two groups (141). Although it seems reasonable that many patients with endometrial cancer can undergo successful laparoscopic management, more experience with the technique and prospective studies are necessary to determine the specific indications for and complications of this approach.

Radical Hysterectomy

Radical hysterectomy, with removal of the parametria and upper vagina, as well as bilateral pelvic lymphadenectomy, does not improve survival of patients with clinical stage I disease compared with extraperitoneal hysterectomy and bilateral salpingo-oophorectomy alone (142,143,144 and 145). Radical hysterectomy also increases both intraoperative and postoperative morbidity and should not, therefore, be performed for treatment of apparent early endometrial cancer.

Radiation Therapy

Primary surgery followed by individualized radiation therapy has become the most widely accepted treatment for early-stage endometrial cancers. However, about 5% to 15% of endometrial cancer patients have severe medical conditions that render them unsuitable for surgery (61). These patients tend to be elderly and obese with multiple chronic or acute medical illnesses, such as hypertension, cardiac disease, diabetes mellitus, and pulmonary, renal, and neurologic diseases.

Several series have demonstrated that radiotherapy is effective treatment for patients with inoperable endometrial cancer (146,147,148,149,150,151,152,153,154 and 155) (Table 30.13). One reported on the treatment of 120 patients with clinical stage I and 17 patients with clinical stage II endometrial cancer with radiation alone, 85% of whom received only intracavitary irradiation. Because of the high incidence of death caused by intercurrent illness in this group of patients, the 5- and 10-year overall survival rates were only 55% and 28%, respectively, compared with disease-specific survival rates of 87% and 85%, respectively. There was no difference in disease-specific survival rates between patients with stage I and II disease. Intrauterine cancer recurred in 14% of patients, and extraterine pelvic disease recurred in 3%. The authors also treated 15 patients with stage III and IV disease, usually with a combination of external-beam and intracavitary radiation therapy, yielding a
Adjuvant postoperative whole pelvis irradiation are those with cervical involvement, pelvic lymph node metastases, or pelvic disease outside the uterus. External pelvic irradiation decreases the risk for pelvic recurrence after hysterectomy in certain high-risk groups. Patients found to benefit most from external pelvic irradiation otherwise meet the aforementioned criteria.

External Pelvic Irradiation

Vaginal irradiation is most commonly administered using colpostats to deliver a surface dose of 6,000 to 7,000 cGy to the upper vagina. More recently, afterloading outpatient techniques using high-dose rate have been employed at some centers (87). In a 10-year follow-up of a randomized trial comparing surgery alone (total abdominal hysterectomy and bilateral salpingo-oophorectomy) with preoperative and postoperative radium treatment in patients with clinical stage I endometrial adenocarcinoma, the incidence of vaginal recurrence was 7.5% with postoperative vaginal vault radium use has been found to decrease the incidence of vaginal recurrence from 14% to 1.7% and to improve 5-year survival rates from 75% to 90% (87). In a 10-year follow-up of a randomized trial comparing surgery alone (total abdominal hysterectomy and bilateral salpingo-oophorectomy) with preoperative and postoperative radium treatment in patients with clinical stage I endometrial adenocarcinoma, the incidence of vaginal recurrence was 7.5% with postoperative hysterectomy alone, 4.5% with preoperative intracavitary radium followed by hysterectomy, and 0% with hysterectomy followed by postoperative vaginal radium (156). In a subsequent study of 92 patients with surgical stage I disease who had grade 1 or 2 tumors with less than 50% myometrial invasion treated with total abdominal hysterectomy and bilateral salpingo-oophorectomy and postoperative vaginal cesium or radium, there were no recurrences, and the 5-year estimated disease-free survival rate was 99% (157). There was only one minor complication, proctitis, which responded to conservative treatment.

In a GOQ study of surgical and pathologic risk factors and outcomes, none of the three recurrences in the vaginal radiation implant group were vaginal or pelvic, whereas 7.4% of recurrences in the pelvic radiation therapy group were vaginal, and 18.2% of recurrences were vaginal in the group that did not receive adjuvant radiation. The investigators concluded that postoperative vaginal cuff irradiation reduced local recurrence and had a therapeutic ratio superior to whole pelvis irradiation in patients at risk for isolated vaginal cuff recurrence (75).

Postoperative vaginal irradiation is most commonly administered using colpostats to deliver a surface dose of 6,000 to 7,000 cGy to the upper vagina. More recently, afterloading outpatient techniques using high-dose rate have been employed at some centers (158). Morbidity is low, although vaginal stenosis and dyspareunia may be a problem for postmenopausal patients in the absence of regular vaginal dilation. Patients most likely to benefit from vaginal irradiation are those who have surgical stage I grade 1 and 2 tumors with superficial (<50%) myometrial invasion or grade 3 tumors with no invasion and some patients with stage IIa disease who otherwise meet the aforementioned criteria.

External Pelvic Irradiation

External pelvic irradiation decreases the risk for pelvic recurrence after hysterectomy in certain high-risk groups. Patients found to benefit most from adjuvant postoperative whole pelvis irradiation are those with cervical involvement, pelvic lymph node metastases, or pelvic disease outside the uterus.
(adnexa, parametria), and patients with clinical stage I disease who are at significant risk for nodal metastasis [grade 3 tumors with any degree of myometrial invasion, grade 1 and 2 tumors with more than 50% myometrial invasion, large (>2 cm) grade tumors with superficial myometrial invasion, and any grade tumor with lymph-vascular space invasion] (159).

Of 41 endometrial cancer patients treated with postoperative pelvic irradiation (5,000 to 5,040 cGy) who had grade 3 tumors or deep myometrial invasion and histologically negative paraaortic lymph nodes (pelvic lymph nodes not sampled), 4 patients (9.7%) developed recurrences, but only one of the recurrences (2.4%) was within the treatment field, and the 5-year estimated disease-free survival rate was 88% (157). In the GOG study, the pelvic recurrence rate was higher in the surgery-only group of patients (31.8%) than in the patients who received postoperative external beam radiation therapy (16.8%) (76).

In 1980, the first randomized study was performed to evaluate the possible benefit of postoperative pelvic irradiation in clinical stage I endometrial cancer (93). After total abdominal hysterectomy and bilateral salpingo-oophorectomy, all 540 patients received vaginal vault radium and were then randomized to receive either 4,000 cGy of whole-pelvis irradiation or no further therapy. The addition of pelvic irradiation did not affect the overall 5-year survival rate. Patients receiving pelvic irradiation had a lower pelvic failure rate but a higher distant failure rate. Of note, patients with grade 3 tumors and more than 50% myometrial invasion had a lower rate of death from cancer if they received postoperative pelvic irradiation (18.2% versus 27.5%). This study has been criticized for a lack of complete surgical staging (no lymph node biopsies were done) and the relatively low dose of external-beam irradiation (4,000 cGy) used.

The GOG recently completed a prospective, randomized study of surgery alone versus surgery plus adjuvant pelvic irradiation in intermediate-risk endometrial cancer (stages Ib to Ib' occult). Of patients accrued to the study, more than 80% were actually low-risk patients (90.6% stage I, 81.6% grade 1 to 2, 82% <50% myometrial invasion). The pelvic failure rate was 13% (22 of 171 patients) in the surgery-alone group, compared with 0.6% (1 of 179 patients) in the postoperative pelvic irradiation-alone group. Disease-free survival was also better in the patients receiving postoperative pelvic irradiation than in those treated only with surgery (93.7% versus 84.7%, respectively) (169).

Another randomized trial of surgery and postoperative pelvic radiotherapy versus surgery alone for 714 patients with stage I endometrial carcinoma was carried out by the Netherlands PORTEC Study Group. Eligibility criteria were stage IC, grade 1 to 2 and stage IB, grade 2 to 3; patients with stage IB, grade 3 made up only 10% of the study population, and lymph node biopsies and peritoneal cytology were not required. Loco-regional recurrences developed in 13.7% of the surgery group, compared with 4.2% of the postoperative pelvic irradiation group. Overall, the 5-year survival rate was no different between the two groups (85% versus 81%, respectively) (163).

Postoperative whole pelvis external-beam radiation usually involves the delivery of 4,500 to 5,040 cGy in 180 cGy daily fractions over 5 to 6 weeks to a field encompassing the upper half of the vagina inferiorly, the lower border of the L-4 vertebral body superiorly, and 1 cm lateral to the margins of the bony pelvis. The dose of radiation to the vagina is usually prescribed to an isodose that passes through 6,000 to 7,000 cGy by a variety of techniques. The most frequently reported side effects are gastrointestinal, usually abdominal cramps and diarrhea, although more serious complications such as bleeding, proctitis, bowel obstruction, and fistula can occur and may require surgical correction. The urinary system may also be affected in the form of hematuria, cystitis, or fistula. The overall complication rate ranges from 25% to 40%; however, the rate of serious complications requiring surgical intervention is about 1.5% to 3%.

Patients at high risk for recurrence may benefit from pelvic irradiation. The pelvic failure rate is reduced and, at least in patients with grade 3 tumors and deep myometrial invasion, survival rates also appear to be improved. Patients with cervical extension and extraperitoneal pelvic disease, including adnexal spread, parametrial involvement, and pelvic lymph node metastases, in the absence of extrapelvic disease, also should benefit from postoperative pelvic irradiation.

**Extended-field Irradiation**

Patients with histologically proven paraaortic node metastases who have no other evidence of disease spread outside the pelvis should be treated with extended-field irradiation. The entire pelvis, common iliac lymph nodes, and paraaortic lymph nodes are included within the radiation field. The paraaortic radiation dose is limited to 4,500 to 5,000 cGy. **Extended-field radiotherapy appears to improve survival in patients with endometrial cancer who have positive paraaortic lymph nodes** (76,162,163,164 and 165).

Five-year survival rates of 47% and 43% have been reported for patients with surgically confirmed paraaortic lymph node metastases only and for those with paraaortic as well as pelvic lymph node metastases, respectively, using postoperative extended-field irradiation. Only one case of severe enteric morbidity occurred in 48 patients, a complication rate of 2% (162). In a GOG study, 37 of 48 patients with positive paraaortic nodes received postoperative paraaortic irradiation, 36% of whom remained tumor free at 5 years (76). A comparison of patients with positive paraaortic nodes treated with megestrol acetate alone versus megestrol acetate and extended-field irradiation showed that the survival rate in the patients receiving extended-field irradiation was significantly better: 53% versus 12.5%, respectively (163). In another study of 18 patients with positive paraaortic nodes, 5-year survival rates were 67% for microscopic nodal disease and 17% for gross nodal disease (164).

**Whole-abdomen Irradiation**

Whole-abdomen radiation therapy usually is reserved for patients with stage III and IV endometrial cancer. It may also be considered for patients who have papillary serous tumors, which have a high rate of paraaortic recurrence (166-168,169 and 171). The recommended dose to the whole abdomen is 3,000 cGy in 20 daily fractions of 150 cGy with kidney shielding at 1,500 to 2,000 cGy, along with an additional 1,500 cGy to the paraaortic lymph nodes and 2,000 cGy to the pelvis. Gastrointestinal side effects, including nausea, vomiting and diarrhea, sometimes make it necessary to interrupt therapy, but it is rare for patients not to finish treatment because of these symptoms. Hematologic toxicity can be expected to occur during whole-abdominal irradiation, but it is usually mild. The incidence of late complications, mainly chronic diarrhea and small bowel obstruction, is generally low (5% to 10%).

In a series of 27 patients treated with surgical stage III endometrial cancer with whole-abdomen irradiation, patients with spread to the adnexa, positive peritoneal cytology, or both had a 5-year, relapse-free survival of 90%, whereas all patients with macroscopic disease beyond the adnexa had recurrence (166). Similar results were reported by others (167). Some have advocated the use of adjuvant whole-abdomen radiotherapy for patients with high-risk stage I and II endometrial carcinoma, including those with deep myometrial invasion, high-grade tumors, and papillary serous histology, because of the high proportion of recurrences in the upper abdomen. A 5-year recurrence-free survival rate of 85% has been reported (169,170). With whole-abdomen irradiation in patients at increased risk for intraabdominal metastatic disease, such as those with nonnodal extraterine disease and papillary serous histology, an actuarial 5-year relapse-free survival rate of 70% has been reported, with no significant toxicity (171). Similarly, others have noted a 3-year disease-free survival rate of 79% in patients with stage III and IV endometrial adenocarcinoma treated with whole-abdomen irradiation (172). Still other reports of using adjuvant postoperative whole-abdomen irradiation in early-stage uterine papillary serous carcinoma suggest a reduction in recurrence rates (173,174 and 175). Unfortunately, most recurrences are in the upper abdomen in all of these patients, despite this type of radiotherapy. In summary, it is reasonable to use whole-abdomen irradiation postoperatively to treat patients with adnexal or upper abdominal disease, such as in the omentum, that has been completely excised and patients who are at very high risk for intraabdominal recurrence, such as those with papillary serous tumors, but it should not be used in patients with gross residual intraabdominal disease.

**Intraperitoneal Phosphorus-32**

Apparently favorable results for the treatment of positive peritoneal cytology with intraperitoneal 32P have been reported (195). In 23 patients who had positive washings, treatment with 32P resulted in a lower recurrence rate than in historical controls, but the groups differed in risk factors, making conclusions regarding the effectiveness of the treatment questionable. Subsequently, it was reported that when 32P was combined with external pelvic irradiation, 20% of patients suffered serious bowel complications requiring surgical intervention, and two patients died of operative complications (176). At present, the role of 32P in the postoperative management of endometrial cancer patients with positive cytology is limited because of the lack of evidence of a therapeutic benefit and the complications when combined with external pelvic irradiation, which these patients often receive for prevention of local pelvic recurrence.

**Progestins**

Because most endometrial cancers have both estrogen and progesterone receptors and progestins have been used successfully to treat metastatic endometrial cancer, postoperative adjuvant progestin therapy has been attempted to reduce the risk for recurrence. This therapy is attractive because it provides systemic treatment and has few side effects. Unfortunately, several large randomized, placebo-controlled studies have failed to identify a benefit for adjuvant progestin therapy
Because the incidence of pelvic lymph node metastases is about 36% in stage II endometrial cancer, any treatment protocol should include treatment of these nodes. The presence of extraperitoneal disease was the only significant risk factor for recurrence, and no benefit to adjuvant chemotherapy could be demonstrated.

Chemotherapy

Adjuvant cytotoxic chemotherapy has been studied in a few trials. The GOG treated 181 patients who had poor prognostic factors with postoperative irradiation and then randomly assigned patients to receive no further therapy or doxorubicin (Adriamycin) chemotherapy. After 5 years of observation, there was no difference in recurrence rates between the two groups (183).

Researchers at the M. D. Anderson Cancer Center treated 62 high-risk patients with postoperative adjuvant cisplatin, doxorubicin and cyclophosphamide (PAC) chemotherapy. The relatively small number of true stage II cases in reported series and the lack of randomized, prospective studies preclude formulation of a definitive treatment plan. Three areas must be addressed in any treatment plan:

1. For optimal results, the uterus should be removed in all patients.
2. Because the incidence of pelvic lymph node metastases is about 36% in stage II endometrial cancer, any treatment protocol should include treatment of these lymph nodes.
3. Because the incidence of disease spread outside the pelvis to the paraaortic lymph nodes, adnexal structures, and upper abdomen is higher than in stage I disease, attention should be directed to evaluating and treating extrapelvic disease.

The two approaches have usually been taken to the treatment of clinical stage II disease:

1. Radical hysterectomy, bilateral salpingo-oophorectomy, and pelvic and paraaortic lymphadenectomy.
2. Combined radiation and surgery (external pelvic irradiation and intracavitary radium or cesium followed in 6 weeks by total abdominal hysterectomy and bilateral salpingo-oophorectomy).

Clinical Stage II

Endometrial cancer involving the cervix either contiguously or by lymphatic spread has a poorer prognosis than disease confined to the corpus (186,201). Prooperative assessment of cervical involvement is difficult. Endocervical curettage has relatively high false-positive (50% to 80%) and false-negative rates. Histologic proof of cancer infiltration of the cervix or presence of obvious tumor on the cervix is the only reliable means of diagnosing cervical involvement, although ultrasound, hysteroscopy, or MRI may demonstrate cervical invasion.

The most common, traditional approach to the management of clinical stage II endometrial cancer has been to use external and intracavitary irradiation followed by excisional hysterectomy. This combined approach has resulted in 5-year survival rates of 60% to 80%, with severe gastrointestinal or urologic complications occurring in about 10% of patients. Patients who have medically inoperable disease are usually treated with external-beam irradiation and one or two intracavitary insertions. Compared with combined radiation and surgery, the results with radiation alone are diminished, but about 50% of patients are long-term survivors (155). An initial radical surgical approach to treatment of clinical stage II endometrial cancer has the advantage of allowing accurate surgical-pathologic information to be obtained. Conversely, many patients with endometrial cancer are elderly and obese and have medical problems that make this approach unsuitable. In addition, reported results are better than with combined radiation and less radical surgical therapy. The use of radical hysterectomy may be limited to patients with anatomic problems that prevent optimum dosimetry or other conditions that conflict with the use of radiation therapy.

The most common, traditional approach to the management of clinical stage II endometrial cancer has been to use external and intracavitary irradiation followed by excisional hysterectomy. This combined approach has resulted in 5-year survival rates of 60% to 80%, with severe gastrointestinal or urologic complications occurring in about 10% of patients. Patients who have medically inoperable disease are usually treated with external-beam irradiation and one or two intracavitary insertions. Compared with combined radiation and surgery, the results with radiation alone are diminished, but about 50% of patients are long-term survivors (155). An initial radical surgical approach to treatment of clinical stage II endometrial cancer has the advantage of allowing accurate surgical-pathologic information to be obtained. Conversely, many patients with endometrial cancer are elderly and obese and have medical problems that make this approach unsuitable. In addition, reported results are better than with combined radiation and less radical surgical therapy. In addition, reported results are better than with combined radiation and less radical surgical therapy. The use of radical hysterectomy may be limited to patients with anatomic problems that prevent optimum dosimetry or other conditions that conflict with the use of radiation therapy.

Clinical Stages III and IV

Clinical stage III disease accounts for about 7% to 10% of all endometrial carcinomas (202,203,204,205,206,207,208 and 209). Patients usually have clinical evidence of disease spread to the parametria, pelvic sidewall, or adnexal structures; less frequently, there is spread to the vagina or pelvic peritoneum. Treatment for stage III endometrial cancer must be individualized, but initial operative evaluation and treatment should be considered because of the high risk for occult lymph node metastases and intrapelvic spread when disease is known to extend outside of the uterus into the pelvis. In the presence of an adenocarcinoma, surgery should be performed initially to determine the nature of the mass. Surgery should also be performed to determine the extent of disease and to remove the bulk of the disease if possible. This should include peritoneal washings for cytologic examination, selective paraaortic and pelvic lymphadenectomy, as well as removal of any enlarged lymph nodes, biopsy or excision of any suspicious areas within the peritoneal cavity, and partial omentectomy and peritoneal biopsies. Except in patients with bulky parametrial disease, total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed. Surgical eradication of all macroscopic disease should be the goal because this finding is of major prognostic importance in the management of patients with clinical stage III disease. Postoperative radiotherapy can then be tailored to the extent of disease.

Results of therapy depend on the extent and nature of disease. A 5-year survival rate of 54% has been reported for all patients with stage III disease; however, the survival rate for patients with pelvic adenocarcinoma has only been 20%, compared with 50% when other extraperitoneal pelvic structures were involved (203). Patients with surgical-pathologic stage III disease have a much better survival rate (40%) than those with clinical stage III disease (16%) (194). Patients who are treated with combined surgery and irradiation fare better than patients who receive radiation therapy alone (209).

Stage IV endometrial adenocarcinoma, in which tumor invades the bladder or rectum or extends outside the pelvis, makes up about 3% of cases (209,210,211,212 and 213). Treatment of stage IV disease is patient dependent but usually involves a combination of surgery, radiation therapy, and systemic hormonal or chemotherapy. One objective of surgery and radiation therapy is to achieve local disease control in the pelvis to provide palliative relief of bleeding, discharge, and complications involving the bladder and rectum. Control of pelvic disease has been achieved in 28% of 72 patients with stage IV disease treated with radiation alone or in combination with surgery, progestins, or both (210). Several reports have noted a positive impact of cytoreductive surgery on survival, the median survival being about 3 times greater with optimal cytoreduction (18 to 34 months versus 8 to 11 months, respectively) (212,213). Pelvic exenteration may be considered in the very rare patient in whom disease is limited to the bladder, rectum, or both (214,215).

Recurrent Disease

About one fourth of patients treated for early endometrial cancer develop recurrent disease. More than half of the recurrences develop within 2 years, and about three fourths occur within 3 years of initial treatment. The distribution of recurrences is dependent in large part on the type of primary therapy; surgery alone versus surgery plus pre- or postoperative radiotherapy. In a GOG study of 791 patients with stage I disease, vaginal and pelvic recurrences were noted to make up 53% of all recurrences in the group treated with surgery alone, whereas only 30% of recurrences were vaginal or pelvic in the group treated with combined surgery and radiotherapy (76). Therefore, after combined surgery and radiotherapy (vaginal or external beam), 70% or more of patients who fail treatment have distant
metastases, and most of these patients do not have evidence of local or pelvic recurrence. The most common sites of extrapelvic metastases are the lung, abdomen, lymph nodes (aortic, supraclavicular, inguinal), liver, brain, and bone. In general, patients with isolated vaginal recurrences fare better than those with pelvic recurrences, who in turn have a better chance of cure than those with distant metastases. Patients who initially have well-differentiated tumors or who develop recurrent cancer more than 3 years after the primary therapy also tend to have an improved prognosis.

In a 1984 report on 379 patients with recurrent endometrial cancer seen at the Norwegian Radium Hospital from 1960 to 1976 (216), site of recurrence was local or regional in 190 patients (50%), distant in 108 patients (28%), and local and distant in 81 patients (21%). The median time to recurrer was 14 months for patients with local recurrences and 19 months for patients with distant metastases. Of all recurrences, 34% were detected within 1 year, and 76% were detected within 3 years of primary treatment. At the time of diagnosis of recurrence, 32% of patients had no symptoms. Vaginal bleeding was the most common symptom associated with local recurrence, and pelvic pain was most often present with pelvic recurrence. Hemopposite was the initial symptom in 32% of patients with lung metastases, but 45% of cases of lung metastases were asymptomatic and picked up on routine chest x-ray. Only 9% of patients with metastases at other sites did not have symptoms; most had pain (37%) or other symptoms such as anorexia, nausea and vomiting, or ascites related to intraabdominal carcinomatosis, neurologic symptoms such as seizures from brain metastases, or jaundice caused by liver metastases.

Overall, only 29 (7.7%) of the 379 patients were alive without evidence of disease from 3 to 19 years. This included 22 patients (12%) with local or pelvic recurrence, 5 patients (1.3%) with distant metastases, and 2 patients (2%) with both local and distant recurrences. The best results were obtained in the 24 patients with vaginal vault recurrences who were treated with radiotherapy, resulting in a 24% survival rate. None of the 78 patients with pelvic soft tissue recurrence survived. Three patients (7%) with only lung metastases treated with progestins, two patients with lymph node metastases treated with combined radiotherapy and progestins, and two patients with localized recurrence and lung metastases treated with radiotherapy, surgery, and progestins survived.

**Surgery**

A small subset of patients who develop recurrent endometrial cancer may benefit from surgical intervention. Pelvic or vaginal recurrence in patients who have not received prior pelvic irradiation is best treated with external irradiation plus some type of brachytherapy. Surgical resection of a metastatic nodule greater than 2 cm in diameter before irradiation, however, may improve local control. Pretherapy investigation for extrapelvic metastasis in these patients may include surgical evaluation of the peritoneal cavity and retroperitoneal lymph nodes for evidence of subclinical metastases. Upper abdominal disease has been found at laparotomy in 3 (37.5%) of 8 patients with presumed localized pelvic recurrence (217). Presence of subclinical extrapelvic metastases was associated with larger pelvic tumor size (>2 cm) and elevated serum CA125 levels. A few patients with extrapelvic recurrence may benefit from laparotomy to relieve intestinal obstruction, or tumor-reductive surgery may be performed before whole-abdomen radiation therapy or systemic hormonal therapy.

Isolated central pelvic recurrence after irradiation is exceedingly rare. In patients with this type of recurrence, exploratory laparotomy may be performed with the plan to proceed with pelvic exenteration if there is no evidence of disease outside the pelvis and no lymph node metastases. Exenterative surgery for recurrent endometrial cancer in the pelvis has rarely been of value because of the high incidence of associated occult extrapelvic metastases. Of 36 patients who underwent pelvic exenteration for recurrent endometrial carcinoma, 75% died of their cancer within 1 year of operation, and only 14% were alive after 5 years (215).

**Radiation Therapy**

Patients with isolated local or regional recurrences after initial surgical treatment of endometrial cancer should be treated with radiotherapy (218, 219, 220, 221, 222, 223, 224 and 225). The best local control and subsequent cure are usually achieved by a combination of external-beam radiation therapy followed by a brachytherapy boost to deliver a total tumor dose of at least 6,000 cGy. Women with low-volume disease limited to the pelvis have the best outcome. For patients with isolated vaginal recurrence treated with irradiation, reported survival rates range from 24% to 45%. Conversely, for those patients who have pelvic extension of their disease treated with irradiation, lower survival rates from 0% to 24% have been reported. Initial endometrial cancer grade 1, younger patient age at recurrence, recurrent tumor size 2 cm or less, and time to recurrence less than or equal to 1 year, vaginal versus pelvic disease, and radiation therapy that included brachytherapy are independent factors in determining control of pelvic disease and survival in patients with locally recurrent endometrial cancer.

**Hormone Therapy**

Progestational agents for treatment of metastatic endometrial cancer were first described in 1961 (226). The researchers observed an objective response rate of 29% in 21 patients. A beneficial response has been observed in 35% of 308 patients (227). Subsequent reports have noted somewhat less optimistic response rates, probably as a result of more strictly applied criteria for objective responses (228, 229, 230 and 231) (Table 30.15). Objective response rates of 16% and 11%, respectively, have been noted, with an additional 15% to 40% of patients exhibiting stable disease for at least 3 months (228, 229).

Table 30.15. Response to Progestin Therapy in Advanced or Recurrent Endometrial Cancer

In 1986, the GOG initially reported on the use of oral medroxyprogesterone acetate for treatment of patients with advanced or recurrent endometrial cancer (239). Of 219 patients with measurable disease, 8% had a complete response, 6% had a partial response, 52% had stable disease, and 34% developed progressive disease within 1 month. The mean survival time for the entire group was 10.4 months. In a follow-up study comparing two different doses of oral medroxyprogesterone acetate, similar response rates were achieved (26% for 200 mg/d and 18% for 1,000 mg/d) (231). Neither the type, dose, nor route of administration of the progestin seemed to have an effect on response in these studies.

Response of metastatic endometrial carcinoma to progestin therapy is related to several clinical and pathologic factors. Higher response rates are observed in well-differentiated tumors. A 20.5% response in low-grade tumors and only 1.4% response in high-grade tumors have been noted (239). Likewise, the probability of an objective response to progestin therapy is about 75% for tumors that are estrogen and progesterone receptor positive, compared with about 5% to 15% for tumors that are negative for both receptors. A longer disease-free interval is associated with higher response rates to progestins. The response rate to progestins has been found to range from 6% in patients with an interval from primary treatment to recurrence of less than 6 months to 65% in patients in whom disease recurred more than 5 years after initial treatment (227). Other observed, but less well documented, factors that may have an adverse effect on response to progestins are disease recurrence within a prior radiation field, large tumor burden, and advanced primary versus recurrent disease (227, 229).

Tamoxifen, a nonsteroidal antiestrogen with some estrogenic properties, has been evaluated for treatment of metastatic endometrial carcinoma, based on experience in using this agent in breast cancer treatment. Its use as either a single agent or in combination with a progestin is related to its ability to inhibit the binding of estradiol to the estrogen receptor and to increase progesterone receptors. In a review of eight studies using tamoxifen, 20 to 40 mg/d, in patients with metastatic endometrial carcinoma, the overall response rate was 22%, with a range of 0% to 53% (232). Responses to tamoxifen were more likely to be observed in patients with low-grade, hormone receptor–positive tumors who had demonstrated a prior response to progestin therapy. In an attempt to reverse the hormone receptor downregulation seen with progestin therapy, tamoxifen has been given along with progestins, but the overall responses to combined tamoxifen and progestin therapy have been similar to
Progestins are currently recommended as initial treatment for all patients with recurrent endometrial cancer. Radiation therapy, surgery, or both should be used whenever feasible for treatment of localized recurrent cancer such as vaginal, pelvic, bone, and peripheral lymph node disease; however, these patients should also be given long-term progestin therapy unless they are known to have a progesterone receptor-negative tumor. Patients with nonlocalized recurrent tumors, especially if progesterone receptors are known to be positive, are candidates for progestin therapy, either megestrol acetate, 80 mg twice daily, or medroxyprogesterone acetate, 50 to 100 mg three times daily. Progestin therapy should be continued for at least 2 to 3 months before assessing response. If a response is obtained, the progestin should be continued for as long as the disease is static or in remission. In the presence of a relative contraindication to high-dose progestin therapy (e.g., prior or current thromboembolic disease, severe heart disease, or inability of the patient to tolerate progestin therapy), tamoxifen, 20 mg twice daily, is recommended. Failure to respond to hormonal therapy is an indication for initiating chemotherapy.

Chemotherapy

Although several chemotherapeutic agents or combinations of agents are capable of inducing objective responses and even remissions in patients with metastatic endometrial carcinoma, response and survival times are short, and all cytotoxic therapy should be considered palliative (232,233 and 234). The most active chemotherapeutic agents are doxorubicin, the platinum compounds cisplatin and carboplatin, and paclitaxel (Taxol). Doxorubicin, in dosages of 50 to 60 mg/m² every 3 weeks, and carboplatin, 350 to 400 mg/m² every 4 weeks, have been associated with response rates of 21% to 29%. Paclitaxel, 250 mg/m² as a 24-hour infusion with granulocyte colony-stimulating factor support (235), or 175 mg/m² as a 3-hour infusion every 3 weeks (236,237), has produced response rates of about 36%. Alkylating agents such as cyclophosphamide and melphalan, 5-fluorouracil, and altretamine (hexamethylmelamine) have shown activity against endometrial cancer. Most responses obtained with use of these agents have been partial, generally averaging only 3 to 6 months, with the median survival time ranging from 4 to 8 months.

Combination chemotherapy regimens employing doxorubicin and cisplatin (AP), cyclophosphamide, doxorubicin, and cisplatin (CAP), and paclitaxel and cisplatin with or without doxorubicin (238,239) have resulted in response rates ranging from 36% to 76%. Most responses have been partial, with durations of 4 to 8 months. Despite these fairly impressive response rates, the median survival time has generally been less than 12 months.

Response to chemotherapy in patients with metastatic endometrial cancer does not appear to be affected by prior or concurrent progestin therapy. Metastatic site, age, disease-free interval, histology, and tumor grade also appear to have no effect on chemotherapy response. However, patients with long disease-free intervals and better performance status may live longer. Initial progestin therapy is advised before chemotherapy is undertaken, reserving the use of more toxic chemotherapy agents for situations in which endocrine therapy has failed. Alternatively, eligible patients should be entered into clinical trials.

Treatment Results

Comprehensive survival data for endometrial cancer are provided by FIGO (240). Survival in relation to clinical and surgical stage is shown in Table 30.16 and in relation to surgical stage and grade in Table 30.17. The overall 5-year survival rate was 76%. Surgically staged patients had much better 5-year survival rates than clinically staged patients across all stages (respectively): stage I, 87% versus 54%; stage II, 76% versus 41%; stage III, 57% versus 23%; stage IV, 18% versus 12%. Survival in surgical stage I disease ranged from 90% to 93% for stage IA grades 1 and 2 and stage IB grades 1 and 2 to 63% for stage IC grade 3.

Follow-up after Treatment

History and physical examination remain the most effective methods of follow-up in patients treated for endometrial cancer (241,242,243 and 244). Patients should be examined every 3 to 4 months during the first 2 years and every 6 months thereafter. About half of patients discovered to have recurrent cancer have symptoms, and 75% to 80% of recurrences are detected initially on physical examination. Particular attention should be given to peripheral lymph nodes, the abdomen, and the pelvis. Vaginal cytology should be performed at each visit. Although very few asymptomatic recurrences are detected by vaginal cytology, these early recurrences are often amenable to successful therapy.

Chest x-ray every 12 months is an important method of posttreatment surveillance. Almost half of all asymptomatic recurrences are detected by chest x-ray. Other radiologic studies, such as intravenous pyelography and CT scans, are not indicated for routine follow-up of patients who do not have symptoms.

Serum CA125 measurement has been suggested for posttreatment surveillance of endometrial cancer (245,246). Elevated CA125 levels have been documented in patients with recurrent tumor, and these levels have correlated with the clinical course of disease. However, CA125 levels may be normal in the presence of small recurrences, making the utility of CA125 measurements for follow-up of patients after treatment of early-stage disease suspect. CA125 determinations should be obtained in patients with elevated levels at the time of diagnosis or with known extraperitoneal disease.

Estrogen Replacement Therapy after Treatment of Endometrial Cancer

A history of endometrial cancer has long been considered a contraindication to estrogen replacement therapy because of the concern that occult metastatic disease...
might be activated by estrogen. Although this is a reasonable concern, the magnitude of this risk has never been quantified and, in fact, there is no evidence that estrogen therapy after apparently successful treatment of endometrial cancer increases the risk for cancer recurrence.

In a nonrandomized, retrospective follow-up study of 221 patients with clinical stage I endometrial cancer, 47 patients who had received estrogen after treatment were compared with 174 who had not been treated with estrogen. There were no significant differences between the two groups with respect to known risk factors for cancer recurrence. There were 26 (14.9%) recurrences in the patients not treated with estrogen, compared with only 1 (2.1%) recurrence in the patients treated with estrogen. Moreover, in the group not receiving estrogen, there were 26 deaths (16 from cancer and 10 from intercurrent disease), compared with only 1 death among those taking estrogen (247). Similarly in another report, no recurrent cancers and no intercurrent deaths were found in 44 women who took estrogen after treatment for endometrial cancer, compared with eight recurrences and eight intercurrent deaths (five from myocardial infarction) in 99 women who did not take estrogen (248). In a subsequent study of 123 surgical stage I and II endometrial cancer patients 62 (50.5%) who received estrogen replacement therapy postoperatively were identified. After controlling for risk factors for recurrence, there was no detectable difference in recurrence rate or time to recurrence between those patients who had received estrogen replacement therapy and those who had not (249). More recently, a retrospective cohort study of matched treatment-control pairs found two recurrences (1%) among the 75 women using estrogen, compared with 11 recurrences (14%) in the 75 women not using estrogen after primary therapy for endometrial cancer (250). In all of these studies, however, estrogen replacement therapy did not commence immediately after surgery in most patients.

Because many women who have been successfully treated for endometrial cancer suffer side effects of estrogen deficiency, such as vasomotor instability, vaginal dryness and dyspareunia, as well as the long-term risks of osteoporosis and atherosclerotic heart disease, treatment with estrogen is desirable. The American College of Obstetricians and Gynecologists has stated that for women with a history of endometrial cancer, hormone replacement therapy could be used for the same indications as for any other woman, except that "the selection of appropriate candidates for estrogen treatment should be based on prognostic indicators ... and the risk she is willing to assume." A compromise between immediate postoperative estrogen replacement therapy and no hormone therapy might be to withhold estrogen for 1 to 3 years after treatment, during which time most recurrences develop, thereby minimizing the chances of administering estrogen to patients with residual cancer. In the interim, symptomatic relief of hot flashes can be achieved by prescribing progestins such as medroxyprogesterone acetate, 10 mg orally daily or 150 mg intramuscularly every 3 months, or nonhormonal agents such as bethanechol, clonidine, and venlafaxine.

Uterine Sarcoma

Uterine sarcomas are relatively rare tumors of mesodermal origin. They constitute 2% to 6% of uterine malignancies (251). There is an increased incidence of uterine sarcomas, usually malignant mixed mullerian tumors (MMMTs), after radiation therapy to the pelvis for either carcinoma of the cervix or a benign condition. The risk of sarcoma arising after pelvic sarcoma after pelvic radiotherapy has been estimated to be 5.38, with an interval of usually 10 to 20 years (252). Uterine sarcomas are, in general, the most malignant group of uterine tumors and differ from endometrial cancers with regard to diagnosis, clinical behavior, pattern of spread and management.

Classification

The three most common histologic variants of uterine sarcoma are endometrial stromal sarcoma (ESS), leiomyosarcoma (LMS), and MMMTs of both homologous and heterologous type (252) (Table 30.18). Variations in the relative incidences of uterine sarcomas occur in different published series, probably related to the strictness of criteria used to classify smooth muscle and endometrial stromal tumors as sarcomas. In general, LMS and MMMT each make up about 40% of tumors, followed by ESS (15%) and other sarcomas (5%), although MMMTs predominate in more recent reports. Staging of uterine sarcomas is based on the FIGO system for endometrial carcinoma (Table 30.6 and Table 30.7).

Table 30.18. Classifications of Uterine Sarcomas

<table>
<thead>
<tr>
<th>Endometrial Stromal Tumors</th>
</tr>
</thead>
<tbody>
<tr>
<td>Stromal tumors occur primarily in perimenopausal women between 45 and 50 years of age; about one third occur in postmenopausal women. There is no relationship to parity, associated diseases, or prior pelvic radiotherapy. These tumors are rare in African American women. The most frequent symptom is abnormal uterine bleeding; abdominal pain and pressure due to an enlarging pelvic mass occur less often, and some patients do not have symptoms. Pelvic examination usually reveals regular or irregular uterine enlargement, sometimes associated with rubbery parametrial induration. The diagnosis may be determined by endometrial biopsy, but the usual preoperative diagnosis is uterine leiomyoma. At surgery, the diagnosis is suggested by the presence of an enlarged uterus filled with soft, gray-white to yellow necrotic and hemorrhagic tumors with bulging surfaces associated with wormlike elastic extensions into the pelvic veins. Endometrial stromal tumors are composed purely of cells resembling normal endometrial stroma. They are divided into three types on the basis of mitotic activity, vascular invasion, and observed differences in prognosis: (a) endometrial stromal nodule, (b) low-grade stromal sarcoma, and (c) high-grade or undifferentiated ESS.</td>
</tr>
</tbody>
</table>

Endometrial stromal nodule is an expansive, noninfiltrating, solitary lesion confined to the uterus with pushing margins, no lymphatic or vascular invasion, and usually less than 3 mitotic figures per 10 high-power microscopic fields (3 MF/10 HPF). These tumors should be considered benign because there have been no recurrences or tumor-associated deaths reported after surgery (254). Low-grade ESS or endolymphatic stromal myosis is distinguished from high-grade or undifferentiated ESS microscopically by a mitotic rate of less than 10 MF/10 HPF as well as clinically by a more protracted course. Recurrences typically occur late, and local recurrence is more common than distant metastases (255,256,257,258 and 259). Although low-grade stromal sarcoma often behaves in a histologically aggressive fashion, it lacks the aneuploid DNA content and high proliferative index associated with high-grade stromal sarcoma, and flow cytometric analysis can be used to differentiate the two conditions and predict response to therapy. Low-grade stromal sarcoma has extended beyond the uterus in 40% of cases at the time of diagnosis, but the extraterine spread is confined to the pelvis in two thirds of the cases. Upper abdominal, pulmonary, and lymph node metastases are uncommon. Recurrence occurs in almost half of cases at an average interval of about 5 years after initial therapy. Prolonged survival and even cure are not uncommon even after the development of recurrent or metastatic disease.

Optimum initial therapy for patients with low-grade stromal sarcoma consists of surgical excision of all grossly detectable tumor. Total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed. The adnexa should always be removed because of the propensity for tumor extension into the parametria, broad ligaments, and adnexal structures as well as the possible stimulating effect of estrogen from retained ovaries on the tumor cells. A beneficial effect of radiation therapy has been reported, and pelvic irradiation is recommended for inadequately excised or locally recurrent pelvic disease (255). There is also evidence that low-grade stromal sarcoma is hormone dependent or responsive. Objective responses to progestin therapy have been noted in 6 of 13 patients (48%) (259). Recurrent or metastatic lesions may also be amenable to surgical excision.
Almost all of these tumors occur after menopause, at a median age of 62 years. There is a higher incidence in African American women. These tumors are often found in bone, or striated muscle (heterologous). These tumors are most likely derived from totipotential endometrial stromal cells (resemble the normal endometrial stroma (homologous or the so-called carcinosarcoma), or it may be composed of tissues foreign to the uterus, such as cartilage, MMMTs are composed histologically of a mixture of sarcoma and carcinoma. The carcinomatous element is usually glandular, whereas the sarcomatous element may resemble the normal endometrial stroma (homologous or the so-called carcinosarcoma), or it may be composed of tissues foreign to the uterus, such as cartilage, bone, or striated muscle (heterologous). These tumors are most likely derived from totipotential endometrial stromal cells (281,282 and 283).

Almost all of these tumors occur after menopause, at a median age of 62 years. There is a higher incidence in African American women. These tumors are often found in bone, or striated muscle (heterologous). These tumors are most likely derived from totipotential endometrial stromal cells (resemble the normal endometrial stroma (homologous or the so-called carcinosarcoma), or it may be composed of tissues foreign to the uterus, such as cartilage, bone, or striated muscle (heterologous). These tumors are most likely derived from totipotential endometrial stromal cells (281,282 and 283).

Malignant Mixed Müllerian Tumors

MMMTs are composed histologically of a mixture of sarcoma and carcinoma. The carcinomatous element is usually glandular, whereas the sarcomatous element may resemble the normal endometrial stroma (homologous or the so-called carcinosarcoma), or it may be composed of tissues foreign to the uterus, such as cartilage, bone, or striated muscle (heterologous). These tumors are most likely derived from totipotential endometrial stromal cells (281,282 and 283).

Figure 30.8 Leiomyosarcoma of the uterus. Interlacing bundles of spindle cells have fibrillar cytoplasm, irregular and hyperchromatic nuclei, and multiple mitotic figures. (Reproduced or modified from Berek JS, Hacker NF. Practical gynecologic oncology. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)
references in association with other medical conditions, such as obesity, diabetes mellitus, and hypertension. A history of previous pelvic irradiation can be obtained in 7% to 37% of patients.

The most frequent presenting symptom is postmenopausal bleeding, which occurs in 80% to 90% of cases. Other less common symptoms are vaginal discharge, abdominal or pelvic pain, weight loss, and anemia. The duration of symptoms is usually only a few months. On physical examination, uterine enlargement is present in 50% to 95% of patients, and a polypoid mass may be seen within or protruding from the endocervical canal in up to 50% of patients. Diagnosis can usually be determined by biopsy of an endocervical or endometrial curettement.

The tumor grows as a large, soft, polypoid mass filling and distending the uterine cavity; necrosis and hemorrhage are prominent features. The myometrium is invaded to various degrees in almost all cases. The most frequent areas of spread are the pelvis, lymph nodes, peritoneal cavity, lungs, and liver. This metastatic pattern suggests that these neoplasms spread by local extension and regional lymph node metastasis in a manner similar to that of endometrial adenocarcinoma but behave more aggressively.

The most important single factor affecting prognosis in patients with MMT is the extent of tumor at the time of treatment. In patients with tumor apparently confined to the uterine corpus (stage I), a 53% 2-year survival rate has been noted, whereas the survival rate dropped to 8.5% when disease had extended to the cervix, vagina, or parametria (stage II and III); no patients with disease outside the pelvis (stage IV) survived (294).

Unfortunately, disease has clinically already extended outside the uterus in 40% to 60% of cases at the time of diagnosis, indicating the highly malignant nature of this lesion. Even when disease is believed to be confined to the uterus preoperatively and potentially is still curable, surgical and pathologic staging identifies extraperitoneal spread in a significant number of cases. In one study, 55% of women with clinical stage I MMT had a higher surgical-pathologic stage. Only 28% of tumors were actually confined to the uterine corpus, 16% had extension to the cervix, and 56% showed extraterine spread (285). A significant occurrence of lymph node metastases and positive peritoneal cytology, respectively, has been found in early-stage MMT (286–287). Deep myometrial invasion, which is present in about half of stage I cases, is associated with poor prognosis. Almost all patients in whom tumor involves the outer half of the myometrium die from the disease. Patients who die from MMT also tend to have larger tumors and a higher incidence of LVSI. Patients with a history of prior pelvic irradiation generally have a poorer prognosis. Overall, the 5-year survival rate for patients with MMT is about 20% to 30%.

Adenosarcoma is an uncommon variant of MMT (288,289). It consists of an admixture of benign-appearing neoplastic glands and a sarcomatous stroma. Most patients present with postmenopausal vaginal bleeding, and the disease is diagnosed and suspected based on endometrial curettement. Most adenosarcomas are well circumscribed and limited to the endometrium or superficial myometrium. The treatment is hysterectomy and bilateral salpingo-oophorectomy with or without adjuvant radiotherapy. Recurrences, mostly local pelvic or vaginal, have been reported in 40% to 50% of cases, leading some authors to recommend adjuvant postoperative intravaginal or pelvic irradiation.

TREATMENT OF UTERINE SARCOMAS

Recurrences develop in more than half of cases of uterine sarcoma, even when disease is apparently localized at the time of treatment (290,291) and (292). At least half of recurrences occur outside the pelvis, with isolated pelvic failures accounting for less than 10% of recurrences. The most common sites of recurrence are the abdomen and lungs. These data emphasize that the major limitation to cure of uterine sarcomas is distant spread.

Based on this type of evidence, treatment of most stage I and II uterine sarcomas should include hysterectomy, bilateral salpingo-oophorectomy, and treatment of the pelvic lymphatics by irradiation or surgery. Strong consideration should also be given to the use of adjuvant chemotherapy to decrease the incidence of distant metastases. Stage III uterine sarcomas are probably best treated by an aggressive approach of combined surgery, radiation therapy, and chemotherapy. Stage IV disease must be treated with combination chemotherapy.

SURGERY

The first step in the treatment of early uterine sarcoma should be exploratory laparotomy. Because extirpative survey is the most important aspect of treatment, and knowledge of the extent and spread of the disease is important for further management, one should not forego or delay surgery by using radiation therapy or chemotherapy first. At the time of surgery, the peritoneal cavity should be carefully explored, and special attention should be given to the pelvic and paraaortic lymph nodes. Total abdominal hysterectomy is the standard procedure, and bilateral salpingo-oophorectomy should also be performed in all patients except premenopausal women with leiomyosarcoma. Based on the surgical and pathologic findings, additional therapy with radiation therapy or chemotherapy can then be planned. Rarely, a patient may be cured by excision of an isolated pulmonary metastasis (293).

RADIATION THERAPY

Most studies have found adjuvant preoperative or postoperative radiation therapy to be of value in decreasing pelvic recurrences and thereby increasing quality of life in patients with localized ESS and MMT, but not leiomyosarcoma (294,295,296,297,298, and 299). Radiation therapy thus appears to have a role with surgery in the combined treatment of MMT and ESS confined to the pelvis by increasing the disease-free progression interval and by increasing pelvic control, thereby probably increasing the overall survival to some degree.

CHEMOTHERAPY

Several chemotherapeutic agents have been found to have activity in sarcomas, including vincristine, actinomycin D, cyclophosphamide, doxorubicin, dimethyl triazeno imidazole carboxamide (dacarbazine, DTIC), cisplatin, ifosfamide (300,301). Doxorubicin appears to be the most active single agent in the treatment of leiomyosarcoma, producing a 25% response rate (302). Ifosamide also has some lesser activity (303). On the other hand, cisplatin and ifosfamide have demonstrated clear activity in MMMTs, with response rates of 18% to 42% and 32%, respectively (304,305 and 306). Doxorubicin has demonstrated less than a 10% response rate in MMMTs (309).

Combination chemotherapy with doxorubicin and DTIC or these two drugs plus vincristine (VAD) and cyclophosphamide (CYVADIC) has been reported to yield somewhat higher response rates (300,301,307). More recently, ifosfamide with mesna uroprotection, Doxorubicin and DTIC (MAID) have been combined to treat metastatic sarcomas. Combined ifosfamide and cisplatin chemotherapy has resulted in a higher response rate (54% versus 36%) and a longer progression-free survival than ifosfamide chemotherapy alone for treatment of advanced MMMTs (308).

Because of the relatively low survival in localized uterine sarcomas and the high incidence of failure due to subsequent distant metastasis, adjuvant treatment programs employing chemotherapy have been tested. Unfortunately, most reports have been unable to demonstrate a clear improvement in survival by the addition of postoperative adjuvant chemotherapy in early uterine sarcoma. The GOG conducted a trial of postoperative adjuvant doxorubicin in stage I and II uterine sarcoma patients. Of the 75 patients randomized to receive doxorubicin, 41% developed a recurrence, compared with 53% of 81 patients receiving no adjuvant chemotherapy, but these differences were not significant (309). Other smaller, nonrandomized adjuvant chemotherapy studies (310) employing CYVADIC and cisplatin plus doxorubicin reported recurrence rates of 35% and 24%, respectively (310,311).

REFERENCES

Cervical and Vaginal Cancer

Chapter 31

Invasive cervical cancer in the United States is relatively infrequent, and the low incidence of cervical cancer is attributable to the effectiveness of screening with Papanicolaou’s (Pap) test and detecting premalignant precursors. However, cervical carcinoma remains a significant health care problem worldwide. In Third World countries where no screening programs exist, cervical carcinoma is a significant cause of mortality. Because cervical cancer is potentially preventable, it is imperative that gynecologists and other primary care providers who administer health care to women be familiar with screening techniques, diagnostic procedures, and risk factors for cervical cancer, especially its premalignant precursors. Vaginal cancer is a relatively uncommon tumor.

**Cervical Cancer**

**Epidemiology and Risk Factors**

Invasive cancer of the cervix has been considered a preventable cancer because it has a long preinvasive state, because cervical cytology screening programs are available, and because the treatment of preinvasive lesions is effective. However, 13,000 new cases of invasive cervical cancer resulting in about 4,100 deaths were anticipated in the United States in 2002 (1). Although cervical cancer has not been eliminated, the incidence of invasive disease is decreasing, and it is being diagnosed earlier, leading to better survival rates (2,3). The mean age for cervical cancer is 52.2 years, and the distribution of cases is bimodal, with peaks at 35 to 39 years and 60 to 64 years of age (4).

There are numerous risk factors for cervical cancer: young age at first intercourse (<16 years), multiple sexual partners, cigarette smoking, race, high parity, and low socioeconomic status. The relationship to oral contraceptive use has been debated in the literature. Some investigators have proposed that use of oral contraceptives may increase the incidence of cervical glandular abnormalities of the cervix (3,4); however, this hypothesis has not been consistently supported. Many of these risk factors are linked to sexual activity and exposure to sexually transmitted diseases. Infection with herpes virus was previously thought to be the initiating event in cervical cancer. However, infection with the human papillomavirus (HPV) has now been determined to be involved in the development of cervical cancer.

The initiating event in cervical dysplasia and carcinogenesis is likely to be infection with HPV. HPV infection has been detected in up to 99% of women with squamous cervical carcinoma (5). There are more than 80 different types of HPV, 25 of which affect the lower genital tract. There are 13 high-risk HPV subtypes; two of the high-risk subtypes, 16 and 18, are found in up to 62% of cervical carcinomas. The mechanism by which HPV affects cellular growth and differentiation is by interactions of viral E6 and E7 proteins with p53 and Rb, resulting in gene inactivation (6). The role of human immunodeficiency virus (HIV) in cervical cancer is thought to be mediated through immune suppression. The Centers for Disease Control and Prevention have described cervical cancer as an illness that defines acquired immune deficiency syndrome (AIDS) in patients infected with HIV (7).

**Evaluation**

Vaginal bleeding is the most common symptom occurring in patients with cancer of the cervix. Most often, this is postcoital bleeding, but it may occur as irregular or postmenopausal bleeding. Patients with advanced disease may have a malodorous vaginal discharge, weight loss, or obstructive uropathy. On general physical examination, the supraclavicular and groin lymph nodes should be palpated to exclude the presence of metastatic disease. On pelvic examination, a speculum is inserted into the vagina, and the cervix is inspected for suspicious areas. The vagina is inspected for extension of disease. With invasive cancer, the cervix is usually firm and expanded, and these features should be evaluated by digital examination. Rectal examination is important to help establish cervical consistency and size, particularly in patients with endocervical carcinomas. It is the only way to determine cervical size if the vaginal fornices have been obliterated by menopausal changes or by the extension of disease. Parametrial extension of disease is best determined by the finding of nodularity beyond the cervix on rectal examination. When obvious tumor growth is present, cervical biopsy performed on an outpatient basis is usually sufficient for diagnosis. Colposcopy may be helpful in directing the examiner toward the most invasive area for biopsy. If the diagnosis cannot be established conclusively with outpatient biopsy, diagnostic conization may be necessary.

Cervical conization is required to assess correctly the depth and the linear extent of involvement of microinvasion. The earliest invasion is characterized by a protrusion from the stromoeppithelial junction. This focus consists of cells that appear better differentiated than the adjacent noninvasive cells and have abundant...
Abnormal reticular vessels represent the terminal capillaries of the cervical epithelium. Normal capillaries are best seen in a postmenopausal woman with atrophic

**Figure 31.1 Microinvasive squamous carcinoma.** Multiple irregular tongue-like processes and isolated nests of malignant cells are seen, some surrounded by clear spaces, simulating capillary lymphatic invasion. This is an artifact caused by tissue shrinkage. The depth of stromal invasion is measured from the basement membrane of the overlying cervical intraepithelial neoplasia (CIN). In this case, it is 1.5 mm. (From Berek JS, Hacker F. Practical gynecologic oncology. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

The depth of invasion should be measured with the micrometer from the base of the epithelium to the deepest point of invasion. The depth of invasion is significant for the development of pelvic lymph node metastasis and tumor recurrence. Although lesions that have invaded 3 mm or less rarely metastasize, patients in whom lesions invade more than 3 to 5 mm have positive pelvic lymph nodes in 3% to 8% of cases (19). Although the significance of the cutoff at 3 mm has not been identified completely, it may be postulated that capillary-lymphatic spaces are extremely small at this level, and it is unclear whether they can carry tumor cells beyond the specific zone. Uneven shrinkage of tissue by fixative often creates space between the tumor nests and the surrounding fibrous stroma, stimulating vascular lymphatic invasion (Fig. 31.1). A suspected vascular involvement with invasion of less than 3 mm should be interpreted with care. A lack of endothelial lining indicates that the space is an artifact of shrinkage rather than true vascular invasion.

**Colposcopic Findings**

For patients with suspected early invasive cancer based on Pap test results and a grossly normal-appearing cervix, colposcopic examination is mandatory. Colposcopic findings that suggest invasion are (a) abnormal blood vessels, (b) irregular surface contour with loss of surface epithelium, and (c) color tone change. Colposcopically directed biopsies may permit the diagnosis of frank invasion and thus avoid the need for diagnostic cone biopsy, allowing treatment to be administered without delay. If there is debate about the depth of invasion based on the cervical biopsies, and if the clinical stage may be upstaged to stage Ia2 or Ib1, the patient should undergo cold knife conization. A large cervical biopsy showing invasion greater than 3 mm or two biopsy specimens separated by 7 mm showing invasive cervical carcinoma would allow no delay in therapy, and the patient could undergo a radical hysterectomy or radiation therapy.

**Abnormal Blood Vessels** Abnormal vessels may be looped, branching, or reticular. Abnormal looped vessels are the most common finding and arise from the punctuation and mosaic vessels present in cervical intraepithelial neoplasia (CIN). As the neoplastic growth process proceeds, the need for nutrition leads to proliferation of the blood vessels, and the punctate vessels at the surface produce double and triple loops. These surface tufting vessels then proliferate and push out over the surface of the epithelium in an erratic fashion. Some are straight, although most have a loop, a corkscrew, or a J-shaped pattern (Fig. 31.2). Abnormal branching vessels arise from the cervical stroma and are pushed to the surface as the underlying cancer invades and pushes upward. The normally branching cervical stromal vessels are best observed over nabothian cysts. In this area, the branches are generally at acute angles, with the caliber of vessels becoming smaller after branching, much like the arborization of a tree. The abnormal branching blood vessels seen with cancer tend to form obtuse or right angles, with the caliber sometimes enlarging after branching (Fig. 31.3). Sharp turns, dilations, and narrowings also mark the behavior of these vessels. The surface epithelium may be lost in these areas, leading to irregular surface contour and friability.

**Abnormal reticular vessels** represent the terminal capillaries of the cervical epithelium. Normal capillaries are best seen in a postmenopausal woman with atrophic

---

*Figure 31.2 Abnormal looped vessels in invasive cervical cancer. (From Berek JS, Hacker F. Practical gynecologic oncology. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)*

*Figure 31.3 Abnormal branching vessels in invasive cervical cancer. (From Berek JS, Hacker F. Practical gynecologic oncology. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)*
epithelium. When cancer involves this epithelium, the surface is again eroded, and the capillary network is exposed. These vessels are very fine, short, and composed of small commas without an organized pattern (Fig. 31.4). They are not specific to invasive cancer; atrophic cervicitis may also have this appearance.

Irregular Surface Contour Abnormal surface patterns are observed as the tumor growth proceeds. The surface epithelium ulcerates as the cells lose intercellular cohesiveness secondary to the loss of desmosomes. Irregular contour also may occur because of a papillary characteristic of the lesion (Fig. 31.5). This finding sometimes can be confused with an HPV papillary growth on the cervix; for that reason, biopsies should be performed on all papillary cervical growths.

Color Tone Color tone may change as a result of increasing vascularity, surface epithelial necrosis, and in some cases, production of keratin. The color tone is yellow-orange rather than the expected pink of intact squamous epithelium or the red of the endocervical epithelium.

Adenocarcinoma Adenocarcinoma of the cervix does not have a specific colposcopic appearance. All of the aforementioned blood vessels may be seen in these lesions as well. Because adenocarcinomas tend to develop within the endocervix, endocervical curettage is required as part of the colposcopic examination.

Clinical Staging

The current FIGO staging system is presented in Table 31.1 and Fig. 31.6. The staging procedures allowed by FIGO are listed in Table 31.2. When there is doubt concerning the stage to which a cancer should be allocated, the earlier stage should be selected. After a clinical stage is assigned and treatment has been initiated, the stage must not be changed because of subsequent findings by either extended clinical staging or surgical staging. The “upstaging” of patients during treatment will produce an erroneous improvement in the results of treatment of low-stage disease. Following is a breakdown of the incidence of cervical cancer by stage at diagnosis: 38%, stage I; 32%, stage II; 26%, stage III; and 4%, stage IV (2,9,12).

mixture of more than one cell type. By histologic examination alone, some of these tumors are indistinguishable from those arising elsewhere in the endometrium or predominantly of cells of the endocervical type with mucin production. The remaining tumors are populated by endometrioid cells, clear cells, intestinal cells, or a

Invasive adenocarcinoma may be pure (Fig. 31.7). Evaluation of the paraaortic lymph nodes with lymphangiography is associated with a false-positive rate of 20% to 40% and a false-negative rate of 10% to 20% (11,12,13,14,15 and 16). Early MRI data are comparable to CT scanning (17). When abnormalities are noted by these procedures, fine-needle aspiration (FNA) showing metastatic disease allows the radiation treatment field to be extended and obviates the need for exploratory laparotomy to determine the status of the lymph nodes.

Surgical Staging

The clinical staging system developed by FIGO is based on the belief that cervical cancer is a local disease and that, because most cases of cervical cancer occur in developing countries, surgical staging is not feasible with limited health care resources. The accuracy of clinical staging is somewhat limited, and surgical evaluation, which is not practical or feasible in many patients, is more accurate. Surgical staging has been advocated by providers in the United States who believe that this information details the extent of disease and affects treatment (18). Radiation oncologists may desire this information when designing treatment plans for patients. However, other providers believe that surgical staging should be limited to patients who are enrolled in a clinical trial or research protocol. These beliefs are based on the fact that there is no randomized control study demonstrating a survival benefit in patients who have had surgical staging. The specifics of surgical staging are discussed later in this chapter.

distinct cell borders indicative of squamous differentiation. (From Berek JS, Hacker F. Practical gynecologic oncology. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Figure 31.7 Invasive squamous cell carcinoma, large cell nonkeratinizing type. Tumor cells form irregular nests and have abundant eosinophilic cytoplasm and distinct cell borders indicative of squamous differentiation. (From Berek JS, Hacker F. Practical gynecologic oncology. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Pathology

Squamous Cell Carcinoma

Invasive squamous cell carcinoma is the most common variety of invasive cancer in the cervix. Histologically, there are large cell keratinizing, large cell nonkeratinizing, and small cell types (19). Large cell keratinizing tumors are made up of tumor cells forming irregular infiltrative nests with laminated keratin pearls in the center. Large cell nonkeratinizing carcinomas reveal individual cell keratinization but do not form keratin pearls (Fig. 31.7). The category of small cell carcinoma includes poorly differentiated squamous cell carcinoma and small cell anaplastic carcinoma. If possible, these two tumors should be differentiated. The former contains cells that have small- to medium-sized nuclei, open chromatin, small or large nucleoli, and more abundant cytoplasm than those of the latter. The designation of small cell anaplastic carcinoma should be reserved for lesions resembling oat cell carcinoma of the lung. It infiltrates diffusely and consists of tumor cells that have scanty cytoplasm, round to oval small nuclei, coarsely granular chromatin, and high mitotic activity. The nucleoli are absent or small. Immunohistochemistry or electron microscopy differentiates the small cell neuroendocrine tumors. Patients with the large cell type of carcinoma, with or without keratinization, have a better prognosis than those with the small cell variant. Furthermore, small cell anaplastic carcinomas behave more aggressively than poorly differentiated squamous carcinomas that contain small cells. Infiltration of parametrial tissue and pelvic lymph node metastasis affect the prognosis.

Adenocarcinoma

In recent years, there has been an increasing number of cervical adenocarcinomas affecting young women in their 20s and 30s. Adenocarcinoma in situ is believed to be the precursor of invasive adenocarcinoma, and it is not surprising that the two often coexist (20). In addition, squamous neoplasia, intraepithelial or invasive, also occurs in 30% to 50% of cervical adenocarcinomas. It should be noted that adenocarcinoma in situ appears to pose a diagnostic and therapeutic dilemma when compared with squamous cell carcinoma. The incidence of residual adenocarcinoma in situ after conization has led some investigators to recommend hysterectomy in patients with this preneoplastic lesion. However, in two recent reports, patients with negative cone biopsy margins were followed conservatively, with few requiring repeat surgical procedures (21,22). Because cervical adenocarcinoma in situ tends to affect women during their reproductive years, a thorough risk and benefit discussion should take place, and treatment should be individualized.

Adenocarcinoma may be detected by cervical sampling, but less reliably so than squamous carcinomas. A definitive diagnosis may require cervical conization. Invasive adenocarcinoma may be pure (Fig. 31.8) or mixed with squamous cell carcinoma—adenosquamous carcinoma. Within the category of pure adenocarcinoma, the tumors are quite heterogeneous (19), with a wide range of cell types, growth patterns, and differentiation. About 80% of cervical adenocarcinomas are made up predominantly of cells of the endocervical type with mucin production. The remaining tumors are populated by endometrioid cells, clear cells, intestinal cells, or a mixture of more than one cell type. By histologic examination alone, some of these tumors are indistinguishable from those arising elsewhere in the endometrium or ovary.

Table 31.2. Staging Procedures
Within each tumor type, the growth patterns and nuclear abnormalities vary according to the degree of differentiation. In well-differentiated tumors, tall columnar cells line the well-formed branching glands and papillary structures, whereas pleomorphic cells tend to form irregular nests and solid sheets in poorly differentiated neoplasms. The latter may require mucicarmine and periodic acid–Schiff (PAS) staining to confirm their glandular differentiation.

There are several special variants of adenocarcinoma. Minimal deviation adenocarcinoma (adenoma malignum) is an extremely well-differentiated form of adenocarcinoma in which the branching glandular pattern strongly simulates that of the normal endocervical glands. In addition, the lining cells have abundant mucinous cytoplasm and uniform nuclei. Because of this, the tumor may not be recognized as malignant in small biopsy specimens, thereby causing considerable delay in diagnosis. Earlier studies reported a dismal outcome for women with this tumor, but more recent studies have found a favorable prognosis if the disease is detected early. Although rare, similar tumors have also been reported in association with endometrioid, clear, and mesonephric cell types.

An entity described as villoglandular papillary adenocarcinoma also deserves special attention. It primarily affects young women, some of whom are pregnant or users of oral contraceptives. Histologically, the tumors have smooth, well-defined borders, and are either in situ or superficially invasive. The follow-up information is encouraging; however, none of these tumors has recurred after cervical conization or hysterectomy. Among women undergoing pelvic nodal dissection, no metastases have been detected. This tumor appears to have limited risk for spread beyond the uterus.

In mature adenosquamous carcinomas, the glandular and squamous carcinomas are readily identified on routine histologic evaluation and do not cause diagnostic problems. In poorly differentiated or immature adenosquamous carcinomas, however, glandular differentiation can be appreciated only with special stains, such as mucicarmine and PAS. In one study, 30% of squamous cell carcinomas demonstrated mucin secretion when stained with mucicarmine. These squamous cell carcinomas with mucin secretion have a higher incidence of pelvic lymph node metastases than squamous cell carcinomas without mucin secretion and are similar to the signet-ring variant of adenosquamous carcinoma.

Glassy cell carcinoma has been recognized as a poorly differentiated form of adenosquamous carcinoma. Individual cells have abundant eosinophilic, granular, ground-glass cytoplasm, large round to oval nuclei, and prominent nucleoli. The stroma is infiltrated by numerous lymphocytes, plasma cells, and eosinophils. About half of these tumors contain glandular structures or stain positive for mucin. The poor diagnosis of this tumor is linked to understaging and resistance to radiotherapy.

Other variants of adenosquamous carcinoma include adenoid basal carcinoma and adenoid cystic carcinoma. Adenoid basal carcinoma simulates the basal cell carcinoma of the skin. Nest of basaloid cells extend from the surface epithelium deep into the underlying tissue. Cells at the periphery of tumor nests form a “toadstool” arrangement, the so-called peripheral palisading. An “adenoid” pattern occasionally develops, with “hollowed-out” nests of cells. Mitoses are rare, and the tumor often extends deep into the cervical stroma.

Adenoid cystic carcinoma of the cervix behaves much like such lesions elsewhere in the body. The tumors tend to invade into the adjacent tissues and metastasize late, often 8 to 10 years after the primary tumor has been removed. Like other adenoid cystic tumors, they may metastasize directly to the lung. The pattern simulates that of the adenoid basal tumor, but there is a cystic component, and the glands of the cervix are involved. Mitoses may be seen but are not numerous.

Sarcoma

The most important sarcoma of the cervix is the embryonal rhabdomyosarcoma, which occurs in children and young adults. The tumor has grapelike polyoid nodules—the botryoid sarcoma—and the diagnosis depends on the recognition of rhabdomyoblasts. Leimyosarcomas and mixed mesodermal tumors involving the cervix may be primary but are more likely to be secondary to uterine tumors. Cervical adenosarcoma has been described as a low-grade tumor with a good prognosis.

If recurrence develops, it is generally a central recurrence that may be treated with resection and hormonal therapy.

Malignant Melanoma

On rare occasions, melanosis has been seen in the cervix. Thus, malignant melanoma may arise de novo in this area. Histopathologically, it simulates melanoma elsewhere, and the prognosis depends on the depth of invasion into the cervical stroma.

Metastatic Cancer

The cervix is commonly involved in cancer of the endometrium and vagina. The latter is rare, and most lesions that involve the cervix and vagina are designated cervical primaries. Consequently, the clinical classification is that of cervical neoplasia extending to the vagina, rather than vice versa. Endometrial cancer may extend into the cervix by three modes: direct extension from the endometrium, submucosal involvement by lymph vascular extension, and multifocal disease. The latter is most unusual, but occasionally a focus of adenocarcinoma may be seen in the cervix, separate from the endometrium. This lesion should not be diagnosed as metastasis but rather as multifocal disease. Malignancies involving the peritoneal cavity (e.g., ovarian cancer) may be found in the cul-de-sac and extend directly into the vagina and cervix. Carcinomas of the urinary bladder and colon occasionally extend into the cervix. Cervical involvement by lymphoma, leukemia, and carcinoma of the breast, stomach, and kidney is usually part of the systemic spread. However, an isolated metastasis to the cervix may be the first sign of a primary tumor elsewhere in the body.

Neuroendocrine Carcinoma

The classification of neuroendocrine cervical carcinoma includes four histologic subtypes: small cell, large cell, classical carcinoid, and atypical carcinoid. Neuroendocrine tumors of the cervix are rare, and treatment regimens have been based on small case series of patients. Small cell (neuroendocrine type) carcinoma of the cervix is aggressive in nature and is similar to cancer arising from the bronchus. At the time of diagnosis, it is usually disseminated, with bone, brain, liver, and bone marrow being the most common sites of metastases. In one study, 11 patients with what was apparent disease confined to the cervix and were found to have a high rate of lymph node metastasis. Pathologically, the diagnosis is aided by the finding of neuroendocrine granules on electron microscopy as well as by immunoperoxidase studies that are positive for a variety of neuroendocrine proteins such as calcitonin, insulin, glucagon, somatostatin, gastrin, and adrenocorticotropic hormone (ACTH). In addition to the traditional staging for cancer of the cervix, these patients should undergo bone, liver, and brain scanning as well as bone marrow aspiration and biopsy. Therapy generally consists of surgery, chemotherapy, and radiation. Patients with early-stage disease have a chance of distant metastases, and it has been recommended that patients should have multimodal therapy. The main active chemotherapeutic agent is etoposide. The hallmark of neuroendocrine tumors is their aggressive malignant behavior with the propensity to metastasize.

Patterns of Spread
Cancer of the cervix spreads by (a) direct invasion into the cervical stroma, corpus, vagina, and parametrium; (b) lymphatic metastasis; (c) blood-borne metastasis; and (d) intraperitoneal implantation. The incidence of pelvic and paraaortic nodal metastasis is shown in Table 31.3.

**Treatment**

The treatment of cervical cancer is similar to the treatment of any other type of malignancy; that is, both the primary lesion and potential sites of spread should be treated. The therapeutic modalities for achieving this goal include primary treatment with surgery, radiotherapy, or chemoradiation. Whereas radiation therapy can be used in all stages of disease, surgery alone is limited to patients with stage I and IIa disease. The 5-year survival rate for stage I cancer of the cervix is about 85% with either radiation therapy or radical hysterectomy. A recent study using the National Cancer Institute's Surveillance Epidemiology and End Results data showed by an intent-to-treat analysis that patients who were in the surgery arm had an improved survival when compared with patients in the intent-to-treat radiation arm (34).

In general, optimal therapy would consist of radiation or surgery to limit the increased morbidity when the two treatment modalities are combined. There have recently been great strides in the treatment of cervical carcinoma, including adjuvant radiation and chemoradiation in patients discovered to have high-risk cervical carcinoma after radical hysterectomy and in patients with locally advanced cervical carcinoma. The Gynecologic Oncology Group (GOG) released results from five randomized control trials evaluating radiation therapy and chemoradiation for high-risk early cervical carcinoma and advanced cervical carcinoma (discussed later).

**Surgery**

There are advantages to the use of surgery instead of radiotherapy, particularly in younger women for whom conservation of the ovaries is important. Chronic bladder and bowel problems that require medical or surgical intervention occur in up to 8% of patients undergoing radiation therapy (35). Such problems are difficult to treat because they result from fibrosis and decreased vascularity. This is in contrast to surgical injuries, which in general are easily repaired and without long-term complications. Sexual dysfunction after radiation therapy is more likely to occur because of vaginal shortening, fibrosis, and atrophy of the epithelium. The surgical procedure shortens the vagina, but gradual lengthening can be brought about by sexual activity. The epithelium does not become atrophic because it responds either to the patient's endogenous estrogen or to exogenous estrogens if the patient is postmenopausal.

In general, radical hysterectomy is reserved for women who are in good physical condition. Chronologic age should not be a deterrent. With improvements in anesthesia, elderly patients withstand radical surgery almost as well as their younger counterparts (36). Generally, it is prudent not to operate on lesions that are larger than 4 cm in diameter because these patients will require postoperative radiation therapy. When selected in this manner, the urinary fistula rate is less than 2% (37), and the operative mortality rate is less than 1% (38). An advantage of radiotherapy is its applicability to all stages and to most patients regardless of their age, height, weight, and medical condition. A summary of the surgical management of early cervical cancer is presented in Table 31.4.

### Table 31.4. Surgical Management of Early Invasive Cancer of the Cervix

**Radical Hysterectomy and Pelvic Node Dissection**

The radical hysterectomy performed most often in the United States is that described by Meigs (39) in 1944. The operation includes pelvic lymph node dissection along with removal of most of the uterosacral and cardinal ligaments and the upper one third of the vagina. This operation has been referred to as the type III radical hysterectomy (40).

The hysterectomy described by Wertheim is less extensive than a radical hysterectomy and removes the medial half of the cardinal and uterosacral ligaments (40). This procedure is often referred to as the modified radical or type II hysterectomy. Wertheim's original operation did not include pelvic lymph node dissection but instead included selective removal of enlarged lymph nodes.

Radical hysterectomies can be further classified as extended radical hysterectomy (type IV). In the type IV operation, the periureteral tissue, superior vesicle artery, and up to three fourths of the vagina are removed (40). In the type V operation, portions of the distal ureter and bladder are resected. This procedure is rarely performed because radiotherapy should be used when such extensive disease is encountered (40).

The abdomen is opened through either a midline incision or a low transverse incision after the methods of Maylard or Cherney. The low transverse incision requires division of the rectus muscles and provides excellent exposure of the lateral pelvis. It allows adequate pelvic node dissection and wide resection of the primary tumor. After the abdomen is entered, the peritoneal cavity is explored to exclude metastatic disease. The stomach is palpated to ensure that it has been decompressed to facilitate packing of the intestines. The liver is palpated, and the omentum is inspected for metastases. Both kidneys are palpated to ensure their proper placement and lack of congenital and other abnormalities. The paraaortic nodes are palpated transperitoneally.

During exploration of the pelvis, the fallopian tubes and ovaries are inspected for any abnormalities. In patients younger than 40 years of age, the ovaries are generally conserved. The peritoneum of the vesicouterine fold and the rectouterine pouch should be inspected for signs of tumor extension or implantation. The cervix is then palpated between the thumb anteriorly and the fingers posteriorly to determine its extent, and the cardinal ligaments are palpated for evidence of lateral tumor extension or nodularity.

**Paraaortic Lymph Node Evaluation** If the patient has no evidence of disease extending beyond the cervix or vaginal fornix (i.e., surgical stage Ib or IIa), the...
The cardinal ligament anteriorly
The sacrum posteriorly
The obliterated umbilical artery running along the bladder medially

**Development of Pelvic Spaces** The pelvic spaces are developed by sharp and blunt dissection (Fig. 31.9). The paravesical space is bordered by the following structures:

1. The obliterated umbilical artery running along the bladder medially
2. The obturator internus muscle along the pelvic sidewall laterally
3. The cardinal ligament posteriorly
4. The pubic symphysis anteriorly

The attachments of the vagina to the tendinous arch form the floor of the paravesical space.

The pararectal space is bordered by the following structures:

1. The rectum medially
2. The cardinal ligament anteriorly
3. The hypogastric artery laterally
4. The sacrum posteriorly

The coccygeus (levator ani) muscle forms the floor of the pararectal space. The development of these spaces before pelvic lymphadenectomy will aid in identification and dissection of the pelvic lymph nodes as well as dissection of the ureter as it passes into the vesicouterine ligament tunnel.

**Pelvic Lymphadenectomy** Pelvic lymphadenectomy can proceed after lymph node evaluation or it can be deferred until the hysterectomy has been completed, depending on the preference of the surgeon. The pelvic lymph node dissection is begun by opening the round ligaments at the pelvic sidewall and developing the paravesical and pararectal spaces. The ureter is elevated on the medial flap by a Deaver retractor to expose the common iliac artery. The common iliac and external iliac nodes are dissected, with care taken to avoid injuring the genitofemoral nerve, which lies laterally on the psoas muscle. At the bifurcation of the common iliac artery, the external iliac node chain is divided into lateral and medial portions.

The lateral chain is stripped free from the artery to the circumflex iliac vein distally. A hemaclip is placed across the distal portion of the lymph node chain to reduce the incidence of lymphocyst formation. The medial chain is then dissected. The obturator lymph nodes are dissected next; for this procedure, the lymph nodes are grasped just under the external iliac vein, and traction is applied medially. Although most patients have both the obturator artery and vein dorsal to the obturator nerve, 10% have an aberrant vein arising from the external iliac vein. The node chain is separated from the nerve and vessels and clipped caudally. They are dissected cephalad to the hypogastric artery. The cephalad portion of the obturator space should be entered lateral to the external iliac artery and medial to the psoas muscle, where the remainder of the obturator node tissue can be dissected as far cephalad as the common iliac artery. In general, drainage of the pelvic and paraaortic lymph node beds is not performed because of the increase in complications in patients in whom drains have been used (Fig. 31.9).

**Dissection of the Bladder** A critical step is the dissection of the bladder from the anterior part of the cervix and vagina. Occasionally, tumor extension into the base of the bladder (which cannot be detected with cystoscopy) precludes adequate mobilization of the bladder flap, leading to the abandonment of the operation. Therefore, this portion of the operation should be undertaken early in the procedure. The dissection should be performed in a manner to mobilize the bladder off of the upper third of the vagina in order to remove the tumor safely and with adequate margins.

**Dissection of the Uterine Artery** The superior vesicle artery is dissected away from the cardinal ligament at a point near the uterine artery. The uterine artery, which usually arises from the superior vesicle artery, is thus isolated and divided, and the vesicle arteries are preserved. The uterine vessels are then brought over the ureter by application of gentle traction. Occasionally, the uterine vein passes under the ureter.

**Dissection of the Ureter** The ureter is dissected free from its medial peritoneal flap at the level of the uterosacral ligament. As the ureter passes near the uterine artery, there is a consistent branch from the uterine artery to the ureter. This branch is sacrificed in the standard radical (type III) hysterectomy but preserved in the modified radical (type II) hysterectomy. Dissection of the ureter from the vesicouterine ligament (ureteral tunnel) now may be accomplished. If the patient has a deep pelvis, ligation of the uterosacral and cardinal ligaments may be undertaken first to bring the ureteral tunnel dissection closer to the operator. The roof of the ureteral tunnel is the anterior vesicouterine ligament. It should be ligated and divided to expose the posterior ligament. This ligament is also divided in the radical (type III) hysterectomy but conserved in the modified radical (type II) hysterectomy (Fig. 31.10).

**Figure 31.10** Radical hysterectomy. Uterine artery is ligated, ureter is dissected, and sites for division of the vesicouterine and uterosacral ligaments are shown.
**Posterior Dissection** The peritoneum across the cul-de-sac is incised, exposing the uterosacral ligaments. The rectum is rolled free from the uterosacral ligaments, and these ligaments are divided midway to the sacrum in a radical (type III) hysterectomy and near the rectum in the modified radical (type II) operation. This allows the operator to develop the cardinal ligament separate from the rectum. A surgical clamp is placed on the cardinal ligament at the lateral pelvic sidewall in a radical hysterectomy and at the level of the ureteral bed in the modified radical procedure. A clamp is placed on the specimen side to maintain traction and is left on to ensure that the full cardinal ligament is excised with the specimen. A right-angled clamp then is placed caudad to this clamp across the paravaginal tissues. A second paravaginal clamp is usually needed to reach the vagina.

The vagina is entered anteriorly, and the upper one third of the vagina is removed with the specimen. More vaginal epithelium can be excised if necessary, depending on the previous colposcopic findings. The vaginal edge may be sutured in a hemostatic fashion and left open with a drain from the pelvic space or closed with a suction drain placed percutaneously. The ureteral fistula and pelvic lymphocyst rates from these two techniques are similar.

**Modified Radical Hysterectomy**

The modified radical hysterectomy differs from the radical hysterectomy in the following ways:

1. The uterine artery is transected at the level of the ureter, thus preserving the ureteral branch to the ureter.
2. The cardinal ligament is not divided near the sidewall but instead is divided at about its midportion near the ureteral dissection.
3. The anterior vesicouterine ligament is divided, but the posterior vesicouterine ligament is conserved.

A smaller margin of vagina is removed.

**Complications of Radical Hysterectomy**

**Acute Complications** The acute complications of radical hysterectomy include the following (42):

- Blood loss (average, 0.8 l)
- Ureterovaginal fistula (1% to 2%)
- Vesicovaginal fistula (1%)
- Pulmonary embolus (1% to 2%)
- Small bowel obstruction (1%)
- Febrile morbidity (25% to 50%)

Febrile morbidity is most often pulmonary (10%) and frequently is seen with pelvic cellulitis (7%) and urinary tract infection (6%). Wound infection, pelvic abscess, and phlebitis all occur in fewer than 5% of patients (43).

**Subacute Complications** The subacute effects of radical hysterectomy are postoperative bladder dysfunction and lymphocyst formation. For the first few days after radical hysterectomy, bladder volume is decreased, and filling pressure is increased. The sensitivity to filling is diminished, and the patient is unable to initiate voiding. The cause of this dysfunction is unclear. It is important to maintain adequate bladder drainage during this time to prevent overdistention. Bladder drainage is accomplished with a suprapubic catheter. It is more comfortable for the patient and allows the physician to perform cystometrography and determine residual urine volume without the need for frequent catheterization. In addition, the patient is able to accomplish trial voiding at home by clamping the catheter, voiding, and releasing to check the residual urine level. Cystometrography may be performed 3 to 4 weeks after surgery. For use of the catheter to be discontinued, the patient must be able to sense the fullness of the bladder, initiate voiding, and void with a residual urine level of less than 75 mL. Otherwise, voiding trials should continue at home until these criteria can be fulfilled.

Lymphocyst formation occurs in fewer than 5% of patients (43), and the cause is uncertain. Adequate drainage of the pelvis after radical hysterectomy may be an important step in prevention. However, routine placement of retroperitoneal drains has not been shown to reduce this morbidity (41). Ureteral obstruction and partial venous obstruction and thrombosis may occur from lymphocyst formation. Simple aspiration of the lymphocyst is generally not curative, but percutaneous catheters with chronic drainage may allow healing. If this treatment is unsuccessful, operative intervention with excision of a portion of the lymphocyst wall and placement of either large bowel or omentum into the lymphocyst should be performed.

**Chronic Complications** The most common chronic effect of radical hysterectomy is bladder hypotonia or, in extreme instances, atony. This condition occurs in about 3% of patients, regardless of the method of bladder drainage used (44,45). It may be a result of bladder denervation and not simply a problem associated with bladder overdistention (46). Voiding every 4 to 6 hours, increasing intraabdominal pressure with Credé’s maneuver, and intermittent self-catheterization may be used to manage the hypotonic bladder.

Ureteral strictures are uncommon in the absence of postoperative radiation therapy, recurrent cancer, or lymphocyst formation (37). If the stricture is associated with lymphocyst formation, treatment of the lymphocyst usually alleviates the problem. Strictures that occur after radiation therapy should be managed with ureteral stenting. If a ureteral stricture is noted in the absence of radiotherapy or lymphocyst formation, recurrent carcinoma is the most common cause. A CT scan of the area of obstruction should be obtained and cytologic assessment by FNA cytology should be performed to exclude carcinoma if there is a target lesion. If the results of these tests are negative, a ureteral stent may be placed to relieve the stricture. Close observation for recurrent carcinoma is necessary, and the diagnosis of recurrence may ultimately require laparotomy.

**Surgical Treatment of Early-stage Cervical Cancer**

**Stage Ia Microinvasive Carcinoma** Until 1985, no FIGO recommendation existed concerning the size of lesion or the depth of invasion that should be considered microinvasive (stage Ia). This led to considerable confusion and controversy in the literature. Over the years, as many as 18 different definitions have been used to describe “microinvasion.” In 1974, the Society of Gynecologic Oncologists recommended a definition that is now accepted by FIGO: A microinvasive lesion is one in which neoplastic epithelium invades the stroma to a depth of more than 3 mm beneath the basement membrane and in which lymphatic or blood vascular involvement is not demonstrated. The purpose of defining microinvasion is to identify a group of patients who are not at risk for lymph node metastases or recurrence and who therefore may be treated with less than radical therapy.

Diagnosis must be determined on the basis of a cone biopsy of the cervix. The treatment decision rests with the gynecologist and should be determined based on a review of the conization specimen with the pathologist. It is important that the pathologic condition be described in terms of (a) depth of invasion, (b) width and breadth of the invasive area, and (c) presence or absence of lymph–vascular space invasion. These variables are used to determine how extensive the operation should be and whether the regional lymph nodes should be treated (41). Ureteral obstruction and partial venous obstruction and thrombosis may occur from lymphocyst formation. Simple aspiration of the lymphocyst is generally not curative, but percutaneous catheters with chronic drainage may allow healing. If this treatment is unsuccessful, operative intervention with excision of a portion of the lymphocyst wall and placement of either large bowel or omentum into the lymphocyst should be performed.

**Stage Ia1 E 3 mm Invasion** Lesions with invasion that is less than or equal to 3 mm deep have a less than 1% incidence of pelvic node metastases. Although this observation is controversial, it appears that the patients most at risk for nodal metastases or central pelvic recurrence are those with definitive evidence of tumor emboli in lymph vascular spaces (42,47). Therefore, patients with less than 3 mm invasion and no lymph–vascular space invasion may be treated with extracapsular hysterectomy without lymph node dissection. Therapeutic conization appears to be adequate therapy for these patients if childbearing capability is desired. Surgical margins must be free of disease. If there is lymph–vascular space invasion, an alternative is a pelvic node dissection with a type I (extracapsular) or I (modified radical) hysterectomy.

Treatment of microinvasive cervical adenocarcinoma has been complicated by a lack of agreement on approaches in the literature. Recent reports have shown that patients with stage Ia1 cervical adenocarcinoma may be treated in a fashion similar to patients with this stage and a squamous lesion. Some providers disagree with this interpretation because of the difficulty of establishing a pathologic diagnosis of microinvasion from a glandular lesion. Patients diagnosed with microinvasive

(From Berek JS, Hacker F. Practical gynecologic oncology. 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000, with permission.)
cervical adenocarcinoma should have expert pathologic assessment before considering treatment with extrafascial hysterectomy.

**Stage Ia2**

Lesions with invasion of 3 to 5 mm have a 3.8% incidence of pelvic node metastases (47,48 and 49); thus, pelvic node dissection is necessary for these lesions. The primary tumor may be treated with a modified radical hysterectomy (type II).

**Surgical Treatment of Stage Ib to Ia**

**Stage Ib and Ia Invasive Cancer**

Stage Ib lesions are subdivided into stage Ib1, which denotes lesions that are 4 cm or smaller in maximum diameter, and stage Ib2, which denotes lesions that are larger than 4 cm. Stage Ia is direct extension to the proximal vagina. Surgical therapy of stage Ib and Ia carcinoma of the cervix involves radical hysterectomy, pelvic lymphadenectomy, and paraaortic lymph node evaluation.

A comparison of radical hysterectomy with radiation has resulted in similar survival rates for the two treatment modalities. A randomized study comparing patients treated by radical hysterectomy or radiation therapy showed similar survival rates for both groups (50). Similar outcomes also were reported when patients were treated with radiation therapy or radical surgery (51). However, patients treated with type III radical hysterectomy who subsequently received postoperative radiation had a higher rate of intestinal and urinary morbidity. Therefore, many advocate using radiation and avoiding surgery in these patients because many will require adjuvant postoperative radiation. The results from the GOG showing that patients with stage Ib (≥4 cm) and Ia disease treated with concurrent chemoradiation had improved survival are presented below. Thus many would advocate that the treatment of choice in patients with stage Ib and Ia disease who have a primary lesion that is larger than 5 cm should be treated with chemoradiation.

**Prognostic Variables for Early-stage Cervical Cancer**

The survival of patients with early-stage cervical cancer after radical hysterectomy and pelvic lymphadenectomy depends on several factors (42,51,52,53,54,55,56,57,58,59,60,61,62,63,64 and 65):

1. Status of the lymph nodes
2. Size of the tumor
3. Involvement of parametrial tissue
4. Depth of invasion
5. Presence or absence of lymph-vascular space invasion

**Lymph Nodes**

The most dependent variable associated with survival is the status of the lymph nodes. Patients with negative nodes have an 85% to 90% 5-year survival rate (44,66), whereas the survival rate for those with positive nodes ranges from 20% to 74%, depending on the number of nodes involved and the location and size of the metastases (60,61 and 62,66,67,68 and 69).

Data on lymph node status can be summarized as follows:

1. When the common iliac lymph nodes are positive, the 5-year survival rate is about 25%, compared with about 65% when only the pelvic lymph nodes are involved (70,71 and 72).
2. Bilateral positive pelvic lymph nodes portend a less favorable prognosis (22% to 40% survival rate) than unilateral positive pelvic nodes (59% to 70%) (70,71).
3. The presence of more than three positive pelvic lymph nodes is accompanied by a 68% recurrence rate, compared with 30% to 50% when three or fewer lymph nodes are positive (60,67).
4. Patients in whom tumor emboli are the only findings in the positive pelvic lymph node have an 82.5% 5-year survival rate, whereas the survival rate with micrometastases (73,74,75 and 76).

**Lesion Size**

Lesion size is an independent predictor of survival. Patients with lesions smaller than 2 cm have a survival rate of about 90%, and patients with lesions larger than 2 cm have a 80% survival rate (54). When the primary tumor is larger than 4 cm, the survival rate drops to 40% (52,63). An analysis of a GOG prospective study of 310 women showed a 94.6% 3-year disease-free survival rate for patients with occult lesions, 85.5% for those with tumors smaller than 3 cm, and 68.4% for patients with tumors larger than 3 cm (64).

**Depth of Invasion**

Patients in whom depth of invasion is less than 1 cm have a 5-year survival rate of about 90%, but the survival rate falls to 63% to 78% if the depth of invasion is more than 1 cm (42,64,68). Patients with spread to the parametrium have a 5-year survival rate of 69%, compared with 95% when the parametrium is negative. When the parametrium is involved and pelvic lymph nodes are also positive, the 5-year survival rate falls to 39% to 42% (55,69).

**Lymph–Vascular Space Involvement**

The significance of involvement of lymph–vascular space involvement is somewhat controversial. Several reports have shown a 50% to 70% 5-year survival rate when lymph–vascular space invasion is present and a 90% 5-year survival rate in its absence (42,64,58,72,73,74,75 and 76). Others have found no significant difference in survival if the study is controlled for other risk factors (63,64,77,78 and 79). Lymph–vascular space involvement may be a predictor of lymph node metastasis and not an independent predictor of survival.

**Postoperative Radiation**

In an effort to improve survival rates, postoperative radiotherapy has been recommended for patients with high-risk factors such as metastasis to pelvic lymph nodes (42,53,66,72), invasion of paracervical tissue (55,56), deep cervical invasion (68), or positive surgical margins (67,81). Although most authors agree that postoperative radiotherapy is necessary in the presence of positive surgical margins, the use of radiation in patients with other high-risk factors is controversial. Increasing evidence supports the use of adjuvant radiation, however. Particularly controversial but best studied is the use of radiation in the presence of positive pelvic lymph nodes. The rationale for treatment is the knowledge that radiotherapy can sterilize cancer in pelvic lymph nodes and that pelvic node dissection does not remove all of the nodal and lymphatic tissue. The hesitancy to recommend postoperative radiotherapy relates to the significant rate of postradiotherapy bowel and urinary tract complications (82). Most of the data currently available are retrospective. However, the GOG has recently completed a randomized study comparing radiation with no further treatment for patients at high risk for negative pelvic nodes (83).

Based on retrospective studies, it appears that postoperative radiation therapy for positive pelvic nodes can decrease pelvic recurrence but does not improve 5-year actuarial survival rates. One multinstitutional study showed no difference in survival in patients with three or fewer positive pelvic nodes (59% versus 60%) (68).

However, there seemed to be a benefit when radiotherapy was given to those with more than three positive nodes.

In a study of 60 pairs of irradiated and nonirradiated women matched for age, lesion size, and number and location of positive nodes after radical hysterectomy (84), no significant difference was found in projected 5-year survival rates (72% for surgery alone, 64% for surgery plus radiation). The proportion of recurrences confined to the pelvis was 67% in patients treated with surgery only and 27% in patients treated with postoperative radiation (p = 0.03). In a Cox regression analysis of 320 women who underwent radical hysterectomy, 72 of whom received postoperative radiation (81), there was a significant decrease in pelvic recurrence but no survival benefit. A multinstitutional retrospective study was performed in 185 women with positive pelvic nodes after radical hysterectomy, 103 of whom received postoperative radiotherapy (63). Multivariate analysis disclosed that radiotherapy was not an independent predictor of survival, whereas age, lesion diameter, and number of positive nodes were found to influence survival. These authors concluded that additional treatment is needed to improve survival rates. Because survival is limited by distant site recurrence, the addition of chemotherapy to postoperative radiotherapy has been proposed. A 75% disease-free survival rate was reported at 3 years in 40 high-risk patients given cisplatin, vinblastine, and bleomycin after radical hysterectomy, and a 46% disease-free survival rate was found in 79 comparable patients who refused treatment (85). Only 4 (11.8%) of 34 patients with positive pelvic nodes had recurrences, whereas disease recurred in 8 (33%) of 24 untreated patients with positive nodes. An 82% rate of disease-free survival was reported at 2 years among 32 patients who were treated with postoperative radiation therapy plus cisplatin and bleomycin (86).

The location of pelvic node metastases is apparently relevant to postirradiation recurrence rates. When common iliac lymph nodes are involved, the survival rate drops to 20% (73). As the number of positive pelvic nodes increases, the percentage of positive common iliac and paraaortic nodes increases (73). When pelvic lymph nodes are negative, 6.3% with one positive pelvic node, 21.4% with two or three positive nodes, and 73.3% with four or more positive nodes. This information has been used to recommend extended-field radiotherapy to patients with positive pelvic lymph nodes in an attempt to treat undetected extrapelvic nodal disease (73). A 3-year disease-free survival rate of 85% occurred in patients with positive pelvic nodes and a survival rate of 51% in patients with positive common
Surgical staging procedures designed to discover the presence of positive nodes have been devised. Transperitoneal exploration was first used, but it was associated with a 16% to 33% mortality rate from radiotherapy-induced bowel complications and a 5-year survival rate of only 9% to 12% (92,93). The radiotherapy dose to the paraaortic chain was 5,500 to 6,000 cGy, which is now known to be excessive. Postoperative adhesions entrap the intestine in the radiotherapy field; therefore, the bowel receives the full dose of radiation. In the absence of postsurgical adhesions, the small bowel would move in and out of the radiotherapy field and receive a lesser dose. To avoid these postsurgical adhesions, extraperitoneal dissection of the paraaortic nodes is now recommended, and the radiation dose should be reduced to 5,000 cGy or less (94,95). When such an approach is used, postradiotherapy bowel complications occur in fewer than 5% of patients (96,97), and the 5-year survival rate is 15% to 28% in patients with positive paraaortic nodes (98,97). Survival appears to be related to the amount of disease in the paraaortic nodes and to the size of the primary tumor. In patients whose metastases to the paraaortic lymph nodes are microscopic and whose central tumor has not extended to the pelvic sidewall, the 5-year survival rate improves to 20% to 50% (98,99). Surgical staging techniques have improved to include laparoscopic assessment of the paraaortic and pelvic lymph nodes. Studies have demonstrated benefit from surgical staging with improved survival and changes in treatment plans of 40% of patients (95,96).

Surgical “Staging” before Radiation

Surgical staging procedures designed to discover the presence of positive nodes have been devised. Transperitoneal exploration was first used, but it was associated with a 16% to 33% mortality rate from radiotherapy-induced bowel complications and a 5-year survival rate of only 9% to 12% (92,93). The radiotherapy dose to the paraaortic chain was 5,500 to 6,000 cGy, which is now known to be excessive. Postoperative adhesions entrap the intestine in the radiotherapy field; therefore, the bowel receives the full dose of radiation. In the absence of postsurgical adhesions, the small bowel would move in and out of the radiotherapy field and receive a lesser dose. To avoid these postsurgical adhesions, extraperitoneal dissection of the paraaortic nodes is now recommended, and the radiation dose should be reduced to 5,000 cGy or less (94,95). When such an approach is used, postradiotherapy bowel complications occur in fewer than 5% of patients (96,97), and the 5-year survival rate is 15% to 28% in patients with positive paraaortic nodes (98,97). Survival appears to be related to the amount of disease in the paraaortic nodes and to the size of the primary tumor. In patients whose metastases to the paraaortic lymph nodes are microscopic and whose central tumor has not extended to the pelvic sidewall, the 5-year survival rate improves to 20% to 50% (98,99). Surgical staging techniques have improved to include laparoscopic assessment of the paraaortic and pelvic lymph nodes. Studies have demonstrated benefit from surgical staging with improved survival and changes in treatment plans of 40% of patients (95,96).

Supraclavicular Lymph Node Biopsy

Although not standard practice, the performance of a supraclavicular lymph node biopsy has been advocated in patients with positive paraaortic lymph nodes before the initiation of extended-field irradiation as well as in patients with a central recurrence before exploration for possible exenteration. The incidence of metastatic disease in the supraclavicular lymph nodes in patients with positive paraaortic lymph nodes is 5% to 30% (100). FNA cytologic assessment can obviate the need for an excisional biopsy and thus should be performed if any enlarged nodes are present. If the scalene lymph nodes are found to be positive, the disease is incurable,
Complications during Brachytherapy

Perforation of the uterus may occur at the time of insertion of the uterine tandem. This is a problem particularly for elderly patients and those who have had a previous diagnostic conization procedure. When perforation is recognized, the tandem should be removed, and the patient should be observed for bleeding or signs of peritonitis. Survival may be decreased in patients who have had uterine perforation (101), possibly because these patients have more extensive uterine disease, which predisposes them to perforation. Fever may occur after insertion of the uterine tandem and ovoids. Fever most often results from infection of the necrotic tumor and occurs 2 to 6 hours after the insertion of the interstitial devices. If uterine perforation has been excluded by ultrasonography, intravenous broad-spectrum antibiotic coverage, usually with a cephalosporin, should be administered. If the fever does not decrease promptly or if the temperature is higher than 38.5°C, an aminoglycoside and a β-lactamase-resistant β-lactam antibiotic should be administered. If fever persists or if the patient shows signs of septic shock or peritonitis, the intracavitary system must be removed. Antibiotics are continued until the patient has recovered, and the intracavitary application is delayed for 1 to 2 weeks.

Acute Morbidity

The acute effects of radiotherapy occur after 2,000 to 3,000 cGy and are caused by ionizing radiation on the epithelium of the intestine and bladder. Symptoms include diarrhea, abdominal cramps, nausea, frequent urination, and occasionally bleeding from the bladder or bowel mucosa. The bowel symptoms can be treated with a low-gluten, low-lactose, and low-protein diet. Antidiarrheal and antispasmodic agents also may help. The bladder symptoms may be treated with antispasmodic medication. Severe symptoms may require a week of rest from radiotherapy.

Chronic Morbidity

The chronic effects of radiotherapy result from the induction of vasculitis and fibrosis, and they are more serious than the acute effects. These complications occur several months to several years after radiotherapy has been completed. The bowel and bladder fistula rate after pelvic radiotherapy for cervical cancer is 1.4% to 5.3% (35,37). Other serious toxicity (e.g., bowel bleeding, stricture, stenosis, or obstruction) occurs in 6.4% to 8.1% of patients (35,37).

Proctosigmoiditis

Bleeding from proctosigmoiditis should be treated with a low-residue diet, antidiarrheal medications, and steroid enemas. In extreme cases, a colostomy may be required to rest the bowel completely, and occasionally resection of the rectosigmoid must be performed.

Rectovaginal Fistula

Rectovaginal fistulas or rectal strictures occur in fewer than 2% of patients. The successful closure of fistulas with bulbocavernosus flaps has been reported (102), as has a technique of sigmoid colon transposition to repair rectosigmoid fistulas or rectal strictures (103). Occasionally, resection with anastomosis is feasible. Diversion resulting in colostomy may be the optimal therapy in patients who have poor vascular supply to the pelvis and a history of anastomotic leak or breakdown from prior repairs.

Small Bowel Complications

Patients with previous abdominal surgery are more likely to have pelvic adhesions and thus sustain more radiotherapy complications in the small bowel. The terminal ileum may sustain chronic damage because of its relatively fixed position at the apex. The patient typically has a long history of crampy abdominal pain, intestinal restlessness, and distention characteristic of partial small bowel obstruction. Often, low-grade fever and anemia accompany the symptoms. Patients who have no evidence of disease should be treated aggressively with total parenteral nutrition, nasogastric suction, and early operation after the anaerobic nutritional intake has been attained. The type of procedure performed depends on individual circumstances (104). Small bowel fistulas that occur after radiotherapy rarely close spontaneously while total parenteral nutrition is maintained. Recurrent cancer should be excluded; then aggressive fluid replacement, nasogastric suction, and wound care should be instituted. Fistulography and a barium enema should be performed to exclude a combined large and small bowel fistula. The fistula-containing loop of bowel may be either resected or isolated and left in situ. In the latter case, the fistula will act as its own mucous fistula.

Urinary Tract

Chronic urinary tract complications occur in 1% to 5% of patients and depend on the dose of radiation to the base of the bladder. Vesicovaginal fistulas are the most common complication and usually require supravesicular urinary diversion. Occasionally, a small fistula can be repaired with either a bulbocavernous flap or an omental pedicle. Ureteral strictures are usually a sign of recurrent cancer, and an FNA cytologic sample should be obtained at the site of the obstruction under CT scan control. If the findings are negative, the patient should undergo exploratory surgery to determine the status of the disease. If radiation fibrosis is the cause, ureterolysis may be possible, or indwelling ureteral stents may be passed through the open urinary bladder.

Treatment of Stage Ib to Iva

Traditional therapy for patients with stage Ib or greater cervical cancer was radiation therapy. In certain clinical situations, such as patients who have stage Iva disease and present with vesicovaginal or rectovaginal fistula, urinary or rectal diversion should be performed, followed by radiation therapy. Patients with stage Ib to Iva cervical carcinoma are considered candidates for palliative radiation therapy because cure is not attainable for these patients. Control of symptoms with the least morbidity is of concern for this patient population.

Primary pelvic radiotherapy fails to control the disease in 30% to 82% of patients with cervical carcinoma (2). About two thirds of these failures occur in the pelvis (105). A variety of agents have been used in an attempt to increase the effectiveness of radiation therapy in patients with large primary tumors. Hydroxyurea has produced some improvement in response rate and survival rates when compared with radiation therapy alone in a controlled series of patients (106,107). The use of 5-fluorouracil (5-FU) or hydroxyurea alone in the treatment of advanced cervical cancer has been reported to have some therapeutic advantage (108). Cisplatin has been shown to have cytotoxic activity against cervical carcinoma (109) and recently has been demonstrated to be a radiation sensitizer (110). It has produced some improvement in response and survival rates when used with radiation therapy for cervical cancer as compared with radiation therapy alone (110,111). The results of GOG studies presented later in this chapter demonstrate that combination chemoradiation is superior to radiation therapy.

Concurrent Chemoradiation

Radiation therapy has failed to achieve control of cancer in 20% to 65% of patients with advanced cervical cancer. Chemotherapy, despite its lack of success in treating patients with cervical cancer, has been studied as neoadjuvant treatment in combination with surgery. Concomitant chemoradiation with radiation has been studied extensively by GOG, and results of five randomized studies have been reported. The concept of chemoradiation enhances the benefits of regional therapy with radiation and the use of chemotherapy to sensitize cells to radiation therapy, thus improving locoregional control. These new results have changed the way cervical cancer is treated in many medical centers.

An intergroup trial involving the GOG, the Southwest Oncological Group, and the Radiation Therapy Oncology Group evaluated postoperative chemoradiation therapy in patients with stage Ia2, Ib, or Ila cervical cancer who were found to have positive pelvic lymph nodes, or parametrial extension, or positive vaginal margins at the completion of radical hysterectomy (88). A total of 243 patients were assessed in this trial, with 127 receiving chemoradiation (cisplatin, 5-FU, radiation therapy) and 116 receiving radiation alone. The results of this trial showed a statistically significant improvement in progression-free survival and overall survival at 43 months for the patients receiving concurrent chemoradiation. The 4-year survival rates for the patients receiving chemoradiation and radiation alone were 81% and 71%, respectively. The toxicity in the two groups was acceptable, with a higher rate of hematologic toxicity in the concurrent chemoradiation arm.

This study showed that in patients with these high-risk factors after radical hysterectomy for stage Ia2, Ib, and Ila disease, chemoradiation is the postoperative treatment of choice.

Concurrent chemoradiation was evaluated in patients with advanced cervical carcinoma. The GOG protocol 85 was a prospective study that enrolled patients with stage IIB to IVB disease and compared concurrent chemoradiation (112). There were 177 patients treated with cisplatin, 5-FU, and radiation. These patients were compared with the 191 patients treated with hydroxyurea and radiation. The median follow-up of patients who were alive at the time of the analysis was 8.7 years. Patients who received concurrent chemoradiation were treated with cisplatin and 5-FU and had a statistically significant improvement in progression-free interval (112). The hematologic toxicity between the two groups was similar. This study showed that cisplatin-based concurrent chemoradiation was a superior treatment when compared with hydroxyurea and concurrent radiation.

The GOG protocol 120 was initiated to evaluate patients with negative paraaortic and cervical carcinoma stage Ib to Iva and concurrent chemoradiation. The treatment arms in this study consisted of radiation plus weekly cisplatin, or cisplatin, 5-FU, and hydroxyurea, or hydroxyurea. There were 176 patients in the weekly cisplatin arm; 173 patients in the cisplatin, 5-FU, and hydroxyurea arm; and 177 patients in the hydroxyurea arm (113). The two treatment arms with cisplatin-based chemotherapy and radiation showed an improvement in progression-free interval and overall survival at a median follow-up of 35 months. The relative risks for progression of disease or death were 0.55 and 0.57, respectively, for patients treated with cisplatin-based chemotherapy and radiation, compared with the patients treated with hydroxyurea and radiation (114). This study confirmed the findings of GOG 85 and again suggested that cisplatin-based concurrent therapy is the standard of care for patients with advanced cervical carcinoma.
chemoradiation is the treatment of choice for patients with advanced-stage cervical cancer.

A third GOG trial evaluated patients with stage IIb to IVA cervical cancer. Of the patients enrolled in this study, 70% had stage IIb or IIIa disease (115). A total of 403 patients were enrolled and evaluated. The 5-year survival rates were 73% in patients treated with chemoradiation and 58% in patients treated with radiation therapy alone. The cumulative rates of disease-free survival at 5 years were 67% in patients treated with concurrent chemoradiation and 40% in patients treated with radiation therapy alone. Survival and progression-free intervals for patients receiving concurrent chemoradiation were significantly improved (115). The results of this study suggested that chemoradiation is the treatment for stage IIb to IVA disease and that those patients with stage IIb and IIIa disease also may benefit from chemoradiation. The role of extended-field radiation was evaluated in this trial, but its role in therapy for patients with no evidence of paraaortic metastasis still needs to be defined.

A GOG study of chemoradiation comparing concurrent cisplatin and radiation with radiation alone in patients with bulky IIb cervical cancer also included adjuvant hysterectomy after completion of the radiation (119). There were 168 patients assigned to the concurrent chemotherapy and radiation arm, and 186 patients treated with radiation alone. The median duration of follow-up was 36 months, with disease recurrence detected in 37% of the patients treated with radiation alone, compared with 21% who were treated with concurrent chemoradiation (114). The 3-year survival rates were 83% in the group who received concurrent chemoradiation and 74% in the group that received radiation alone (114). The study also included adjuvant hysterectomy after completion of radiation treatment. However, with the results of GOG 71 not showing an improvement in survival by using adjuvant hysterectomy, the authors concluded that adjuvant hysterectomy would not be part of their recommendations. This study supported the results of previous studies and showed that patients with bulky stage IIb and IIIa cervical cancer had survival rates superior to those in patients treated with concurrent chemoradiation. These two studies suggest that patients with bulky stage IIb and IIIa disease should have primary treatment consisting of chemoradiation, with the chemotherapy agent being weekly cisplatin.

Patient Evaluation and Follow-up after Therapy

Patients who receive radiotherapy should be closely monitored to assess their response. Tumors may be expected to regress for up to 3 months after radiotherapy. During the pelvic examination, progressive shrinkage of the cervix and possible stenosis of the cervical os and surrounding upper vagina should be noted. During rectovaginal examination, careful palpation of the uterosacral and cardinal ligaments for nodularity is most important. FNA cytologic assessment of suspicious areas should be performed to allow early diagnosis of persistent disease. In addition to the pelvic organs, the supraclavicular and inguinal lymph nodes should be carefully examined, and cervical or vaginal cytologic assessment should be performed every 3 months for 2 years and then every 6 months for the next 3 years. Endocervical curettage may be performed in patients with large central tumors.

An x-ray film of the chest may be obtained yearly in patients who have advanced disease. Metastasis to the lung has been reported in 1.5% of cases; solitary nodules are not unusual. If a chest x-ray shows a metastatic lesion, the patient may benefit from another persistent disease may yield some long-term survivors (116). Although intravenous pyelography (IVP) is not a part of routine postradiotherapy surveillance, it should be performed if a pelvic mass is detected or if urinary symptoms warrant it. The finding of ureteral obstruction after radiotherapy in the absence of a palpable mass may indicate unresectable pelvic sidewall disease, but this finding should be confirmed, usually by FNA cytologic assessment (117).

Patients who have had radical hysterectomy and who are at high risk for recurrence may benefit from early recognition of recurrence because they might be saved with radiation therapy. In these patients, a routine IVP to 12 months after surgery may be beneficial. After radical hysterectomy, about 80% of recurrences are detected within 2 years (116). The larger the primary lesion, the sooner the median time to recurrence (119).

Special Considerations

The incidence of adenocarcinoma of the cervix appears to be increasing relative to that of squamous cancers. Older reports indicated that 5% of all cervical cancers were adenocarcinomas (120), whereas newer reports show a proportion as high as 18.5% to 27% (121,122). The FIGO annual report indicates a poorer prognosis for adenocarcinoma than for squamous cell carcinoma in every stage. A Cox proportional hazard analysis of 203 women with adenocarcinoma and 756 women with squamous carcinoma supports these findings (122). This study showed 5-year survival rates of 90% versus 60%, 62% versus 47%, and 36% versus 8% for stages I, II, and III, respectively. Although some have attributed these rates to a relative resistance to radiation, they are more likely a reflection of the tendency of adenocarcinomas to grow endophytically and to be undetected until a large volume of tumor is present.

The clinical features of stage I adenocarcinomas have been well studied (121,123,124 and 125). These studies have identified size of tumor, depth of invasion, grade of tumor, and age of the patient as significant correlates of lymph node metastasis and survival. When matched with squamous carcinomas for lesion size, age, and depth of invasion, the incidence of lymph node metastases and the survival rate appear to be the same (123,124). Patients with stage I adenocarcinomas can be selected for treatment according to the same criteria as for those with squamous cancers (124).

The choice of treatment for bulky stage I and II tumors is controversial. Radiation alone has been advocated by some (126), but others support radiation plus chemotherapy. Radiation therapy is used to reduce the bulk of disease to stage IB or IIa, and the pelvic nodes are treated with radiation alone and an 83.8% survival rate for those who had radiation plus surgery. The central persistent disease rate was 8.3%, compared with 4% for those who had radiation plus surgery. In stage IIb disease, the 5-year survival rate was 41.9% for radiation alone and 53.7% for radiation plus extraphasic hysterectomy (129).

Patients with adenocarcinoma of the cervix have been reported to have a poorer prognosis than those with pure adenocarcinoma or squamous carcinoma (130). Whether this is true when corrected for size of lesion is controversial (123,124).

The association of adenocarcinoma with squamous intraepithelial neoplasia is well documented (131). A squamous intraepithelial lesion may be observed colposcopically and treated with outpatient therapy, and the coexistent adenocarcinoma in the canal may be overlooked. Performing endocervical curettage at colposcopy will help prevent such an occurrence.

Cervical Cancer during Pregnancy

A review of the literature concluded that the incidence of invasive cervical cancer associated with pregnancy was one in 2,200 (132). A Pap test should be performed on all pregnant patients at the initial prenatal visit, and any grossly suspicious lesions should be excised for biopsy. Diagnosis is often delayed during pregnancy because of the patient's fear of complications. If the results of the Pap tests are positive for malignant cells and invasive cancer cannot be diagnosed using colposcopy and biopsy, a diagnostic conization procedure may be necessary. Because conization subjects the mother and fetus to complications, it should be performed only in the second trimester and only in patients with colposcopy findings consistent with cancer and biopsy-proven microinvasive cervical cancer. Patients with stage I disease may benefit from chemoradiation. Close follow-up throughout pregnancy may allow the cervix to evert and develop an ectropion, allowing satisfactory colposcopy in the second or third trimester. Conization in the first trimester of pregnancy is associated with an abortion rate of up to 33% (132,133). Patients with an obvious cervical carcinoma may undergo cervical biopsy and clinical staging similar to that of nonpregnant patients.

After conization, there appears to be no harm in delaying definitive treatment until fetal maturity is achieved in patients with stage I cervical cancer (134,135). Patients with less than 3 mm of invasion and no lymphatic or vascular space involvement may be followed to term and delivered vaginally. A vaginal hysterectomy may be performed 6 weeks postpartum if further childbearing is not desired.

Patients with 3 to 5 mm of invasion and those with lymph–vascular space invasion may also be followed to term (132,135). They may be delivered by cesarean birth, followed immediately by modified radical hysterectomy and pelvic lymph node dissection. Patients with more than 5 mm invasion should be treated as having frankly invasive cancer. Treatment depends on the stage of gestation and the wishes of the patient. Modern neonatal care affords a 75% survival rate for infants delivered at 28 weeks of gestation and 90% for those delivered at 32 weeks of gestation. Fetal pulmonary maturity can be determined by amniocentesis, and prompt treatment can be instituted when pulmonary maturity is documented. Although timing is controversial, it is probably wise to delay therapy for longer than 4 weeks (134,135). The recommended treatment is classic cesarean delivery followed by radical hysterectomy with pelvic lymph node dissection. There should be a thorough discussion of the risks and options with both parents before any treatment is undertaken.
Patients with cervical cancer in stages II to IV should be treated with radiotherapy. If the fetus is viable, it is delivered by classic cesarean birth, and therapy is begun postoperatively. If the pregnancy is in the first trimester, external radiation therapy can be started with the expectation that spontaneous abortion will occur before the delivery of 4,000 cGy. In the second trimester, a delay of therapy may be entertained to improve the chances of fetal survival. If the patient wishes to delay therapy, it is important to ensure fetal pulmonary maturity before delivery is undertaken.

The clinical stage is the most important prognostic factor for cervical cancer during pregnancy. Overall survival is slightly better for patients with cervical cancer in pregnancy because an increased proportion of these patients have stage I disease. For patients with advanced disease, there is evidence that pregnancy impairs the prognosis (132,135). The diagnosis of cancer in the postpartum period is associated with a more advanced clinical stage and a corresponding decrease in survival.

Cancer of the Cervical Stump

Cancer of the cervical stump is less common today than it was several decades ago when supracervical hysterectomy was popular. Early-stage disease is treated surgically, with very little change in technique from that used when the uterus is intact (136). Advanced-stage disease may present a therapeutic problem for the radiotherapist if the length of the cervical canal is less than 2 cm. This length is necessary to allow satisfactory placement of the uterine tandem. If the uterine tandem cannot be placed, radiation therapy can be completed with vaginal ovoids or with an external treatment plan in which lateral ports are used to augment the standard anterior and posterior ports. Such a technique will reduce the dosage to the bowel and bladder and thus reduce the incidence of complications.

Pelvic Mass

The origin of a pelvic mass must be clarified before treatment is initiated. An IVP can exclude a pelvic kidney, and a barium enema helps to identify diverticular disease or carcinoma of the colon. An abdominal x-ray film may show calcifications typically associated with benign ovarian teratomas or uterine leiomyomas. Pelvic ultrasonography differentiates between solid and cystic masses and indicates uterine or adnexal origin. Solid masses of uterine origin are most often leiomyomas and generally do not need further investigation.

Pyometra and Hematometra

An enlarged fluid-filled uterine cavity may be a pyometra or a hematometra. The hematometra can be drained by dilatation of the cervical canal and will not interfere with treatment. The pyometra also should be drained, and the patient should be given antibiotics to cover Bacteroides species, anaerobic Staphylococcus and Streptococcus species, and aerobic coliform bacterial infection. Placement of a large mushroom catheter through the cervix has been advocated, but the catheter itself may become obstructed, leading to further occlusion of the drainage. Repeated dilatation of the cervix with aspiration of pus every 2 to 3 days is more effective.

If the disease is stage I, a radical hysterectomy and pelvic node dissection may be performed. However, a pyometra is usually found in patients with advanced disease, and thus radiotherapy is required. External-beam therapy can begin when the pyometra has healed. Patients often have a significant amount of pus in the uterus or a tuboovarian abscess without signs of infection; therefore, a normal temperature and a normal white blood cell count do not necessarily exclude infection. Repeat physical examination or pelvic ultrasonography is necessary to ensure adequate drainage.

Cervical Carcinoma after Extradescal Hysterectomy

When invasive cervical cancer is found after simple hysterectomy, it may be treated with radiotherapy or reoperation involving a pelvic node dissection and radical excision of parametrial tissue, cardinal ligaments, and the vaginal stump (137).

Reoperation Reoperation is indicated particularly for a young patient who has a small lesion and in whom preservation of ovarian function is desirable. It is not indicated for patients who have positive margins or obvious residual disease (137). Survival rates after radical reoperation are similar to those after radical hysterectomy for stage I disease.

Radiation Therapy Survival after radiotherapy depends on the volume of disease, the status of the surgical margins, and the length of delay from surgery to radiotherapy. Patients with microscopic disease have a 95% to 100% 5-year survival rate; the 5-year survival rate is 82% to 84% in those with macroscopic disease and free margins, 38% to 87% in those with microscopically positive margins, and 20% to 47% in those with obvious residual cancer (138,139 and 140). A delay in treatment of more than 6 months is associated with a 20% survival rate (140).

Stage IVa

Although primary exenteration may be considered for patients with direct extension to the rectum or bladder, it is rarely performed. For patients with extension to the bladder, the survival rate with radiation therapy is as high as 30%, with a urinary fistula rate of only 3% (141). The presence of tumor in the bladder may prohibit cure with radiation therapy alone; thus, consideration must be given to removal of the bladder on completion of external-beam radiation treatment. This is particularly true if the disease persists at that time and the geometry is not conducive to implant therapy. Rectal extension is less commonly observed but may require diversion of the fecal stream before therapy to avoid septic episodes from fecal contamination.

Acute Hemorrhage

Occasionally, a large lesion can produce life-threatening hemorrhage. A biopsy of the lesion should be performed to verify neoplasia, and a vaginal pack soaked in Monsel's solution (ferric subsulfate) should be packed tightly against the cervix. After proper staging, external radiation therapy can be started with the expectation that control of bleeding may require 8 to 10 daily treatments at 180 to 200 cGy/d. Broad-spectrum antibiotics should be used to reduce the incidence of infection. If the patient becomes febrile, the pack should be removed. Rapid replacement of the pack may be necessary, and a fresh pack should be immediately available. This approach to management of hemorrhage in patients previously untreated is preferable to exploration and vascular ligation. Occasionally, vascular embolization under fluoroscopic control may be required in severe cases, and this procedure may obviate a laparotomy. However, vascular occlusion ultimately may lead to decreased blood flow and oxygenation of the tumor; because the effect of radiotherapy is dependent on tissue oxygen content, the efficacy of the radiotherapy may be compromised.

Ureteral Obstruction

Treatment of bilateral ureteral obstruction and uremia in previously untreated patients should be determined on an individual basis. Transvesical or percutaneous ureteral catheters should be placed in patients with no evidence of distant disease, and radiotherapy with curative intent should be instituted. Patients with metastatic disease beyond curative treatment fields should be presented with the options of ureteral stenting, palliative radiotherapy, and chemotherapy for the metastatic disease. A median survival rate of 17 months for these patients may be achieved with aggressive management (142).

Barrel-shaped Cervix

The expansion of the upper endocervix and lower uterine segment by tumor has been referred to as a barrel-shaped cervix. Patients with tumors larger than 6 cm in diameter have a 17.5% central failure rate when treated with radiotherapy alone because the tumor at the periphery of the lower uterine segment is too far from the standard intracavitary source to receive an adequate tumoricidal dose (143). Attempts have been made to overcome this problem radiotherapeutically by means of interstitial implants into the tumor with a perineal template, but high central failure rates have also been reported with this technique (144).

Most oncologists prefer a combination of radiotherapy and surgery for treatment of patients with a barrel-shaped cervix. The usual approach is to perform an extrasceral hysterectomy 6 weeks after the completion of radiation therapy in an effort to resect a small, centrally persistent tumor. The dose of external radiotherapy is reduced to 4,000 cGy, and a single intracavitary treatment is given, which is followed by an extrasceral hysterectomy (145,146). This approach appears to result in a lower rate of central failure (2%), although it is not clear that the overall survival rate is improved. There is disagreement concerning the need for extrasceral
hysterectomy, and the GOG is undertaking a randomized study to compare adjuvant hysterectomy with radiotherapy alone in patients who have no evidence of occult metastases in the paraaortic nodes.

The narrow upper vagina of older patients may preclude the use of an intracavitary source of radiation. Such patients must receive their entire course of therapy from external sources, leading to a higher central failure rate and more significant bowel and bladder morbidity. If stage I disease is present in such a patient, a radical hysterectomy with pelvic node dissection is preferable if the patient's medical condition allows such an approach.

### Small Cell Carcinoma

Local therapy alone gives almost no chance of cure of small cell carcinoma. Regimens of combination chemotherapy have improved the median survival rates in small cell bronchogenic carcinoma, and these regimens are now being used for treatment of small cell (neuroendocrine type) carcinoma of the cervix. Combination chemotherapy may consist of either vincristine, doxorubicin, and cyclophosphamide (VAC) or VP-16 (etoposide) and cisplatin (EP) (147). Patients must be monitored carefully because they are at high risk for developing recurrent metastatic disease (148).

### Recurrent Cervical Cancer

Treatment of recurrent cervical cancer depends on the mode of primary therapy and the site of recurrence. Patients who have been treated initially with surgery should be considered for radiation therapy, and those who have had radiation therapy should be considered for surgical treatment. Chemotherapy is palliative only and is reserved for patients who are not considered curable by the other two modalities.

Radiotherapy for recurrence after surgery consists primarily of external treatment. Vaginal ovoids also may be placed in patients with isolated vaginal cuff recurrences. Patients with a regional recurrence may require interstitial implantation with a Syed type of template in addition to external therapy. A 25% survival rate can be expected in patients treated with radiation for a postsurgical recurrence (116).

### Radiation Retreatment

Retreatment of recurrent pelvic disease by means of radiotherapy with curative intent is confined to patients who had suboptimal or incomplete primary therapy. This may allow the radiotherapist to deliver curative doses to the tumor. The proximity of the bladder and rectum to the cancer and their relative sensitivity to radiation injury are the major deterrents to retreatment with radiation. The insertion of multiple interstitial radiation sources into the locally recurrent cancer through a perineal template may help overcome these dosimetric considerations (137,149). However, the fistula rates are high, and the consequences must be considered seriously before interstitial therapy is initiated. In general, for patients considered curable with interstitial implant therapy, pelvic exenteration is a better treatment choice.

Radiotherapy can be palliative with localized metastatic lesions. Painful bony metastases, central nervous system lesions, and severe urologic or vena caval obstructions are specific indications.

### Surgical Therapy

Surgical therapy for postirradiation recurrence is limited to patients with cervical pelvic disease. A few carefully selected patients with small-volume disease limited to the cervix may be treated with an extracavitral or radical hysterectomy. However, the difficulty of assessing tumor volume and the 30% to 50% rate of serious urinary complications in these previously irradiated patients have led most gynecologic oncologists to recommend pelvic exenteration as the patient's last chance for cure (150,151).

### Exenteration

The operation can be an anterior exenteration (removal of the bladder, vagina, cervix, and uterus), a posterior exenteration (removal of the rectum, vagina, cervix, and uterus), or a total exenteration (removal of both bladder and rectum with the vagina, cervix, and uterus). A total exenteration that includes a large perineal phase includes the entire rectum and leaves the patient with a permanent colostomy as well as a urinary conduit. In selected patients, a total exenteration may take place above the levator muscle (suprarelevator), leaving a rectal stump that may be anastomosed to the sigmoid, thus avoiding a permanent colostomy.

### Preoperative Evaluation and Patient Selection

The search for metastatic disease is imperative. Physical examination includes careful palpation of the peripheral lymph nodes with FNA cytologic sampling of any nodes that appear suspicious. A random biopsy of nonsuspicious supraclavicular lymph nodes has been advocated but is not routinely practiced (150,152). A CT scan of the lung can detect disease missed on routine x-ray examination of the chest. Abdominal and pelvic-CT scans are helpful in the detection of liver metastases and enlarged paraaortic nodes. CT-directed FNA cytologic study of any abnormality should be undertaken. If a positive cytologic diagnosis is obtained, it will obviate the need for exploratory laparotomy.

Extension of the tumor to the pelvic sidewall is a contraindication to exenteration; however, this may be difficult for even the most experienced examiner to determine because of radiation fibrosis. If any question of resectability arises, exploratory laparotomy and parametrial biopsies, the patient's last hope for cure, should be offered (153,154,155 and 156). The clinical triad of unilateral leg edema, sciatic pain, and ureteral obstruction is nearly always pathognomonic of unresectable disease on the pelvic sidewall. Preoperatively, the patient should be prepared for a major operation. Total parenteral nutrition may be necessary to place the patient in an anabolic state for optimal healing. A bowel preparation, preoperative antibiotics, and prophylaxis for deep venous thrombosis with low-dose heparin or pneumatic calf compression should be used (157). Surgical mortality increases with age, and the operation should rarely be considered in a patient who is older than 70 years of age. Other medical illnesses should be taken into account; when life expectancy is limited, exenterative surgery is unwise.

### Anterior Exenteration

Candidates for anterior exenteration are those in whom the disease is limited to the cervix and anterior portion of the upper vagina. Proctoscopic examination should be performed because a positive finding would mandate a total exenteration. However, a negative proctoscopic examination finding does not exclude disease in the rectal musculature, and findings at laparotomy still must be considered. Generally, the presence of disease in the posterior vaginal mucosa directly over the rectum mandates removal of the underlying rectum.

### Posterior Exenteration

A posterior exenteration is rarely performed for recurrent cervical cancer. It is indicated, however, for the patient with an isolated posterior vaginal recurrence in which dissemination of the ureters through the cardinal ligaments will not be necessary.

### Total Exenteration

Total exenteration with a large peripheral phase is considered when the disease extends down to the lower part of the vagina. Because distal vaginal lymphatics may empty into the inguinal node region, these nodes should be carefully evaluated preoperatively. A suprarelevator total exenteration with low rectal anastomosis is indicated in the patient whose disease is confined to the upper vagina and cervix (158,159). Frozen-section margins of the rectal edge should be obtained because occult metastases to the muscularis may occur.

The development of techniques to establish continent urinary diversion has helped improve a woman's physical appearance after exenteration (150,154,155,156,157,158,159,160,161,162 and 163). Survival rates are poorer for patients with recurrent disease larger than 3 cm, invasion into the bladder, positive pelvic lymph nodes, and recurrence diagnosed within 1 year after radiotherapy (156). The 5-year survival rate of patients with positive pelvic lymph nodes is less than 5%. Thus, the performance of an extensive lymphadenectomy in the irradiated field is not warranted, but discontinuation of the procedure is advisable if any
nodes are positive for metastatic cancer. Patients who have any disease in the peritoneal cavity have no chance of survival.

Chemotherapy for Recurrent Cervical Cancer

Recurrent cervical cancer is not considered curable with chemotherapy. The delivery of chemotherapy to recurrent tumor in a prior radiated field may be compromised because of altered blood supply caused by radiation. Topotecan has been reported to have a response rate of 17%, with a median duration of 14 months (164). Many other agents have shown activity against cervical cancer and may be used in attempt to help control symptoms of the cancer. A number of clinical trials with various drugs have shown response rates of up to 45% (165). Complete responses are unusual and are generally limited to patients with chest metastases, in whom the dose of drug delivered to the disease is stronger than that delivered to the fibrotic postirradiation pelvis (166).

In a review of the literature on the role of chemotherapy in cervical cancer, the author concludes that present data do not support the claim that toxic combination chemotherapy regimens are superior to cisplatin alone in terms of survival benefit, although further studies are required to determine whether combination chemotherapy may offer a benefit for certain subgroups of patients (166,167). The response rates for single-agent chemotherapy in cervical cancer are about 10% to 25%; cisplatin and carboplatin are among the most active agents. The response rate for cisplatin combination therapies is about 20% to 40% (167). The GOG currently has completed two trials (GOG 149 and 169) evaluating recurrent cervical carcinoma. GOG 169 is comparing cisplatin to cisplatin with paclitaxel. Results of these studies may alter first-line therapy for recurrent cervical carcinoma.

Vaginal Carcinoma

Primary vaginal cancer is a relatively uncommon tumor, representing only 1% to 2% of malignant neoplasms of the female genital tract (168,169). The incidence of invasive vaginal cancer is 0.42 per 100,000 women and has remained relatively unchanged since the 1980s (170). Primary vaginal cancer should be differentiated from cancers metastatic to the vagina. Metastatic cancers constitute the majority of vaginal cancers (80% to 90%) (171).

Staging

The FIGO staging of vaginal cancer requires that a tumor that has extended to the vagina from the cervix be regarded as a cancer of the cervix, whereas a tumor that involves both the vulva and the vagina should be classified as a cancer of the vulva.

The FIGO staging for vaginal carcinoma is shown in Table 31.6. Staging is done by clinical examination and, if indicated, cystoscopy, proctoscopy, chest x-rays, and skeletal x-ray. Information derived from lymphangiography, CT, and MRI cannot be used to change the FIGO stage, but it can be used for planning treatment. Unfortunately, 75% of patients present with stage II to IV disease, indicating delay in diagnosis and complicating the treatment and subsequent cure rates (172-173 and 174).

Table 31.6. FIGO Staging of Vaginal Cancer

Surgical staging and resection of enlarged lymph nodes may be indicated in selected patients. FIGO staging does not include a category for microinvasive disease. Because vaginal cancer is rare and treatment is generally by radiotherapy, there is very little information concerning the spread of disease in relation to depth of invasion, lymph-vascular space invasion, and size of the lesion.

Etiology

The cause of squamous cell carcinoma of the vagina is unknown. The association of cervical cancer with HPV suggests that vaginal cancer may have a similar association (175). In addition, up to 30% of women with vaginal cancer have a history of cervical cancer treated at least 5 years earlier (176,177, and 178). Similar to cervical cancer, there appears to be a premalignant phase called vaginal intraepithelial neoplasia (VAIN) (see Chapter 16). The exact incidence of progression to invasive vaginal cancer from VAIN is not known; however, there are documented cases of invasive disease occurring despite adequate treatment of VAIN (179,180).

By convention, any new vaginal carcinoma developing at least 5 years after the cervical cancer should be considered a new primary lesion. There are three possible mechanisms for the occurrence of vaginal cancer after cervical neoplasia:

1. Residual disease in the vaginal epithelium after treatment of the cervical neoplasia
2. New primary disease arising in a patient with increased susceptibility to lower genital tract carcinogenesis; the role of HPV in this setting is suspected.
3. Increased susceptibility of carcinogenesis caused by radiation therapy

Screening

Routine screening of all patients for vaginal cancer is inappropriate. For women who have had a cervical or vulvar neoplasm, the Pap test is an important part of routine follow-up with each physician visit. This increased risk for vaginal cancer continues for the lifetime of the patient. It is recommended that Pap test surveillance for vaginal cancer be performed yearly after the patient has completed surveillance for cancer of the cervix or vulva. For women who have had a hysterectomy for benign disease, Pap testing every 3 to 5 years has been standard practice in the United States. When adjusted for age and prior cervical disease, the incidence of vaginal cancer is not increased in women who have had hysterectomy for benign disease (181).

Symptoms

Painless vaginal bleeding and discharge are the most common symptoms of vaginal cancer. With more advanced tumors, urinary retention, bladder spasm, hematuria, and frequency of urination may occur. Tumors developing on the posterior vaginal wall may produce rectal symptoms, such as tenesmus, constipation, or blood in the stool.

Diagnosis

The diagnostic workup includes a complete history and physical examination, careful speculum examination and palpation of the vagina, and bimanual pelvic and rectal examinations. It is important to rotate the speculum to obtain a careful view of the entire vagina because posterior wall lesions frequently occur and may be
In early squamous cell lesions, the diagnosis is suggested by an abnormal Pap test result; however, this is not true for clear cell adenocarcinomas, which are characterized by submucosal growth. In these cases, the diagnosis is confirmed by a targeted biopsy using the same instruments as those used for cervical biopsies. The most common site of vaginal cancer is in the upper one third of the vagina on the posterior wall. The developing tumor may be missed during initial inspection because the speculum blades may have obscured it (182). Colposcopy is valuable in evaluating patients with abnormal Pap test results, unexplained vaginal bleeding, or ulcerated erythematous patches in the upper vagina. A colposcopically targeted biopsy may not allow a definitive diagnosis, and a partial vaginectomy to determine invasion may be necessary. Occult invasive carcinoma may be detected by such an excision, particularly in patients who had previous hysterectomies, in whom the vaginal vault closure may bury some of the vaginal epithelium that is at risk for cancer (183).

Pathology

Cancer of the vagina spreads most often by direct extension into the pelvic soft tissues and adjacent organs. Metastases to the pelvic and, subsequently, the paraaortic lymph nodes may occur in advanced disease. Lesions in the lower one third of the vagina may spread directly to the inguinal femoral lymph nodes as well as the pelvic nodes (184). Hematogenous dissemination to the lungs, liver, or bone may occur as a late phenomenon.

Squamous cell carcinomas are the most common form of vaginal cancer, occurring in 80% to 90% of vaginal cancers. These tumors most commonly occur in the upper, posterior wall of the vagina. The mean age of patients with squamous cell cancer is 60 years (185,186). Malignant melanoma is the second most common cancer of the vagina, accounting for 2.8% to 5% of all vaginal neoplasms (187,188 and 189). Other histologic subtypes include adenocarcinoma and sarcoma.

Primary adenocarcinoma of the vagina is rare, constituting 9% of primary tumors of the vagina. However, the most common adenocarcinoma of the vagina is metastatic. Metastatic adenocarcinoma of the vagina may originate from the colon, endometrium, ovary, or rarely, pancreas and stomach. In general, they affect a younger population of women, regardless of whether they were exposed to diethylstilbestrol (DES) in utero (190). Adenocarcinomas may arise in wolffian rest elements, periurethral glands, and foci of endometriosis (191). In women exposed to DES in utero, adenocarcinoma may develop in vaginal adenosis.

DES was used in the United States from 1940 until 1971 to maintain high-risk pregnancies in women with a history of spontaneous abortions. In 1970, Herbst and Scully reported on seven young women with clear cell adenocarcinoma of the vagina (Fig. 31.11). Later, an association between this cancer and maternal ingestion of DES during pregnancy was identified (192). Subsequently, more than 500 cases of clear cell cancer of the vagina and cervix have been reported to the Registry for Research on Hormonal Transplacental Carcinogenesis.

![Figure 31.11 Vaginal clear cell carcinoma. Note the formation of tubules with hobnail cells lining the lumen. These cells are characterized by nuclear protrusion into the apical cytoplasm. (From Berek JS, Hacker F. Practical gynecologic oncology. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)](https://example.com/figure311.png)

The estimated risk for developing clear cell adenocarcinoma from an exposed offspring is 1 in 1,000 or less. The mean age of diagnosis is 19 years (193). Clear cell adenocarcinoma in women with a history of in utero exposure to DES typically presents in the excocervix or upper third of the vagina. These tumors vary greatly in size, and are most frequently exophytic and superficially invasive. Stage is the most important prognostic factor. Other statistically significant factors include a tubulocystic growth pattern, size less than 3 cm², and less than 3 mm stromal invasion. Because the use of DES in pregnant women was discontinued in 1971, most of these tumors probably have been discovered. It is uncertain, however, what will happen to this cohort of women as they move into their fifth, sixth, and seventh decades of life. Continued surveillance of these women is indicated.

Ninety-seven percent of cases of vaginal clear cell adenocarcinoma are associated with adenosin. Adenosis is characterized by the presence of persistent müllerian-type glandular epithelium. Although adenosis is the most common histologic abnormality in women exposed to DES in utero, adenosin can also be found in women without a history of exposure. Adenosis typically appears as red, grapelike clusters in the vagina.

Malignant melanoma of the vagina is rare and extremely lethal. The average age of these patients is 58 years, and malignant melanoma occurs most often in white women (194). Most lesions are deeply invasive, corresponding to a level IV when compared with the staging for vulvar melanomas. The most common location of these tumors is in the lower third of the vagina (195). Melanomas have a wide variety of size, color, and growth patterns (196,197). Radical excision (vaginectomy, hysterectomy, and pelvic lymphadenectomy) has been the mainstay of treatment. The goal of treatment is to avoid local (vaginal) recurrence, which is the most common site of recurrence (194,195). The need to dissect regional lymph nodes is uncertain. Because the disease is deeply invasive, hematogenous spread is the most common lethal recurrence. This finding is consistent with more conservative local excision because there is no difference in overall survival of patients with local as opposed to radical excision (194). The survival rate is about 10% at 5 years.

The most common benign and malignant mesenchymal tumors of the vagina in adult women are smooth muscle tumors (197). Vaginal sarcomas are usually fibrosarcomas or leiomyosarcomas and are extremely rare. Radical local excision, followed by adjuvant chemotherapy or radiation therapy, is the indicated treatment.

The most common malignant mesenchymal tumor of the vagina in children and infants is botryoid rhabdomyosarcoma (Fig. 31.12). Botryoid sarcoma is usually found in the vagina during infancy and early childhood, in the cervix during the reproductive years, and in the corpus uteri during postmenopausal years. Preoperative chemotherapy with vincristine, actinomycin D, and cyclophosphamide, followed by conservative surgery or radiation, has led to improved survival as well as organ preservation.

![Figure 31.12 Embryonal rhabdomyosarcoma of the vagina (botryoid sarcoma). This lesion consists of primitive mesenchymal cells and rhabdomyoblasts, which have abundant eosinophilic cytoplasm. With further differentiation, cross striations may become evident. (From Berek JS, Hacker F. Practical gynecologic oncology.](https://example.com/figure3112.png)
Treatment

Treatment selection is based on the clinical examination, CT scan results, chest x-ray results, age, and condition of the patient. Most tumors are treated by radiation therapy. Surgery is limited to highly selective cases.

Women with stage I disease involving the upper posterior vagina may be treated by radical vaginectomy and pelvic lymphadenectomy. If the uterus is in situ, it is removed as a radical hysterectomy specimen. When margins are clear and lymph nodes are negative, no additional therapy is necessary. Patients with stage IV disease with either rectovaginal or vesicovaginal fistula may be candidates for primary pelvic exenteration with pelvic and paraaortic node dissection (193). Low rectal anastomosis, continent urinary diversion, and vaginal reconstruction are indicated and are more successful in these nonirradiated patients than in patients who received prior radiation therapy (169).

Women with central pelvic recurrence after radiation therapy are candidates for pelvic exenteration similar to that for cervical cancer. Surgical staging with resection of enlarged lymph nodes may improve the control of pelvic disease by radiotherapy techniques. Surgical exploration or laparoscopy at the time of insertion of Syed interstitial implants defines more precisely the placement of the needles and ensures that needles do not pass into adherent loops of bowel.

Radiation therapy is the treatment of choice for all patients except those described previously. Small superficial lesions may be treated with intracavitary radiation alone (193). Larger, thicker lesions should be treated first with external teletherapy to decrease tumor volume and to treat the regional pelvic nodes, followed by intracavitory and interstitial therapy to deliver a high dose to the primary tumor (196,194). If the uterus is intact and the lesion involves the upper vagina, an intruterine tandem and ovoids can be used. If the uterus has been previously removed, a vaginal cylinder may be used for superficial irradiation. If the lesion is more than 0.5 cm thick, interstitial radiation techniques can improve the dose distribution to the primary tumor. Extended-field radiation may be used for vaginal carcinoma in a manner similar to its use for cervical carcinoma. There is no experience reported with this technique in the treatment of vaginal cancer. Likewise, there is no reported experience with combination chemotherapy treatment. However, concurrent use of 5-FU and cisplatin has been highly successful in anal and cervical cancer and should be considered.

Sequeulae

The proximity of the rectum, bladder, and urethra leads to a major complication rate of 10% to 15% for both surgery and radiation treatment. For large tumors, the risk for bladder or bowel fistula is significant. Radiation cystitis and proctitis are common, as are rectal strictures or ulcerations. Radiation necrosis of the vagina occasionally occurs, requiring debridement and often leading to fistula formation. Vaginal fibrosis, stenosis, and stricture are common after radiation therapy. Use of vaginal dilators and resumption of regular sexual relations should be encouraged, along with the use of topical estrogen to maintain adequate vaginal function.

Survival

The overall 5-year survival rate for patients with vaginal cancer is 42% (Table 31.7). Even for patients with stage I disease, the 5-year survival rate is less than 70%, which is 15% lower than that for comparable stages of cervical or vulvar cancer (195,196,197,198 and 199). Most recurrences are in the pelvis, either from enlarged regional nodes or from large central tumors to which it is difficult to deliver an adequate dose of radiation. Radiation techniques, such as interstitial implants with Syed applicator and combination chemoradiation, may improve these results. Careful evaluation of patients who receive radiation therapy to detect central recurrence may allow some patients to be salvaged by pelvic exenteration. Because of the rarity of vaginal cancer, these patients should be treated in a center that is familiar with the complexity of treatment and modalities of therapy.

Of all the gynecologic cancers, ovarian malignancies represent the greatest clinical challenge. Epithelial cancers are the most common ovarian malignancies, and because they are usually asymptomatic until they have metastasized, patients have advanced disease at diagnosis in more than two-thirds of the cases. Ovarian cancer represents a major surgical challenge, requires intensive and often complex therapies, and is extremely demanding of the patient's psychological and physical energy. It has the highest fatality-to-case ratio of all the gynecologic malignancies. There are more than 23,300 new cases annually in the United States, and 13,900 women can be expected to succumb to their illness (1). A woman's risk at birth of having ovarian cancer sometime in her life is nearly 1.5%, and that of dying from ovarian cancer almost 1% (2).

Epithelial Ovarian Cancer

Approximately 90% of ovarian cancers are derived from tissues that come from the coelomic epithelium or mesothelium (2). The cells are a product of the primitive mesoderm, which can undergo metaplasia. A classification of the histologic types of epithelial tumors of the ovary is presented in Table 32.1. Neoplastic transformation can occur when the cells are genetically predisposed to oncogenesis or exposed to an oncogenic agent or both (3).
Pathology

Invasive Cancer

Seventy-five percent of epithelial cancers are of the serous histologic type. Less common types are mucinous (20%), endometrioid (2%), clear cell, Brenner, and undifferentiated carcinomas; each of the last three types represents less than 1% of epithelial lesions (2). Each tumor type has a histologic pattern that reproduces the mucosal features of a section of the lower genital tract (3). For example, the serous or papillary pattern has an appearance similar to that of the glandular epithelial lining and fallopian tube. Mucinous tumors contain cells that resemble the endocervical glands, and the endometrioid tumors resemble the endometrium.

Borderline Tumors

An important group of tumors to distinguish is the tumor of low malignant potential, also called the borderline tumor. Borderline tumors are lesions that tend to remain confined to the ovary for long periods, occur predominantly in premenopausal women, and are associated with a very good prognosis (2, 3, 4, 5, 6, 7, and 8). They are encountered most frequently in women between the ages of 30 and 50 years, whereas invasive carcinomas occur more often in women between the ages of 50 and 70 years (2).

Although uncommon, metastatic implants may occur with borderline tumors. Such implants have been divided into noninvasive and invasive forms. The latter group has a higher likelihood of developing into progressive, proliferative disease in the peritoneal cavity, which can lead to intestinal obstruction and death (26).

The criteria for the diagnosis of borderline tumors (Fig. 32.1) are as follows (7):

1. Epithelial proliferation with papillary formation and pseudostratification
2. Nuclear atypia and increased mitotic activity
3. Absence of true stromal invasion (i.e., without tissue destruction).

It should be emphasized that about 20% to 25% of borderline malignant tumors spread beyond the ovary. The diagnosis of borderline malignant versus malignant ovarian tumor must be based on the histologic features of the primary tumor (7).

Classification of Epithelial Ovarian Tumors

Serous Tumors

Serous tumors develop by invagination of the surface ovarian epithelium and are so classified because they secrete serous fluid (as do tubal secretory cells). Psammoma bodies, more correctly foci of foreign material, frequently are associated with these invaginations and may be a response to irritative agents that produce adhesion formation and the entrapment of the surface epithelium. In the wall of the mesothelial invaginations, papillary ingrowths are common, representing the early stages of development of a papillary serous cystadenoma. There are many variations in the proliferation of these mesothelial inclusions. Several foci may be lined with flattened inactive epithelium; in adjacent cavities, papillary excrecescences are present, often resulting from local irritants (2).

Borderline Serous Tumors Approximately 10% of all ovarian serous tumors fall into the category of a tumor of low malignant potential or borderline tumor, and 50% occur before the age of 40 years. As many as 10% of women with ovarian serous borderline tumors have extraovarian implants, and some will eventually die of the disease (9). Although multiple foci of disease have been documented in the abdominal cavity with secondary deposits in the pelvis, omentum, and adjacent tissues, including lymph nodes, metastases outside the abdominal cavity are rare. Death can occur as the result of intestinal obstruction (10, 11, and 12).

The implants are divided histologically into invasive and noninvasive groups (6, 10). In the noninvasive group, papillary proliferations of atypical cells involve the peritoneal surface and form smooth invaginations (6). The invasive implants resemble well-differentiated serous carcinoma and are characterized by atypical cells forming irregular glands with sharp borders. Bell and associates (6) have reported that only three of 50 women with noninvasive implants died, whereas four of six women with invasive implants died. In the series of McCaughey, two of 13 patients with noninvasive implants and all five patients with invasive implants died (9). Others have noted no differences in prognosis (10, 11).

Rare examples of borderline malignant serous tumors with foci of microinvasion have been reported by Bell and Scully (12). Most patients are young, International Federation of Gynecology and Obstetrics (FIGO) stage I, and sometimes pregnant. Only one of 30 such patients died of disease, and she had stage III disease (12).

Malignant Serous Carcinomas In the malignant tumors, stromal invasion is present (2). The grade of tumor should be identified. In well-differentiated serous adenocarcinomas, papillary and glandular structures predominate (Fig. 32.2); poorly differentiated neoplasms are characterized by solid sheets of cells, nuclear pleomorphism, and high mitotic activity; and moderately differentiated carcinomas are intermediate between these two lesions. Laminated, calcified psammoma
Mucinous Tumors

These cystic tumors have loculi lined with mucin-secreting epithelium. They represent about 8% to 10% of epithelial ovarian tumors. They may reach enormous size, filling the entire abdominal cavity.

Borderline Mucinous Tumors

The mucinous tumor of low malignant potential is often a diagnosis difficult to make. Although it is common to find a rather uniform pattern from section to section in the borderline malignant serous lesions, this is not true in the mucinous tumors. Frequently, well-differentiated mucinous epithelium may be seen immediately adjacent to a poorly differentiated focus. Therefore, it is important to take multiple sections from many areas in the mucinous tumor to identify the most malignant alteration.

Malignant Mucinous Carcinomas

Bilateral tumors occur in 8% to 10% of cases. The mucinous lesions are intraovarian in 95% to 98% of cases. Because most ovarian mucinous carcinomas contain intestinal type cells, they cannot be distinguished from metastatic carcinoma of the gastrointestinal tract on the basis of histology alone. Primary ovarian neoplasms rarely metastasize to the mucosa of the bowel, although they commonly involve the serosa, whereas gastrointestinal lesions frequently involve the ovary by direct extension of vascular lymphatic spread.

Pseudomyxoma Peritonei

In pseudomyxoma peritonei, the neoplastic epithelium secretes large amounts of gelatinous mucinous material. It is most commonly secondary to a well-differentiated appendiceal carcinoma, an ovarian mucinous carcinoma or, less commonly, a mucocele of the appendix.

Endometrioid Tumors

Endometrioid lesions constitute 6% to 8% of epithelial tumors. Endometrioid neoplasia includes all the benign demonstrations of endometriosis. In 1929, Sampson suggested that certain cases of adenocarcinoma of the ovary probably arose in areas of endometriosis. The adenocarcinomas are similar to those seen in the uterine cavity. The malignant potential of endometriosis is very low, although a transition from benign to malignant epithelium may be demonstrated.

Borderline Endometrioid Tumors

The endometrioid tumor of low malignant potential has a wide morphologic spectrum. Tumors may resemble an endometrial polyp or complex endometrial hyperplasia with crowding of glands. When there are back-to-back glands with no intervening stroma, the tumor is classified as a well-differentiated endometrioid carcinoma. Some borderline malignant tumors have a prominent fibromatous component. In such cases, the word adenofibroma is used.

Malignant Endometrioid Carcinomas

Endometrioid tumors are characterized by an adenomatous pattern with all the potential variations of epithelia found in the uterus.

Multifocal Disease

The endometrial or endometrioid tumors afford the greatest opportunity to evaluate multifocal disease. Endometrioid tumors of the ovary are often associated with similar lesions in the endometrium. Identification of multifocal disease is important, because patients with disease metastatic from the uterus...
to the ovaries have a 30% to 40% 5-year survival, whereas those with synchronous multifocal disease have a 75% to 80% 5-year survival (14). When the histologic appearance of endometrial and ovarian tumors is different, the two tumors most likely represent two separate primary lesions. When they appear similar, the endometrial tumor can be considered a separate primary tumor if it is well differentiated and only superficially invasive.

**Clear Cell Carcinomas**

Several basic histologic patterns are present in the clear cell adenocarcinoma (i.e., tubulocystic, papillary, and solid). The tumors are made up of clear cells and hobnail cells that project their nuclei to the apical cytoplasm. The tall clear cells have abundant clear or vacuolated cytoplasm, hyperchromatic irregular nuclei, and nucleoli of various sizes (Fig. 32.5). Focal areas of endometriosis and endometrioid carcinoma sometimes occur. The clear cell carcinoma seen in the ovary is histologically identical to that seen in the uterus or vagina of the young patient who has been exposed to diethylstilbestrol (DES) in utero.

**Brenner Tumors**

*Borderline Brenner Tumors* Borderline, or proliferating, Brenner tumors have been described. In such cases, the epithelium does not invade the stroma. Some investigators subclassify those tumors that resemble low-grade papillary transitional cell carcinoma of the urinary bladder as proliferating tumors and those with a higher grade of transitional cell carcinoma in situ as borderline malignant Brenner tumors (15). Complete surgical removal usually results in cure.

*Malignant Brenner Tumors* These are rare and are defined as benign Brenner tumors coexisting with invasive transitional cells or another type of carcinoma. The tumor infiltrates the tissue with associated destruction.

**Transitional Cell Tumors**

The designation *transitional cell tumor* refers to a primary ovarian carcinoma resembling transitional cell carcinoma of the urinary bladder without a recognizable Brenner tumor. An important finding is that those ovarian carcinomas that contain more than 50% of transitional cell carcinoma are more sensitive to chemotherapy and have a more favorable prognosis than other poorly differentiated ovarian carcinomas of comparable stage (16,17). Transitional cell tumors differ from malignant Brenner tumors in that they are more frequently diagnosed in an advanced stage and, therefore, are associated with a poorer survival rate (18).

Small cell carcinoma occurs mainly in young women, who may have symptoms of hypercalcemia. Immunohistochemical stains are helpful to differentiate this tumor from a lymphoma, leukemia, or sarcoma.

**Peritoneal Carcinomas**

Primary peritoneal tumors are histologically indistinguishable from primary ovarian serous tumors. In the case of borderline serous peritoneal tumors and serous peritoneal carcinomas, the ovaries are normal or minimally involved, and the tumors affect predominately the uterosacral ligaments, pelvic peritoneum, or omentum. The overall prognosis for borderline serous peritoneal tumors is excellent and comparable to that of ovarian borderline serous tumors (21,22, and 23). In the review of 38 cases of peritoneal borderline serous tumors from the literature, 32 women had no persistent disease, four were well after resection of recurrence, one developed an invasive serous carcinoma, and one died from the effects of the tumor (21).

Peritoneal serous carcinomas have the appearance of a moderately to poorly differentiated serous ovarian carcinoma. Primary peritoneal endometrioid carcinoma is less common.

More than 80% of epithelial ovarian cancers are found in postmenopausal women (Fig. 32.6). These cancers are relatively uncommon in women under age 45.

**Mesotheliomas**

Peritoneal malignant mesotheliomas fall into the following four categories (19): (a) fibrosarcomatous, (b) tubulopapillary (papillary-alveolar), (c) carcinomatous, and (d) mixed. These lesions appear as multiple intra-peritoneal masses and can develop after hysterectomy and bilateral salpingo-oophorectomy for benign disease. Malignant mesotheliomas should be distinguished from ovarian tumor implants and primary peritoneal mullerian neoplasms.

The primary malignant transformation of the peritoneum has been called primary *peritoneal carcinoma* or primary *peritoneal papillary serous carcinoma*. Peritoneal carcinoma simulates ovarian cancer clinically. In patients for whom exploratory surgery is performed, there may be microscopic or small macroscopic cancer on the surface of the ovary and extensive disease in the upper abdomen, particularly in the omentum. This phenomenon can thus produce a condition in which so-called ovarian cancer can arise in a patient whose ovaries were surgically removed many years earlier (20).

**Clinical Features**

---

Fig. 32.5 Clear cell mesonephroid carcinoma of the ovary. Note the solid variant of clear cell carcinoma with sheets of cells that have clear cytoplasm (“hobnail” cells). (From Berek JS, Hacker NF, *Practical gynecologic oncology,* 2nd ed. Baltimore: Williams & Wilkins, 1994:144, with permission.)

Fig. 32.6 Ovarian cancer incidence: distribution by age. (From *J Natl Cancer Inst* 1995;87:1280, with permission.)
The peak incidence of invasive epithelial ovarian cancer is at 56 to 60 years of age (23,24). The age-specific incidence of ovarian epithelial cancer rises precipitously from 20 to 80 years of age and subsequently declines (24). Fewer than 1% of epithelial ovarian cancers occur before the age of 21 years, two-thirds of ovarian malignancies in such patients being germ cell tumors (22,24,26). About 30% of ovarian neoplasms in postmenopausal women are malignant, whereas only about 7% of ovarian epithelial tumors in premenopausal patients are frankly malignant (23).

The average age of patients with borderline tumors is approximately 46 years (2,3,5). Eighty to ninety percent of ovarian cancers, including borderline forms, occur after the age of 40 years, whereas 30% to 40% of malignancies occur after the age of 65 years. The chance that a primary epithelial tumor will be of borderline or invasive malignancy in a patient younger than 40 years is approximately 1 in 10, but after that age it rises to one in three (2,3). Fewer than 1% of epithelial ovarian cancers occur before the age of 20 years, with two thirds of ovarian malignancies in such patients being germ cell tumors. Approximately 30% of ovarian neoplasms in postmenopausal women are malignant, whereas only approximately 7% of ovarian epithelial tumors in premenopausal patients are frankly malignant (2).

Etiology

Ovarian cancer has been associated with low parity and infertility (26). Although there have been a variety of epidemiologic variables correlated with ovarian cancer, such as talc use, galactose consumption, and tubal ligation (see Chapter 4), none has been so strongly correlated as prior reproductive history and duration of the reproductive period (28-27). Early menarche and late menopause increase the risk of ovarian cancer (27). The factors and the relationship of parity and infertility to the risk of ovarian cancer have led to the hypothesis that suppression of ovulation may be an important factor. Theoretically, the surface epithelium undergoes repetitive disruption and repair. It is thought that this process might lead to a higher probability of spontaneous mutations that can unmask germ-line mutations or otherwise lead to the oncogenic phenotype (see Chapter 5).

Prevention

Because parity is inversely related to the risk of ovarian cancer, having at least one child is protective of the disease, with a risk reduction of 0.3 to 0.4. Oral contraceptive use reduces the risk of epithelial ovarian cancer (26). Women who use oral contraceptives for 5 or more years reduce their relative risk to 0.5 (i.e., there is a 50% reduction in the likelihood of development of ovarian cancer) (26). Women who have had two children and have used oral contraceptives for 5 or more years have a relative risk of ovarian cancer as low as 0.3, or a 70% reduction (28). Therefore, the oral contraceptive pill is the only documented method of chemoprevention for ovarian cancer, and it should be recommended to women for this purpose. When counseling patients regarding birth control options, this important benefit of oral contraceptive use should be emphasized. This is also important for women with a strong family history of ovarian cancer (see discussion below).

Fenretinide (4-hydroxyretinoic acid), a vitamin A derivative, has been given to women with unilateral breast cancer in an effort to reduce the risk of contralateral breast cancer. In a prospective, randomized, placebo-controlled trial conducted in Italy (29), women with unilateral breast cancer were given for 6 months either fenretinide or a placebo. In the treatment group, no ovarian cancers developed, whereas there were six cases of ovarian cancer in the control group. A larger trial is planned in the United States in an attempt to verify these data.

The performance of a prophylactic oophorectomy reduces, but does not eliminate, the risk of ovarian cancer (20,21). Because the entire peritoneum is at risk, peritoneal carcinomas can occur even after prophylactic oophorectomy. Because the ovaries provide protection from cardiovascular and orthopedic diseases, prophylactic oophorectomy should not be routinely performed in premenopausal women at low risk for ovarian cancer.

Screening

The value of tumor markers and ultrasonography to screen for epithelial ovarian cancer has not been clearly established by prospective studies. Screening results with transabdominal ultrasonography have been encouraging (30,31 and 32), but specificity has been limited. However, advances in transvaginal ultrasonography have been shown to have a very high (>95%) sensitivity for the detection of early-stage ovarian cancer, although this test alone might require as many as 10 to 15 laparotomy procedures be performed for each case of ovarian cancer detected (30,31). Routine annual pelvic examinations have had disappointing results in the early detection of ovarian cancer (33). Transvaginal color-flow Doppler to assess the vascularity of the ovarian vessels has shown to be a useful adjunct to ultrasonography (34,35), but it has not been shown to be useful in screening.

CA125 has been shown to contribute to the early diagnosis of epithelial ovarian cancer (36,37,38,39,40,41 and 42). Regarding the sensitivity of the test, CA125 can detect 50% of patients with stage I disease and 60% of patients if those with stage II disease are included (36). Data suggest that the specificity of CA125 is improved when the test is combined with transvaginal ultrasonography (43) or when the CA125 levels are followed over time (42,43). These data have encouraged the development of prospective screening studies in Sweden and the United Kingdom (38,39). In these studies, patients with elevated CA125 levels (>30 U/mL) have undergone abdominal ultrasonography and 14 ovarian cancers have been discovered among 27,000 women screened. About four laparotomies were performed for each case of cancer detected.

A randomized trial of nearly 22,000 women aged 45 years or older was performed in the United Kingdom (43). The patients were assigned to either a control group of routine pelvic examination (n = 10,977) or to a screening group (n = 10,958). The screening consisted of three annual screens that involved measurement of serum CA125, pelvic ultrasonography if the CA125 was 30 U/mL or higher, and referral for gynecologic examination if the ovarian volume was 8.8 mL or greater on the ultrasonography. Of the 468 women in the screened group with an elevated CA125, 28 were referred for surgery, 6 cancers were discovered, and 23 had false positives. The screening results, yielding a positive predictive value of 20.7%. During a 7-year follow-up period, cancer developed in 10 additional women in the screened group, as it did in 20 women in the control group. Although the median survival of women in whom cancer developed in the screened group was 72.9 months, compared with 41.8 months in the control group (p = 0.0712), the number of deaths did not differ significantly between the control and screened groups (18%10.977 versus 9%10.958; relative risk 2.0 (0.78 to 5.13)). Therefore, these data show that a multimodal approach to ovarian cancer screening is feasible, but a larger trial is necessary to determine whether this approach affects mortality. Such a three-arm randomized trial is ongoing in the United Kingdom, and the anticipated accrual is approximately 50,000 women per study arm and 100,000 women in the control arm.

Given the false-positive results for both CA125 and transvaginal ultrasonography, particularly in premenopausal women, these tests are not cost effective and should not be used routinely to screen for ovarian cancer. In the future, new markers or technologies may improve the specificity of ovarian cancer screening, but proof of this will require a large, prospective study (40,41). Screening in women with a familial risk may have a better yield, but additional study is necessary (44,45).

Genetic Risk for Epithelial Ovarian Cancer

The lifetime risk of ovarian carcinoma for women in the United States is about 1.4% (1,2 and 3).

The risk of ovarian cancer is higher than that in the general population in women with certain family histories (46,47,48,49,50,51,52,53,54 and 55). Most epithelial ovarian cancer is sporadic, with familial or hereditary patterns accounting for 5% to 10% of all malignancies (47).

Hereditary Ovarian Cancer

BRCA1 and BRCA2

Most hereditary ovarian cancer is associated with mutations in the BRCA1 gene, located on chromosome 17 (46). A small proportion of inherited disease has been traced to another gene, BRCA2, located on chromosome 13 (48). Discovered through linkage analyses, these two genes are associated with the genetic predisposition to both ovarian and breast cancer. There may be other, yet undiscovered genes that predispose to ovarian and breast cancer (49).

In the past, it had been thought that there were two distinct syndromes associated with a genetic risk, site-specific hereditary ovarian cancer and hereditary breast-ovarian cancer syndrome. However, it is now believed that these groups essentially represent a continuum of mutations with different degrees of penetrance.
within a given family (50,55). In addition, there is a higher-than-expected risk of ovarian and endometrial cancer in the Lynch II syndrome, known also as the hereditary nonpolyposis colorectal cancer syndrome (HNPPC syndrome) (56).

The mutations are inherited in an autosomal dominant fashion, and therefore a full pedigree analysis (i.e., both maternal and paternal sides of the family) must be carefully evaluated (59). There are numerous distinct mutations that have been identified on each of these genes, and the mutations have different degrees of penetrance that may account for the preponderance of either breast cancer, ovarian cancer, or both, in any given family. Based on analysis of women who have a mutation in the BRCA1 gene and are from high-risk families, the lifetime risk of ovarian cancer may be as high as 28% to 44%, and the risk has been calculated to be as high as 27% for those women with a BRCA2 mutation (47,48,52). The risk of breast cancer in women with a BRCA1 or BRCA2 mutation may be as high as 56% to 87%.

Hereditary ovarian cancers in general occur in women approximately 10 years younger than those with nonhereditary tumors (47). Because the median age of epithelial ovarian cancer is in the mid- to late 50s, a woman with a first- or second-degree relative who had premenopausal ovarian cancer may have a higher probability of carrying an affected gene.

Breast and ovarian cancer may exist in a family in which there is a combination of epithelial ovarian and breast cancers, affecting a mixture of first- and second-degree relatives. Women with this syndrome tend to have these tumors at a young age, and the breast cancers may be bilateral. If two first-degree relatives are affected, this pedigree is consistent with an autosomal dominant mode of inheritance (43,49).

Founder Effect

There is a higher carrier rate of BRCA1 and BRCA2 mutations in women of Ashkenazi Jewish descent and in Icelandic women (52,53,55). There have been three specific mutations carried by the Ashkenazi population, 185delAG and 5382insC on BRCA1, and 6174delT on BRCA2. The total carrier rate for a patient of Ashkenazi Jewish descent to have at least one of these three mutations is 1 in 40, or 2.5%, and thus there is a substantial risk in this population. The increased risk is a result of the founder effect, in which a higher rate of mutations occurs in a defined geographic area.

Pedigree Analysis

The risk of ovarian cancer depends on the number of first- or second-degree relatives (or both) with a history of epithelial ovarian carcinoma or breast cancer (or both), and on the number of malignancies that occur at an earlier age. The degree of risk is difficult to determine precisely unless a full pedigree analysis is performed.

1. In families with two first-degree relatives (i.e., mother, sister, or daughter) with documented premenopausal epithelial ovarian cancer, the risk of a female first-degree relative has an affected gene could be as high as 35% to 40% (48).
2. In families with a single first-degree relative and a single second-degree relative (i.e., grandmother, aunt, first cousin, or grandchild) with epithelial ovarian cancer, the risk that a woman has an affected gene also may be increased. The risk may be 2- to 10-fold higher than in those without a familial history of the disease (48).
3. In families with a single postmenopausal first-degree relative with epithelial ovarian carcinoma, a woman may not have an increased risk of having an affected gene because the case is most likely to be sporadic. However, if the ovarian cancer occurs in a premenopausal relative, this could be significant, and a full pedigree analysis should be undertaken.
4. Women with a primary history of breast cancer have twice the expected incidence of subsequent ovarian cancer (47).

Lynch II Syndrome

This syndrome, which includes multiple adenocarcinomas, involves a combination of familial colon cancer (known as the Lynch I syndrome), a high rate of ovarian, endometrial, and breast cancers, and other malignancies of the gastrointestinal and genitourinary systems (56). The mutations that have been associated with this syndrome are MSH2, MLH1, PMS1, and PMS2. The risk that a woman who is a member of one of these families will develop epithelial ovarian cancer depends on the frequency of this disease in first- and second-degree relatives, although these women appear to have at least 3 times the relative risk of the general population. A full pedigree analysis of such families should be performed by a geneticist to determine the risk more accurately.

Management of Women at High Risk for Ovarian Cancer

The management of a woman with a strong family history of epithelial ovarian cancer must be individualized and depends on her age, her reproductive plans, and the extent of risk. In all of these syndromes, women at risk benefit from a thorough pedigree analysis. A geneticist should evaluate the family pedigree for at least three generations. Decisions about management are best made after careful study and, whenever possible, verification of the histologic diagnosis of the family members' ovarian cancer.

The value of testing for BRCA1 and BRCA2 has yet to be clearly established, although some guidelines for testing now exist (50,55,57). The importance of genetic counseling cannot be overemphasized because the decision is complex. The American Society of Clinical Oncology has offered guidelines that emphasize careful evaluation by geneticists, careful maintenance of medical records, and a clear understanding in a genetic screening clinic of how to counsel and manage these patients. Concerns remain over how the information should be used, the impact on insurability, how the results will be interpreted, and how the information will be used within a specific family (e.g., to counsel children).

Although there are some conflicting data, the behavior of breast cancers arising in women with germline mutations in BRCA1 or BRCA2 is comparable to that of sporadic tumors (49). Women with breast cancer who carry these mutations, however, are at a greatly increased risk of ovarian cancer as well as a second breast cancer.

Although recommended by the National Institutes of Health Consensus Conference on Ovarian Cancer (56), the value of screening with transvaginal ultrasonography, CA125 levels, or other procedures has not been clearly established in women at high risk. Bourne and co-workers (49) have shown that, using this approach, tumors can be detected approximately 10 times more often than in the general population, and thus they recommend screening in high-risk women.

Data derived from a multicenter consortium of genetic screening centers indicate that the use of the oral contraceptive pill is associated with a lower risk for developing ovarian cancer in women who have mutations in either BRCA1 or BRCA2 (58). The risk reduction is significant: in women who have taken oral contraceptives for 5 or more years, the relative risk of ovarian cancer is 0.4, or a 60% reduction in the incidence of the disease.

Prophylactic Oophorectomy

The value of prophylactic oophorectomy in these patients is controversial (50,61). Although the risk of ovarian cancer is significantly diminished, there remains the small risk of peritoneal carcinoma, a tumor for which women who have mutations in BRCA1 and BRCA2 may have a higher predisposition. Women at high risk for ovarian cancer who undergo prophylactic oophorectomy have a risk of harboring occult neoplasia. In one series of 42 such operations, four patients (9.5%) had a malignancy, one of which was noted at surgery and three that were microscopic; all were smaller than 5 mm (51).

Recommendations

Current recommendations for management of women at high risk for ovarian cancer are summarized as follows (57,58):

1. Women who appear to be at high risk for ovarian or breast cancer should undergo genetic counseling and, if the risk appears to be substantial, may be offered genetic testing for BRCA1 and BRCA2.
2. Women who wish to preserve their reproductive capacity can undergo screening by transvaginal ultrasonography every 6 months, although the efficacy of this approach is not clearly established.
3. Oral contraceptives should be recommended to young women before they embark on an attempt to have a family.
4. Women who do not wish to maintain their fertility or who have completed their families may undergo prophylactic bilateral salpingo-oophorectomy. The risk should be clearly documented, preferably established by BRCA1 and BRCA2 testing, before oophorectomy is performed. These women should be counseled that this operation does not offer absolute protection, because peritoneal carcinomas occasionally can occur after bilateral oophorectomy (20,21).
5. In women who also have a strong family history of breast cancer, annual mammographic screening should be performed beginning at age 30 years.
6. Women with a documented HNPCC syndrome should undergo periodic screening mammography, colonoscopy, and endometrial biopsy (56).

**Symptoms**

Most women with epithelial ovarian cancer have no symptoms for long periods of time. When symptoms do develop, they are often vague and nonspecific (3). In early-stage disease, the patient may experience irregular menses if she is premenopausal. If a pelvic mass is compressing the bladder or rectum, she may report urinary frequency or constipation (52,63). Occasionally, she may perceive lower abdominal distention, pressure, or pain, such as dyspareunia. Acute symptoms, such as pain secondary to rupture or torsion, are unusual.

In advanced-stage disease, patients most often have symptoms related to the presence of ascites, omental metastases, or bowel metastases. The symptoms include abdominal distention, bloating, constipation, nausea, anorexia, or early satiety. Premenopausal women may complain of irregular or heavy menses, whereas vaginal bleeding may occur in postmenopausal women (60).

**Signs**

The most important sign of epithelial ovarian cancer is the presence of a pelvic mass on physical examination. A solid, irregular, fixed pelvic mass is highly suggestive of an ovarian malignancy. If, in addition, an upper abdominal mass or ascites is present, the diagnosis of ovarian cancer is almost certain. Because the patient usually complains of abdominal symptoms, she may not have a pelvic examination, and a tumor may be missed.

In patients who are at least 1 year past menopause, the ovaries should have become atrophic and not palpable. It has been proposed that any palpable pelvic mass in these patients should be considered potentially malignant, a situation that has been referred to as the postmenopausal palpable ovary syndrome (65). This concept has been challenged, because subsequent authors have reported that only about 3% of palpable masses measuring <5 cm in postmenopausal women are malignant (45).

**Diagnosis**

Ovarian epithelial cancers must be differentiated from benign neoplasms and functional cysts of the ovaries. A variety of benign conditions of the reproductive tract, such as pelvic inflammatory disease, endometriosis, and pedunculated uterine leiomyomas, can simulate ovarian cancer. Nonneoplastic causes of a pelvic tumor, such as an inflammatory (e.g., diverticular) disease or neoplastic colonic mass, must be excluded (3). A pelvic kidney can simulate ovarian cancer.

Serum CA125 levels have been shown to be useful in distinguishing malignant from benign pelvic masses (66). For a postmenopausal patient with an adnexal mass and a very high serum CA125 level (>95 U/ml), there is a 96% positive predictive value for malignancy. For premenopausal patients, however, the specificity of the test is low because the CA125 level tends to be elevated in common benign conditions.

For the premenopausal patient, a period of observation is reasonable provided the adnexal mass does not have characteristics that suggest malignancy (i.e., it is mobile, mostly cystic, unilateral, and of regular contour). Generally, an interval of no more than 2 months is allowed, during which hormonal suppression with the oral contraceptive may be used. If the lesion is not neoplastic it should regress, as measured by pelvic examination and pelvic ultrasonography. If the mass does not regress or if it increases in size, it must be presumed to be neoplastic and must be removed surgically.

The size of the lesion is important. If a cystic mass is >8 cm in diameter, the probability is high that the lesion is neoplastic, unless the patient has been taking clomiphene citrate or other agents to induce ovulation (30,31,32 and 33). Patients whose lesions are suggestive of malignancy (i.e., predominantly solid, relatively fixed, or irregularly shaped) should undergo laparotomy, as should postmenopausal patients with adnexal masses.

The diagnosis of an ovarian cancer requires an exploratory laparotomy. Before the planned exploration, the patient should undergo routine hematologic and biochemical assessments. A preoperative evaluation in a patient undergoing laparotomy should include a radiograph of the chest and an assessment of the urinary tract with intravenous pyelography. Abdominal and pelvic computed tomography (CT) or magnetic resonance imaging (MRI) are of no value for a patient with a definite pelvic mass. A CT or MRI should be performed for patients with ascites and no pelvic mass to look for liver or pancreatic tumors. The findings only rarely preclude laparotomy (67). If the hepatic enzyme values are normal, the likelihood of liver disease is low. Liver-spleen scans, bone scans, and brain scans are unnecessary unless symptoms or signs suggest metastases to these sites. The preoperative evaluation should exclude other primary cancers metastatic to the ovary. A barium enema or colonoscopy is indicated in some patients over 45 years of age to exclude a primary colonic lesion with ovarian metastasis. This study should be performed for any patient who has evidence of occult blood in the stool or of intestinal obstruction. An upper gastrointestinal radiographic series or gastroscopy is indicated if symptoms indicate gastric involvement (3,68). Bilateral mammography is indicated if there is any breast mass, because occasionally breast cancer metastatic to the ovaries can simulate primary ovarian cancer.

Cervical cytologic study should be performed, although its value for the detection of ovarian cancer is very limited. Patients who have irregular menses or postmenopausal vaginal bleeding should have endometrial biopsy and endocervical curettage to exclude the presence of uterine or endocervical cancer metastatic to the ovary.

**Patterns of Spread**

Ovarian epithelial cancers spread primarily by exfoliation of cells into the peritoneal cavity, by lymphatic dissemination, and by hematogenous spread.

**Transcoelomic**

The most common and earliest mode of dissemination of ovarian epithelial cancer is by exfoliation of cells that implant along the surfaces of the peritoneal cavity. The cells tend to follow the circulatory path of the peritoneal fluid. The fluid tends to move with the forces of respiration from the pelvis, up the paracolic gutters, especially on the right, along the intestinal mesenteries, to the right hemidiaphragm. Therefore, metastases are typically seen on the posterior cul-de-sac, paracolic gutters, right hemidiaphragm, liver capsule, the peritoneal surfaces of the intestines and their mesenteries, and the omentum. The disease seldom invades the intestinal lumen but progressively agglutinates loops of bowel, leading to a functional intestinal obstruction. This condition is known as carcinomatous ileus (63).

**Lymphatic**

Lymphatic dissemination to the pelvic and paraaortic lymph nodes is common, particularly in advanced-stage disease (69,70 and 71). Spread through the lymphatic channels of the diaphragm and through the retroperitoneal lymph nodes can lead to dissemination above the diaphragm, especially to the supraclavicular lymph nodes (69). Burghardt and others (71) reported that 78% of patients with stage III disease have metastases to the pelvic lymph nodes. In another series (70), the rate of paraaortic lymph nodes positive for metastasis was 18% in stage I, 20% in stage II, 42% in stage III, and 67% in stage IV.

**Hematogenous**

Hematogenous dissemination at the time of diagnosis is uncommon. Spread to vital organ parenchyma, such as the lungs and liver, occurs in only about 2% to 3% of patients. Most patients with disease above the diaphragm when diagnosed have a right pleural effusion (3). Systemic metastases are seen more frequently in patients who have survived for some years. Dauplat and others (72) reported that distant metastasis consistent with stage IV disease ultimately occurred in 38% of the patients whose disease was originally intraperitoneal.

**Prognostic Factors**
The outcome of treatment can be evaluated in the context of prognostic factors, which can be grouped into pathologic, biologic, and clinical factors (73).

Pathologic Factors

The morphology and histologic pattern, including the architecture and grade of the lesion, are important prognostic variables (3). Histologic type has not generally been believed to be of prognostic significance, but several papers recently have contained suggestions that clear cell carcinomas are associated with a prognosis worse than that of other histologic types (73,74).

Histologic grade, as determined either by the pattern of differentiation or by the extent of cellular anaplasia and the proportion of undifferentiated cells, seems to be of prognostic significance (75,76,77 and 78). However, studies of the reproducibility of grading ovarian cancers have shown a high degree of intraobserver and interobserver variation (75,80). Because there is significant heterogeneity of tumors and observational bias, the value of histologic grade as an independent prognostic factor has not been clearly established. Baak and colleagues (81) have presented a standard grading system based on morphometric analysis, and the system seems to correlate with prognosis, especially in its ability to distinguish low-grade or borderline patterns from other tumors.

Biologic Factors

Several biologic factors have been correlated with prognosis in epithelial ovarian cancer. Using flow cytometry, Friedlander and co-workers (82) showed that ovarian cancers were commonly aneuploid. Furthermore, they and others showed that there was a high correlation between FIGO stage and ploidy; low-stage cancers tend to be diploid and high-stage tumors tend to be aneuploid (82,83,84,85 and 86). Patients with diploid tumors have a significantly longer median survival than those with aneuploid tumors: 5 years versus 1 year, respectively (82). Multivariate analyses have demonstrated that ploidy is an independent prognostic variable and one of the most significant predictors of survival (82). Flow cytometric analysis also provides data on the cell cycle, and the proliferation fraction (S phase) determined by this technique has correlated with prognosis in some studies (82,83,84,85 and 86).

More than 60 protooncogenes have been identified, and studies have focused on the amplification or expression of these genetic loci and their relationship to the development and progression of ovarian cancer (87,88). For example, Slamon and others (89) reported that 30% of epithelial ovarian tumors expressed HER-2/neu oncogene and that this group had a poorer prognosis, especially patients with more than five copies of the gene. Berchuck and associates (90) reported a similar incidence (32%) of HER-2/neu expression. In their series, patients whose tumors expressed the gene had a poorer median survival (15.7 months versus 32.8 months). Other groups have not substantiated this finding (82,84,85 and 89), and a review of the literature by Leary and others (92) revealed an overall incidence of HER-2/neu expression of only 11%. Thus, the prognostic value of HER-2/neu expression in ovarian cancer is unclear and further study is required.

The most commonly expressed tumor suppressor gene in ovarian cancer is p53 (87,88 and 99). Indeed, as many as one-half of all epithelial ovarian cancers have evidence of mutated p53 in the tumor.

The in vitro clonogenic assay has been studied in relation to ovarian cancer. A significant inverse correlation has been reported between clonogenic growth in vitro and survival (100,101 and 102). Multivariate analysis has found that clonogenic growth in a semisolid culture medium is a significant independent prognostic variable (102), but further study will be needed to evaluate the clinical usefulness of this essay.

Clinical Factors

In addition to stage, the extent of residual disease after primary surgery, the volume of ascites, patient age, and performance status are all independent prognostic variables (103,104,105,106,107,108,109,110 and 111). Among patients with stage I disease, D’Emilio and co-workers (108) showed, in a multivariate analysis, that tumor grade and dense adherence to the pelvic peritoneum had a significant adverse impact on prognosis, whereas intraoperative tumor spillage or rupture did not. Sipilä and others (109) confirmed that early ovarian cancers that undergo intraoperative rupture or spillage do not worsen prognosis, whereas tumors found to have already ruptured preoperatively do have a poorer prognosis. A multivariate analysis of these and several other studies was performed by Vergote (111), who found that early stage disease, poor prognostic variables were tumor grade, capsular penetration, surface excrescences, and malignant ascites, but not iatrogenic rupture.

Initial Surgery for Ovarian Cancer

Staging

Ovarian epithelial malignancies are staged according to the FIGO system listed in Table 32.2 (24). The FIGO staging is based on findings at surgical exploration. A preoperative evaluation should exclude the presence of extraperitoneal metastases.

<table>
<thead>

<td>Involves distant sites, such as liver or diaphragm</td>
</tr>
</tbody>
</table>

Table 32.2. FIGO Staging for Primary Carcinoma of the Ovary

The importance of thorough surgical staging cannot be overemphasized, because subsequent treatment will be determined by the stage of disease. For patients in whom exploratory laparotomy does not reveal any macroscopic evidence of disease on inspection and palpation of the entire intraabdominal space, a careful search for microscopic spread must be undertaken. In earlier series in which patients did not undergo careful surgical staging, the overall 5-year survival for patients with apparent stage I epithelial ovarian cancer was only about 60% (112). Since then, survival rates of 90% to 100% have been reported for patients who were properly staged and were found to have stage Ia or Ib disease (113,114).

Technique for Surgical Staging

For patients whose preoperative evaluation suggests a probable malignancy, a midline or paramedian abdominal incision is recommended to allow adequate access to the upper abdomen (3). When a malignancy is unexpectedly discovered in a patient who has a lower transverse incision, the rectus muscles can be either divided or detached from the symphysis pubis to allow better access to the upper abdomen. If this is not sufficient, the incision can be extended on one side to create a “J” incision (3).

The ovarian tumor should be removed intact, if possible, and a frozen histologic section should be obtained. If ovarian malignancy is present and the tumor is apparently confined to the ovaries or the pelvis, thorough surgical staging should be performed. Staging involves the following steps (3):

1. Any free fluid, especially in the pelvic cul-de-sac, should be submitted for cytologic evaluation.
2. If no free fluid is present, peritoneal washings should be performed by instilling and recovering 50 to 100 ml of saline from the pelvic cul-de-sac, each
paracolic gutter, and beneath each hemidiaphragm. Obtaining the specimens from under the diaphragms can be facilitated with the use of a rubber catheter attached to the end of a bulb syringe.

3. A systematic exploration of all the intraabdominal surfaces and viscera is performed, proceeding in a clockwise fashion from the Cecum cephalad along the paracolic gutter and the ascending colon to the right kidney, the liver and gallbladder, the right hemidiaphragm, the entrance to the lesser sac at the paracolic area, across the transverse colon to the left hemidiaphragm, down the left gutter and the descending colon to the rectosigmoid colon. The small intestine and its mesentery from the Treitz ligament to the cecum should be inspected.

4. Any suspicious areas or adhesions on the peritoneal surfaces should be sampled for biopsy. If there is no evidence of disease, multiple intraperitoneal biopsies should be performed. Tissue from the peritoneum of the pelvic cul-de-sac, both paracolic gutters, the peritoneum over the bladder, and the intestinal mesenteries should be taken for biopsy.

5. The diaphragm should be sampled either by biopsy or by scraping with a tongue depressor and obtaining a sample for cytologic assessment. Biopsies of any irregularities on the surface of the diaphragm can be facilitated by use of the laparoscope and the associated biopsy instrument.

6. The omentum should be resected from the transverse colon, a procedure called an infracolic omentectomy. The procedure is initiated on the underside of the greater omentum, where the peritoneum is incised just a few millimeters away from the transverse colon. The branches of the gastroepiploic vessels are clamped, ligated, and divided, along with all the small branching vessels that feed the infracolic omentum. If the gastrocolic ligament is palpably normal, it does not need to be resected.

7. The retroperitoneal spaces should be explored to evaluate the pelvic and paraaortic lymph nodes. The retroperitoneal dissection is performed by incision of the peritoneum over the psoas muscles. This may be performed on the ipsilateral side only for unilateral tumors. Any enlarged lymph nodes should be resected and submitted for frozen section. If no metastases are present, a formal pelvic lymphadenectomy should be performed.

Results

Metastases in apparent stage I and II epithelial ovarian cancer occur in as many as 3 to 10 patients whose tumors appear to be confined to the pelvis but who have occult metastatic disease in the upper abdomen or the retroperitoneal lymph nodes (70,113,114,115,116,117,118,119,120,121,122, and 123). In a review of the literature (112), occult metastases were found in biopsies of the diaphragm in 7.3% of such patients, biopsies of the omentum in 8.6%, the pelvic lymph nodes in 5.9%, the aortic lymph nodes in 18.1%, and in 26.4% of peritoneal washings. The importance of careful initial surgical staging is emphasized by the findings of a cooperative national study (113) in which 100 patients with apparent stage I and II disease who were referred for subsequent therapy underwent additional surgical staging. In this series, 28% of the patients initially believed to have stage I disease were “upstaged” and 43% of those believed to have stage II disease had more advanced lesions. A total of 31% of the patients were upstaged as a result of additional surgery. Seventy-seven percent were reclassified as having stage III disease. Histologic grade was a significant predictor of occult metastasis. Sixteen percent of the patients with grade 1 lesions were upstaged, compared with 34% with grade 2 disease and 46% with grade 3 disease.

Stage I

The primary surgical treatment for stage I epithelial ovarian cancer is surgical, and patients should undergo total abdominal hysterectomy, bilateral salpingo-oophorectomy, and surgical staging (112,113). In certain circumstances, a unilateral oophorectomy may be performed. Based on the findings at surgery and the pathologic evaluation, patients with stage I ovarian cancer can be grouped into low-risk and high-risk categories (Table 32.3).

Table 32.3. Prognostic Variables in Early-stage Epithelial Ovarian Cancer

Borderline Tumors

The principal treatment of borderline ovarian tumors is surgical resection of the primary tumor. There is no evidence that either subsequent chemotherapy or radiation therapy improves survival. After a frozen section has determined that the histology is borderline, premenopausal patients who desire preservation of ovarian function may undergo a conservative operation, a unilateral oophorectomy (3,123,124). In a study of patients who underwent unilateral ovarian cystectomy only for apparent stage I borderline serous tumors, Lim-Tan and associates (124) found that this conservative operation was also safe; only 8% of the patients had recurrences 2 to 18 years later, all with curable disease confined to the ovaries. Recurrence was associated with positive margins of the removed ovarian cyst (124). Thus, hormonal function and fertility can be maintained (3,123,124). For patients in whom an oophorectomy or cystectomy has been performed and a borderline tumor is later documented in the permanent pathology, no additional immediate surgery is necessary.

Stage I Low-grade, Low-risk

For patients who have undergone a thorough staging laparotomy and for whom there is no evidence of spread beyond the ovary, abdominal hysterectomy and bilateral salpingo-oophorectomy are appropriate therapy. The uterus and the contralateral ovary can be preserved in women with stage la, grade 1 to 2 disease who desire to preserve fertility. The conditions of the women should be monitored carefully with routine periodic pelvic examinations and determinations of serum CA125 levels. Generally, the other ovary and the uterus are removed at the completion of chidbearing.

Guthrie and others (122) studied the outcome of 656 patients with early-stage epithelial ovarian cancer. No untreated patients who had stage la, grade 1 cancer died of their disease; thus, adjuvant radiation and chemotherapy are unnecessary. Furthermore, the Gynecologic Oncology Group (GOG) carried out a prospective, randomized trial of observation versus melphalan for patients with stage la and Ib, grade 1 disease (74). Five-year survival for each group was 94% and 96%, respectively, confirming that no further treatment is needed for such patients.

Stage I High-grade, High-risk

For patients whose disease is more poorly differentiated or in whom there are malignant cells either in ascitic fluid or in peritoneal washings, complete surgical staging must be performed (3). The surgery should include the performance of a hysterectomy and bilateral salpingo-oophorectomy in addition to the staging laparotomy (3). Additional therapy is indicated, and although the optimal therapy for these patients is not known, most patients are treated with chemotherapy, as outlined below.

Cytoreductive Surgery for Advanced-stage Disease

Patients with advanced epithelial ovarian cancer documented at initial exploratory laparotomy should undergo cytoreductive surgery to remove as much of the tumor and its metastases as possible (125,126,127,128,129,130,131,132,133,134,135,136,137,138,139,140,141,142,143,144 and 145). The operation to remove the primary tumor as well as the associated metastatic disease is referred to as debulking surgery. The operation typically includes the performance of a total abdominal hysterectomy and bilateral salpingo-oophorectomy, along with a complete omentectomy and resection of any metastatic lesions from the peritoneal surfaces or from the intestines. The pelvic tumor often directly involves the rectosigmoid colon, the terminal ileum, and the cecum (Fig. 32.8). In a minority of patients,
most or all of the disease is confined to the pelvic viscera and the omentum, so that removal of these organs will result in extirpation of all gross tumor, a situation that is associated with a reasonable chance of prolonged progression-free survival.

Figure 32.7 Treatment scheme for patients with advanced-stage ovarian cancer. (*under selected circumstances or clinical trials). (From Berek JS, Hacker NF. Practical gynecologic oncology, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000:474, with permission.)

Figure 32.8 Extensive ovarian carcinoma involving the bladder, rectosigmoid, and ileocecal area. (From Heintz APM, Berek JS. Cytoreductive surgery for ovarian carcinoma. In: Piver MS, ed. Ovarian malignancies. Edinburgh: Churchill Livingstone, 1987:134, with permission.)

The removal of bulky tumor masses may reduce the volume of ascites present. Often, ascites will completely disappear after removal of the primary tumor and a large omental “cake.” Also, removal of the omental cake often alleviates the nausea and early satiety that many patients experience. Removal of intestinal metastases may restore adequate intestinal function and lead to an improvement in the overall nutritional status of the patient, thereby facilitating the patient's ability to tolerate subsequent chemotherapy.

A large, bulky tumor may contain areas that are poorly vascularized, and such areas will be exposed to suboptimal concentrations of chemotherapeutic agents. Similarly, these areas are poorly oxygenated, so that radiation therapy, which requires adequate oxygenation to achieve maximal cell kill, will be less effective. Thus, surgical removal of these bulky tumors may eliminate areas that are most likely to be relatively resistant to treatment.

In addition, larger tumor masses tend to be composed of a higher proportion of cells that are either nondividing or in the “resting” phase (i.e., G₀ cells, which are essentially resistant to the therapy). A low growth fraction is characteristic of bulky tumor masses, and cytoreductive surgery can result in smaller residual masses with a relatively higher growth fraction.

Goals of Cytoreductive Surgery

The principal goal of cytoreductive surgery is removal of all of the primary cancer and, if possible, all metastatic disease. If resection of all metastases is not feasible, the goal is to reduce the tumor burden by resection of all individual tumors to an optimal status. Griffiths (125) initially proposed that all metastatic nodules should be reduced to <1.5 cm in maximal diameter and showed that survival was significantly longer in patients for whom this was achieved.

Subsequently, Hacker and Berek (126,127, and 128) showed that patients whose largest residual lesions were <5 mm had a superior survival rate, which was substantiated by Van Lindert and co-workers (129). The median survival of patients in this category was 40 months, compared with 18 months for patients whose lesions were <1.5 cm and 6 months for patients with nodules >1.5 cm. Patients whose disease has been completely resected to no macroscopic residual disease have the best overall survival (Fig. 32.9).

Figure 32.9 Survival of patients with stage IIIc epithelial ovarian cancer based on the maximal size of residual tumor after exploratory laparotomy and tumor resection. (From Pecorelli S, Odicino F, Maisonneuve P, et al. Carcinoma of the ovary. Annual Report of the Results of Treatment of Gynaecological Cancer. J Epidemiol Biostat 1998;3:75–102, with permission.)

The resectability of the metastatic tumor is usually determined by the location of the disease. Optimal cytoreduction is difficult to achieve in the presence of extensive disease on the diaphragm, in the parenchyma of the liver, along the base of the small-bowel mesentery, in the lesser omentum, or in the porta hepatitis.

The ability of cytoreductive surgery to influence survival is limited by the extent of metastases before cytoreduction, presumably because of the presence of phenotypically resistant clones of cells in large metastatic masses. A patient whose metastatic tumor is very large (i.e., >10 cm before cytoreductive surgery) has a shorter survival than those with smaller areas of disease (128). Extensive carcinomatosis, the presence of ascites, poor tumor grade, even with lesions that measure <5 mm, may also shorten the survival (131).

Exploration
The supine position on the operating table may be sufficient for surgical exploration of most patients. However, for those with extensive pelvic disease for whom a low resection of the colon may be necessary, the low lithotomy position should be used. Debulking operations should be performed through a vertical incision to gain adequate access to the upper abdomen as well as to the pelvis.

After the peritoneal cavity is opened, ascitic fluid, if present, should be evacuated. In some centers, fluid is submitted routinely for appropriate in vitro research studies, such as molecular analyses. In cases of massive ascites, careful attention must be given to hemodynamic monitoring, especially for patients with borderline cardiovascular function.

The peritoneal cavity and retroperitoneum are thoroughly inspected and palpated to assess the extent of the primary tumor and the metastatic disease. All abdominal viscera must be palpated to exclude the possibility that the ovarian disease is metastatic, particularly from the stomach, colon, or pancreas. If optimal status is not considered achievable, extensive bowel and urologic resections are not indicated, except to overcome a bowel obstruction. However, removal of the primary tumor and omental cake is usually both feasible and desirable.

Pelvic Tumor Resection

The essential principle of removal of the pelvic tumor is to use the retroperitoneal approach. To accomplish this, the retroperitoneum is entered laterally, along the surface of the psoas muscles, which avoids the iliac vessels and the ureters. The procedure is initiated by division of the round ligaments bilaterally if the uterus is present. The peritoneal incision is extended cephalad, lateral to the ovarian vessels within the infundibulopelvic ligament, and caudally toward the bladder. With careful dissection, the retroperitoneal space is explored, and the ureter and pelvic vessels are identified. The pararectal and paravesicular spaces are identified and developed as described in Chapter 31.

The peritoneum overlying the bladder is dissected to connect the peritoneal incisions anteriorly. The vesicouterine plane is identified, and with careful sharp dissection the bladder is mobilized from the anterior surface of the cervix. The ovarian vessels are isolated, doubly ligated, and divided.

Hysterectomy, which is often not a simple operation, is then performed. The ureters must be carefully displayed to avoid injury. During this procedure, the uterine vessels can be identified. The hysterectomy and resection of the contiguous tumor are completed by ligation of the uterine vessels and the remainder of the tissues within the cardinal ligaments.

Because epithelial ovarian cancers tend not to invade the lumina of the colon or bladder, it is usually feasible to resect pelvic tumors without having to resect portions of the lower colon or the urinary tract (137, 138). However, if the disease surrounds the rectosigmoid colon and its mesentery, it may be necessary to remove that portion of the colon to clear the pelvic disease (Fig. 32.10) (137). This is justified if the patient will be left with optimal disease at the end of the cytoreduction. After the pararectal space is identified in such patients, the proximal site of colonic involvement is identified, the colon and its mesentery are divided, and the rectosigmoid is removed along with the uterus en bloc. A reanastomosis of the colon is performed. It is rarely necessary to resect portions of the lower urinary tract. Resection of a small portion of the bladder may be required and, if so, a cystotomy should be performed to assist in resection of the disease (139).

Figure 32.10 The resection of the pelvic tumor may include removal of the uterus, tubes, and ovaries, as well as portions of the lower intestinal tract. The arrows represent the plane of resection. (From Berek JS, Hacker NF. Practical gynecologic oncology, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000:480, with permission.)

Omentectomy

Advanced epithelial ovarian cancer often completely replaces the omentum, forming an omental cake. This disease may be adherent to the parietal peritoneum of the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is then lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is then lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is then lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is then lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is then lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is then lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is then lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is then lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is then lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is then lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection.

Figure 32.11 Separation of the omentum from stomach and transverse colon. (From Heintz APM, Berek JS. Cytoreductive surgery for ovarian carcinoma. In: Piver MS, ed. Ovarian malignancies. Edinburgh: Churchill Livingstone, 1987:134, with permission.)

The disease in the gastrocolic ligament can extend to the hilus of the spleen and splenic flexure of the colon on the right. Usually, the disease does not invade the parenchyma of the liver or spleen, and a plane can be found between the tumor and these organs. However, it will occasionally be necessary to perform splenectomy to remove all the omental disease (139).

Intestinal Resection

The disease may involve focal areas of the small or large intestine, and resection should be performed if it would permit the removal of all or most of the abdominal metastases. Apart from the rectosigmoid colon, the most frequent sites of intestinal metastasis are the terminal ileum, the cecum, and the transverse colon. Resection
of one or more of these segments of bowel may be necessary (137,139).

Resection of Other Metastases

Other large masses of tumor that are located on the parietal peritoneum should be removed, particularly if they are isolated masses and their removal will permit optimal cytoreduction. Resection of extensive disease from the surfaces of the diaphragm is generally neither practical nor feasible, although solitary metastases may be resected, the diaphragm sutured, and a chest tube placed for a few days (149,141). The use of the Caviltron Ultrasonic Surgical Aspirator (CUSA) and the argon beam coagulator may help facilitate resection of small tumor nodules, especially those on flat surfaces (142,143).

Feasibility and Outcome

Although no randomized prospective study has ever been performed to define the value of primary cytoreductive surgery, a prospective trial of interval cytoreductive surgery (performed after three cycles of platinum combination chemotherapy) demonstrated a survival benefit for patients who had optimal resection of their disease at that time compared with those who did not (135). All retrospective studies indicate that the diameter of the largest residual tumor nodule before the initiation of chemotherapy is significantly related to progression-free survival in patients with advanced ovarian cancer. In addition, quality of life is likely to be significantly enhanced by removal of bulky tumor masses from the pelvis and upper abdomen (136). An analysis of the retrospective data available suggests that these operations are feasible for 70% to 90% of patients when performed by gynecologic oncologists (133,139,144). Major morbidity is in the range of 5% and operative mortality is in the range of 1% (139,145). Intestinal resection in these patients does not appear to increase the overall morbidity caused by the operation (137,139). The performance of a pelvic lymphadenectomy in patients with stage III disease has been reported to prolong survival (77), although verification of this awaits a prospective, randomized study.

Treatment with Chemotherapy

Stage I Epithelial Ovarian Cancer

Stage I Low-grade, Low-risk

Guthrie and others (122) studied the outcome of 656 patients with early-stage epithelial ovarian cancer. No patients who had stage Ia, grade 1 cancer who did not receive radiation or chemotheraphy died of their disease; thus adjuvant therapy is unnecessary. Furthermore, the GOG carried out a prospective, randomized trial of observation versus melphalan for patients with stage Ia and Ib, grade 1 disease (74). Five-year survival for each group was 94% and 90%, respectively, confirming that adjuvant treatment did not improve survival. Therefore, no adjuvant chemotherapy is recommended for these patients.

Stage I High-grade, High-risk

In patients whose disease is high-risk (e.g., more poorly differentiated or in whom there are malignant cells either in ascitic fluid or in peritoneal washings), additional therapy is indicated. Most investigators recommend chemotherapy for these patients (146,147,148,149,150,151,152,153,154,155,156,157,158,159,160 and 161). Chemotherapy for patients with early stage high-risk epithelial ovarian cancer can be either single agent or multiagent. Some researchers have questioned the wisdom of overly aggressive chemotherapy in women with early stage disease, suggesting that the evidence for a durable impact on survival is marginal (148,149,155). Furthermore, the risk of leukemia with alkylating agents and platinum make the administration of adjuvant therapy risky unless there is a significant benefit (160,161).

Because cisplatin, carboplatin, cyclophosphamide, and paclitaxel (Taxol) are active single agents against epithelial ovarian cancer, these drugs have been administered in various combinations. There are some series in which cisplatin or cyclophosphamide (PC) or both have been used to treat patients with stage I disease (150,151 and 152). In a GOG trial of three cycles of cisplatin and cyclophosphamide versus intraperitoneal chromic phosphate (72P) in patients with stage Ib and Ic disease, the progression-free survival of women receiving the platinum-based chemotherapy was 31% higher than those receiving the radiocolloid (152). Similar results were also reported by a multicenter trial performed in Italy by the Gruppo Italiano Collaborativo Oncologica Ginecologica (GICOOG) for progression-free survival, although there was no overall survival advantage. Carboplatin can be substituted for cisplatin in the therapy of these patients (158), although it is unclear if there is a survival benefit. The current GOG trial consists of three cycles of carboplatin and paclitaxel followed by a randomization to either observation versus 26 weeks of weekly low-dose (40 mg/m²) paclitaxel.

The recommendations for therapy follow:

- Patients with high-grade, high-risk stage I epithelial ovarian cancer be given adjuvant chemotherapy. The type depends on the patient's overall health and status.
- Treatment with carboplatin and paclitaxel chemotherapy for three to six cycles seems desirable in most patients, whereas a short course of a single agent, either carboplatin or paclitaxel, may be preferable for older women.

Advanced-stage Epithelial Ovarian Cancer

Systemic multiagent chemotherapy is the standard treatment for metastatic epithelial ovarian cancer (162,163,164,165,166,167,168,169,170,171,172,173,174,175,176,177,178,179 and 180). After the introduction of cisplatin in the latter half of the 1970s, platinum-based combination chemotherapy became the most frequently used treatment regimen in the United States. Paclitaxel became available in the 1980s, and this drug was incorporated into the combination chemotherapy in the 1990s (162,163,164,165,166 and 167). Comparative trials of paclitaxel, cisplatin, and carboplatin are summarized below.

In a meta-analysis performed on studies of patients with advanced-stage disease, those patients given cisplatin-containing combination chemotherapy were compared with those treated with regimens that did not include cisplatin (171). Survival differences between the groups were seen from 2 to 5 years, with the cisplatin group having a slight survival advantage, but this difference disappeared by 8 years.

The major advance in the treatment of advanced-stage disease was the incorporation of paclitaxel into the chemotherapeutic regimens. A series of randomized, prospective clinical trials with paclitaxel-containing arms have defined the current recommended treatment protocol in advanced epithelial ovarian cancer (165,166,175,176).

Reporting the GOG data (Protocol 111), McGuire and others showed that the combination of cisplatin (75 mg/m²) and paclitaxel (135 mg/m²) was superior to cisplatin (75 mg/m²) and cyclophosphamide (600 mg/m²), each given for six cycles (165). In suboptimally resected patients, the paclitaxel-containing arm produced a 36% reduction in mortality. These data were verified in a trial conducted jointly by the European Organization for the Research and Treatment of Cancer (EORTC), the Nordic Ovarian Cancer Study Group (NOCOVA), and the National Cancer Institute of Canada (NCIC) in which patients with both optimal and suboptimal disease were treated (166). In this study the paclitaxel-containing arm produced a significant improvement in both progression-free interval and overall survival in both optimal and suboptimal groups (Fig 32.12). Based on these two studies, paclitaxel should be included in the primary treatment of all women with advanced-stage epithelial ovarian cancer, unless precluded by toxicity.
A three-arm comparison of paclitaxel (T) versus cisplatin (P) versus PT in suboptimal stage III and IV patients (protocol 132) showed equivalency in the three groups, but crossover from one drug to the other was permitted (167). The study essentially showed that the combination regimen was better tolerated than the sequential administration of the agents in suboptimally resected patients.

The second-generation platinum analogue, carboplatin, was introduced and developed to have less toxicity than its parent compound, cisplatin. In early trials, carboplatin was shown to have lower overall toxicity (169). Fewer gastrointestinal side effects, especially nausea and vomiting, were observed than with cisplatin, and there was less nephrotoxicity, neurotoxicity, and ototoxicity. Carboplatin is, however, associated with a higher degree of myelosuppression.

The initial studies showed that carboplatin and cisplatin had approximately a 4:1 equivalence ratio. Thus a standard single-agent dose of about 400 mg/m² has been used in most phase II trials. The dose is calculated by using the area under the curve (AUC) and the glomerular filtration rate (GFR) according to the Calvert formula (181). The target AUC is 5–6 for untreated patients with ovarian cancer. Alternatively, a dose of approximately 350 to 450 mg/m² carboplatin can be used initially in patients with a normal serum creatinine and adjusted to toxicity. A platelet nadir of approximately 50,000/ml is a suitable target (169).

**Carboplatin and Paclitaxel**

Two randomized, prospective clinical studies have compared the combination of paclitaxel and carboplatin to paclitaxel and cisplatin (175,176). In both studies, the efficacy and survivals were similar, but the toxicity was more acceptable with the carboplatin-containing regimen. In the first trial, GOG Protocol 158, the randomization was carboplatin AUC = 7.5 and paclitaxel 175 mg/m² over 3 hours versus cisplatin 75 mg/m² and paclitaxel 135 mg/m² over 24 hours. The disease progression–free survival of the carboplatin-containing arm was 22 months versus 21.7 months for the control arm (175). The gastrointestinal and neurotoxicity of the carboplatin arm were appreciably lower than that of the cisplatin arm. A similar result was obtained in a large randomized trial in Germany (176), in which the dose of carboplatin was AUC = 6 and paclitaxel was 185 mg/m² over 3 hours compared with the same dose of paclitaxel and cisplatin 75 mg/m². Ongoing trials are comparing the combination of carboplatin and paclitaxel with single-agent carboplatin or combination cisplatin chemotherapy (177). The preferred regimen in patients with advanced-stage disease is the paclitaxel plus carboplatin combination.

**Intraperitoneal Chemotherapy**

A randomized, prospective trial of intraperitoneal cisplatin versus intravenous cisplatin (100 mg/m²), each given with 750 mg/m² cyclophosphamide, has been performed jointly by the Southwest Oncology Group (SWOG) and the GOG in patients with minimal residual disease (182). The intraperitoneal cisplatin arm had a somewhat longer overall median survival than the intravenous arm, 49 versus 41 months (p = 0.03). In the patients with minimal residual disease (<0.5 cm maximal residual), however, there was no difference between the two treatments, 51 versus 46 months (p = 0.08).

In a follow-up trial (GOG Protocol 114), the dose-intense arm was initiated by giving a moderately high dose of carboplatin (dose AUC = 9) for two induction cycles, followed by intraperitoneal cisplatin 100 mg/m² and intravenous paclitaxel 135 mg/m² over 24 hours, versus intravenous cisplatin 75 mg/m² and intravenous paclitaxel 135 mg/m² (183). The dose-intense arm results were slightly better—the disease progression–free median survival was 27.6 months compared with 22.5 months for the control arm (p = 0.02). However, there was no difference in overall survival (52.9 months versus 47.6 months, p = 0.056). Thus, it is unclear if dose intensification with intraperitoneal hape cisplatin will have a sustained long-term impact on the survival of these patients. A randomized prospective GOG study is comparing intraperitoneal hape cisplatin and hape paclitaxel versus intravenous hape cisplatin and hape paclitaxel.

Based on these two studies, the value of intraperitoneal chemotherapy in the primary treatment of optimally resected stage III ovarian cancer remains unclear.

**Neoadjuvant Chemotherapy**

Some authors have suggested that, for patients with suboptimal stage III and stage IV disease, chemotherapy may be given in lieu of debulking surgery. A series performed by Schwartz and co-workers (184) suggested that the survival of these patients treated with neoadjuvant or cytoreductive chemotherapy was comparable to those historically treated in the same institution with debulking surgery followed by conventional chemotherapy. As other authors have shown a benefit to debulking patients prior to chemotherapy (195), the issue would need to be resolved by a prospective clinical trial.

However, two or three cycles of chemotherapy prior to cytoreductive surgery may be helpful in patients with massive ascites and large pleural effusions. The chemotherapy may dry up the effusions, improve the patient's performance status, and decrease postoperative morbidity, particularly chest morbidity.

**Chemotherapeutic Recommendation in Advanced Epithelial Ovarian Cancer**

For the treatment of advanced-stage epithelial ovarian cancer, the following is recommended (Table 32.4):

<table>
<thead>
<tr>
<th>Stage</th>
<th>Cycle</th>
<th>Drug</th>
<th>Dose</th>
<th>Duration</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>IVA, IVC</td>
<td>1st</td>
<td>Carboplatin</td>
<td>135 mg/m²</td>
<td>100 mg/m²</td>
<td>24 hours</td>
</tr>
<tr>
<td>IVA, IVC</td>
<td>2nd</td>
<td>Paclitaxel</td>
<td>75 mg/m²</td>
<td>135 mg/m²</td>
<td>24 hours</td>
</tr>
</tbody>
</table>

**Table 32.4. Combination Chemotherapy for Advanced Epithelial Ovarian Cancer: Recommended Regimens**
Combination chemotherapy with hape carboplatin and paclitaxel as the treatment of choice for patients with advanced disease. The recommended doses and schedule are hape carboplatin (starting dose AUC = 5 to 6) and hape paclitaxel (175 mg/m^2) given over 3 hours every 3 weeks for six cycles.

In patients who cannot tolerate the combination, single-agent hape carboplatin (AUC = 5 to 6) can be given.

In those who have a hypersensitivity to hape paclitaxel, an alternative active drug can be substituted (e.g., hape cyclophosphamide or hape topotecan).

In patients who cannot tolerate intravenous chemotherapy, an oral alkylating agent can be substituted.

The treatment of all patients with advanced-stage disease is approached in a similar manner, with modifications based on the overall status and general health of the patient, as well as the extent of residual disease present at the time treatment is initiated.

Immunotherapy

There is currently a great deal of interest in the use of immunotherapies in ovarian cancer. Cytokines have been used extensively in second-line therapy, and the activity of hape interferon-a, interferon-g, and hape interleukin-2 has been demonstrated, as discussed below (3). In a recent trial of hape interferon-g plus hape cisplatin combination chemotherapy versus chemotherapy alone, patients who received the hape interferon had a longer disease progression–free survival (185).

Trials of monoclonal antibodies directed toward ovarian cancer–associated antigens are being conducted. Antibodies directed toward CA125 and toward the HMFG (human milk fat globulin) tumor–associated antigens are underway. Herceptin, an antibody directed toward the extracellular protein produced when the HER-2/neu oncogene is overexpressed, has been used extensively in breast cancer where it has been shown to improve the response rate to chemotherapy in selected patients. Trials of this antibody in patients whose ovarian cancers overexpress HER-2/neu are ongoing. Antibodies against mutated p53 tumor suppressor gene are also undergoing clinical testing (3).

Hormonal Therapy

There is no evidence that hormonal therapy alone is appropriate primary therapy for advanced ovarian cancer. The use of pregnotational agents in the treatment of recurrent well-differentiated endometriod carcinomas is supported by the current data. In a study by Rendina and co-workers (186), 30 evaluable patients with recurrent epithelial cancers were treated; 17 (57%) had an objective response, and three (10%) of these patients achieved a complete response. All responding patients had well-differentiated, estrogen receptor–positive tumors. A trial of hape tamoxifen in combination with multiagent chemotherapy is being conducted.

Tumor Markers

Tumor markers are not reliable enough to predict accurately which patients with epithelial tumors will experience complete eradication of disease with a particular therapy. Carcinomerobryonic antigen (CEA) levels are often elevated in patients with ovarian cancer, but the test is too nonspecific and insensitive to have much use in the management of these patients (3).

The level of CA125, a surface glycoprotein associated with müllerian epithelial tissues, is elevated in about 80% of patients with epithelial ovarian cancers, particularly those with nonmucinous tumors. The levels frequently become undetectable after the initial surgical resection and one or two cycles of chemotherapy.

Levels of CA125 have been correlated with findings at second-look operations. Positive levels are useful in predicting the presence of disease, but negative levels are an insensitive determinant of the absence of disease. In a prospective study (197), the predictive value of a positive test was shown to be 100%; if the level of CA125 was positive (>35 U/ml), disease was always detectable in patients at the second-look procedure. The predictive value of a negative test was only 56%; if the level was <35 U/ml, disease was present in 44% of the patients at the time of the second-look surgery. A review of the literature suggests that an elevated CA125 level predicts persistent disease at second-look surgery in 97% of the cases (198), but the CA125 level is not sensitive enough to exclude subclinical disease in many patients.

Serum CA125 levels can be used during chemotherapy to follow those patients whose levels were positive at the initiation of therapy (3,198). The change in level generally correlates with response. Those patients with persistently elevated levels after three cycles of treatment most likely have resistant clones. When levels rise after treatment, almost invariably treatment has failed and continuation of the current regimen is futile.

Radiologic Assessment

For patients with stage I to III epithelial ovarian cancer, radiologic tests generally have been of limited value in assessing the response to therapy for subclinical disease. Ascites can be readily detected, but even quite large peritoneal metastases can be missed on CT scan (199). If liver enzyme levels are abnormal, the liver can be evaluated with a CT scan or ultrasonography. A positive CT scan and fine-needle aspiration (FNA) cytology indicating tumor persistence could obviate the need for second-look surgery, but the false-negative rate of a CT scan is about 45% (200).

Second-look Operations

A second-look operation is one performed on a patient who has no clinical evidence of disease after a prescribed course of chemotherapy to determine the response to therapy.

Second-look Laparotomy

The technique of the second-look laparotomy is essentially identical to that for the staging laparotomy (112). The operation should be performed through a vertical abdominal incision. The incision should be initiated below the level of the umbilicus, so that if pelvic disease is detected in the absence of any palpable upper abdominal disease, a smaller incision might suffice. The incision can be extended cranially as needed.

After multiple cytologic specimens have been obtained, samples of the peritoneal surfaces should be collected for biopsy, particularly in any areas of previously documented tumor. These are the most important areas to sample for biopsy because they are most likely to give a positive result. Any adhesions or surface irregularities should be sampled. In addition, biopsy specimens should be taken from the pelvic side walls, the pelvic cul-de-sac, the bladder, the paracolic gutters, the residual omentum, and the diaphragm. A pelvic and paraaortic lymph node dissection should be performed for those patients whose nodal tissues have not been previously removed.

About 30% of patients with no evidence of macroscopic disease will have microscopic metastases (185). Also, for many patients with microscopic disease, it will be detected in only the occasional biopsy or cytologic specimen. Therefore, a large number of specimens (at least 20 to 30) should be obtained to minimize possibility of false-negative results of the operation. For selected patients in whom gross residual tumor is discovered at second-look surgery, resection of isolated masses may be performed. The removal of all macroscopic areas of disease might facilitate response to salvage therapies (201,202,203,204,205,206 and 207).
Second-look laparotomies have not been shown to influence patient survival (191,192). Therefore, they should be performed only in a research setting, in which second-line or salvage therapies are undergoing clinical trials.

The findings at second look correlate with subsequent outcome and survival (112,186,187,188,189,190,191,192 and 193). Patients who have no histologic evidence of disease have a significantly longer survival than those in whom microscopic or macroscopic disease is documented at laparotomy (192,193).

The attainment of negative findings with second-look surgery is not tantamount to a cure (184,186). Indeed, the reported probability that a patient will have a recurrence after a negative second-look laparotomy ranges from 30% to 50% at 5 years (112,186,187,188,189,191,192 and 193). Clearly, it is not possible to sample every potential site of disease. In addition, disease can become clinically apparent in sites that are occult, such as the liver parenchyma (72). Most recurrences after a negative second-look laparotomy occur in patients with poorly differentiated cancers (193).

Variables associated with the outcome of the second-look laparotomy are (a) initial stage, (b) tumor grade, (c) the size of the residual tumor and the size of the largest metastatic tumor before treatment, and (d) the type of chemotherapy. No single variable or combination of variables is sufficiently predictive to obviate a planned second-look laparotomy (3,112).

Second-look Laparoscopy

The advantage of laparoscopy is that it is less invasive than laparotomy; the disadvantage is that visibility may be limited by the frequent presence of intraperitoneal adhesions (194,195 and 196). The development of newer techniques for retroperitoneal lymph node dissection has potentially increased the utility of the endoscopic approach to a second look. The morbidity and role of this technique are currently being studied by the GOG.

One technique that has been used for second look is called open laparoscopy. This procedure allows placement of the scope after a cutdown to the fascia of the rectus abdominus has been performed. The peritoneum is entered under direct vision, thus avoiding the blind insertion that can be associated with intestinal injury (3,195).

The sensitivity of the laparoscopic technique has been variously defined, by exploratory laparotomy performed immediately after a negative laparoscopy. Thirty-five percent of those who had negative findings on laparoscopy had evidence of disease at laparotomy (196), but these patients did not undergo a lymphadenectomy at laparoscopy.

Laparoscopy has been used immediately before a planned laparotomy. If gross disease is detected and secondary resection of the tumor is not possible, a laparotomy may be omitted (196).

Thus, the role of the laparoscope for patients with epithelial ovarian cancer is still being defined. It may be used to stage disease in patients who have undergone a prior laparotomy for a tumor that was incompletely staged. Second-look laparoscopy may also be useful for patients on experimental treatment protocols, especially second-line treatments that require some evaluation of response.

Second-line Therapy

Secondary Cytoreduction

Patients with persistent or recurrent pelvic and abdominal tumors after primary therapy for ovarian cancer may be candidates for surgical excision of their disease. This operation has been referred to as secondary cytoreductive surgery (201,202,203,204,205,206 and 207). Tumor resection, under these circumstances, should be restricted to carefully selected patients for whom resection has a reasonable chance of either prolonging life or resulting in significant palliation of symptoms, because there is no benefit for most patients with persistent or progressive disease after primary therapy. The patient for whom secondary cytoreduction might be appropriate should be in good general medical condition. A suitable patient would be one who has no evidence of ascites, has not yet received hape cisplatin combination chemotherapy, has had at least a partial response to prior alkylating agent therapy, and has had a reasonably long interval since primary diagnosis. If the patient has previously received hape cisplatin, secondary cytoreduction is justified if there has been a long disease-free survival (longer than 12–24 months), because such patients are likely to respond again to the primary chemotherapy (185,186,187,188,189 and 190).

The goal of secondary debulking is to remove all residual gross tumor, if possible, or to reduce the metastatic tumor burden to <5 mm maximal dimension. Some patients with minimal residual disease will respond to second-line treatment. Those patients in whom the residual disease is completely resected have a significantly longer survival than those who do not (185).

Second-line Chemotherapy

If disease persists at the time of second-look laparotomy, or if clinically progressive disease develops during primary therapy, patients usually have been switched to an alternative treatment, often a second-line chemotherapy. The response rates for secondary-line chemotherapies have been 15% to 35% for most drugs tested by the oral or intravenous route (208,209,210,211,212,213,214,215,216,217,218,219,220,221,222,223,224,225,226,227,228 and 229). Active drugs that have been used as single agents include hape cisplatin, hape carboplatin, paclitaxel, docetaxel (hape Taxotere), hape topotecan, gemcitabine, etoposide (hape VP-16), hape doxorubicin (hape Doxi), hape vinorelbine (hape Navelbine), hape ifosfamide, 5-fluouracil with hape leucovorin, and hape hexamethylmelamine. Single-agent drugs are sometimes used for second-line chemotherapy because of their relative ease of administration and low toxicity.

Platinum-sensitive Versus Platinum-resistant

Second-line therapies have been categorized by whether or not the patients responded to their initial hape platinum-based chemotherapy. Although this concept has been variously defined, hape platinum sensitivity has been related to a disease progression–free interval of 12 to 24 months. Response rates after second-line chemotherapy in patients who have responded previously to hape cisplatin treatment, and response rates in these patients have been 20% to 30% (210). The concept of hape platinum sensitivity and hape paclitaxel sensitivity should influence the choice of second-line chemotherapy.

In patients who have hape platinum- or hape paclitaxel-sensitive tumors, retreatment with a hape platinum drug or hape paclitaxel is appropriate. Second-line responses to hape paclitaxel, carboplatin, and hape cisplatin in those patients who have responded previously to hape cisplatin have been observed in 20% to 25% of patients.

In hape cisplatin-refractory patients, response rates to second-line hape carboplatin are less than 10% (208,211). In hape platinum-resistant disease, persistent disease is best treated with non–cross-resistant agents that have different anticancer mechanisms such as the topoisomerase inhibitors (e.g., hape etoposide and hape topotecan), an anthracycline (e.g., hape doxorubicin (hape Doxi)), an alkylating agent (e.g., hape ifosfamide), or other agents, (e.g., hape hexamethylmelamine). These agents have resulted in second-line response rates of about 8% to 28% in patients with hape platinum-resistant disease (213,214,215,216,217,218,219,220,221,222,223,224,225,226,227,228,229 and 230).

Several new combinations of chemotherapy are now being tested in advanced epithelial ovarian cancer. The rationale for this approach is that the two agents have complementary mechanisms and toxicities of action. Combinations such as hape gemcitabine and hape platinum, and hape topotecan and hape platinum may have greater activity than either agent alone. Various neuroprotective and myelosuppressive protectors, such as hape amifostine, are being tested in hape cisplatin combination regimens.

Intraperitoneal Therapy
For patients with minimal residual (<5 mm) or microscopic disease confined to the peritoneal cavity, consideration can be given to intraperitoneal chemotherapy or immunotherapy. The failure of second-line intravenous chemotherapy to control residual disease has led to the use of intraperitoneal therapies for small, persistent disease. Cytotoxic chemotherapeutic agents, such as hape cisplatin, 5-fluorouracil, cytoxane arabinoside (hape Ara-C ), hape etoposide (hape VP-16), and hape mitomadione, have been used for patients with persistent epithelial ovarian cancer ( 231,232,233,234,235,236,237,238,239 and 240), and complete responses have been seen in patients who begin treatment with minimal residual disease. The surgically documented response rates reported with this approach are about 20% to 40% for carefully selected patients, and the complete response rate is about 10% to 20%. hape Cisplatin seems to be the best drug, although various combinations of agents (e.g., hape cisplatin plus hape etoposide) have been shown to have significant activity (233,234). Although it has been suggested that this approach produces a significant subsequent improvement in survival (236), there are no prospective phase III data, and the patients so treated tend to be those with a more favorable prognosis regardless of subsequent therapy.

Another approach is the use of intraperitoneal immunotherapy such as hape interferon (241,242,243,244,245,246 and 247), hape Interferon has been found to have some activity for patients with minimal residual disease (241,242). Intraperitoneal administration hape interferon-a, hape-g tumor necrosis factor, and hape interleukin-2 has been performed. The response rate for the intraperitoneal cytokines, hape interferon-a and hape interferon-γ is the same as that for the cytotoxic agents (i.e., about 30% to 50%) (241,242,243,244,245,246 and 247). The intraperitoneal administration of hape interferon-a has produced a 32% (9 of 28) surgically documented complete response rate, and a 50% (14 of 28) total response rate for patients with minimal residual disease after primary combination chemotherapy with hape cisplatin (241,242,246).

The interferons have been combined with cytotoxic agents in an effort to increase the overall response rates. In several trials, the combination of hape cisplatin and hape interferon-a seemed to produce a 50% complete response rate, which was greater than that produced by either single agent (244,245 and 246). However, in a prospective, single-arm, phase II trial conducted by the GOG, the intraperitoneal administration of hape cisplatin and hape interferon-a produced only a 7% response rate (247). In this GOG trial, most patients had hape cisplatin-refractory tumors with >5 mm residual disease, generalized carcinomatosis, and ascites. Surgically documented responses to intraperitoneal therapy have been generally limited to patients with minimal residual disease (i.e., <5 mm maximal tumor dimension) and patients whose tumors have been responsive to hape cisplatin chemotherapy.

**Candidates for Intraperitoneal Therapy** Intraperitoneal treatment is not suitable for all patients because it can be cumbersome, requiring catheters that remain functional. Neither patients with extensive intraperitoneal adhesions nor patients with extraperitoneal disease are appropriate candidates. On the basis of these issues and the failure to achieve responses in most patients with bulky, hape platinum-refractory disease, second-line intraperitoneal chemotherapy and immunotherapy should still be considered experimental.

**Hormonal Therapy**

Tamoxifen has been associated with response rates of 15% to 20% in well-differentiated carcinomas of the ovary (250,251). The gonadotropin agonist hape leuprolide acetate (hape Lupron) has been shown to produce a response rate of 10% in one series (252). Trials combining hape tamoxifen and hape leuprolide acetate, and hape tamoxifen and combination chemotherapy are being conducted (253). Aromatase inhibitors (e.g., hape Arimidex), which have been shown to have activity in metastatic breast cancer, are being studied in relapsed ovarian cancer (254).

**Radiation Therapy**

Whole-abdominal radiation therapy given as a salvage treatment has been shown to be associated with a relatively high morbidity. The principal problem associated with this approach is the development of acute and chronic intestinal morbidity. As many as 30% of patients treated with this approach develop intestinal obstruction, which will necessitate exploratory surgery with potentially morbid effects (255).

**Intestinal Obstruction**

Patients with epithelial ovarian cancer often develop intestinal obstruction, either at the time of initial diagnosis or, more frequently, in association with recurrent disease (112,256,257,258,259,260,261,262,263 and 264). Obstruction may be related to a mechanical blockage or to carcinomatous ileus.

The intestinal blockage can be corrected in most patients whose obstruction appears at the time of initial diagnosis. However, the decision to perform an exploratory procedure to ease intestinal obstruction in patients with recurrent disease is more difficult. For patients whose life expectancy is very short (e.g., <2 months), surgical relief of the obstruction is not indicated (256). For those whose projected lifespan is longer, features that predict a reasonable likelihood of correcting the obstruction include young age, good nutritional status, and the absence of rapidly accumulating ascites (257).

For most patients with recurrent ovarian cancer who have intestinal obstruction, initial management should include proper radiographic documentation of the obstruction, hydration, correction of any electrolyte disturbances, parenteral alimentation, and intestinal intubation. For some patients, the obstruction may be alleviated by this conservative approach. A preoperative upper gastrointestinal radiographic series and a barium enema will define possible sites of obstruction.

If exploratory surgery is deemed appropriate, the type of operation to be performed will depend on the site and the number of obstructions. Multiple sites of obstruction are not uncommon in patients with recurrent epithelial ovarian cancer. More than one-half of the patients have small-bowel obstruction, one-third have colonic obstruction, and one-sixth have both (256,259,260,261 and 262). If the obstruction is principally contained in one area of the bowel (e.g., the terminal ileum), this area can either be resected or bypassed, depending on whether a concomitant effort at secondary cytoreduction is indicated. If multiple obstructions are present, resection of several segments of intestine in patients with recurrent disease is usually not indicated, and intestinal bypass surgery or colostomy, or both, should be performed.

Intestinal bypass is generally associated with less morbidity than resection (112,256,259), and in patients with recurrent, progressive cancer, the survival time after these two operations is the same (256). Most frequently, an enterenterostomy or an enterocolostomy is performed (260,261, and 262). Colostomy may be necessary when there is a distal large-bowel obstruction. Occasionally, the performance of an ileostomy or a jejunostomy is warranted when the large bowel is completely encased in tumor (112). In very advanced cases, a gastrostomy may be used for palliative purposes, and the gastrostomy can be placed percutaneously if there is no carcinomatosis around the stomach (263,264).

Among 268 patients reported to have undergone operations for intestinal obstruction resulting from ovarian cancer, the operative mortality was 14% and major complications were seen in 34% of the patients (256,257,258,259,260,261 and 262). The need for multiple reanastomoses and prior radiation therapy increased the morbidity, which consisted primarily of sepsis and enterocutaneous fistulas.

The median survival time for patients who have undergone intestinal surgery for obstruction secondary to ovarian cancer ranges from 2.5 to 7 months, although Castaldo and co-workers (256) reported that 17% of such patients survived longer than 12 months.

**Survival**

The prognosis for patients with epithelial ovarian disease is related to several clinical variables. Survival analyses based on the most commonly used prognostic variables are presented (1,3,4,103,104,105,106 and 107). Including patients at all stages, patients less than 50 years of age have a 5-year survival rate of about 40%, compared with about 15% for patients older than 50 years. The 5-year survival rate for carefully and properly staged patients with stage I disease is 76% to 93%, depending on the tumor grade. The 5-year survival rate for stage II is 60% to 74%. The 5-year survival rate for stage III is 41%, for stage IIIf about 25%, for stage IIIc 23%, and for stage IV disease 11% (ref 32,13).
An analysis of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database reveals a trend toward improved survival for ovarian cancer in the United States during the last period of analysis (1988 to 1994). In this cohort, the survival for stage I was 83%, for stage II 70%, for stage III 37%, and for stage IV 25%. Compared with the interval 1983 to 1987, there was a statistically significant improvement in survival for stages I, III, and IV disease. Survival of patients with borderline tumors is excellent, with stage I lesions having a 98% 15-year survival. When all stages of borderline tumors are included, the 5-year survival rate for grade 1 epithelial ovarian cancers is about 91%, compared with about 74% for grade 2 and 75% for grade 3. For stage II disease, the survivals are 69%, 60%, and 51%, respectively, for grades 1, 2, and 3. Examining stage III to IV patients, the 5-year survival rates for grades 1, 2, and 3, respectively, are 38%, 25%, and 19%. Patients with stage III disease with microscopic residual disease at the start of treatment have a 5-year survival rate of about 40% to 75%, compared with about 30% to 40% for those with optimal disease and only 5% for those with nonoptimal disease. Patients whose Karnofsky's index (KI) is low (<70) have a significantly shorter survival than those with a KI >70.

**Non-epithelial Ovarian Cancers**

Compared with epithelial ovarian cancers, other malignant tumors of the ovary are uncommon. Non-epithelial malignancies of the ovary account for about 10% of all ovarian cancers. Non-epithelial ovarian cancers include malignancies of germ cell origin, sex cord–stromal cell origin, metastatic carcinomas to the ovary, and a variety of extremely rare ovarian cancers (e.g., sarcomas, lipoid cell tumors). Although there are many similarities in the presentation, evaluation, and management of these patients, these tumors also have many unique qualities that require a special approach.

**Germ Cell Malignancies**

Germ cell tumors are derived from the primordial germ cells of the ovary. Their incidence is only about one-tenth the incidence of malignant germ cell tumors of the testis, so most of the advances in the management of these tumors have been extrapolations from experience with the corresponding testicular tumors. Although malignant germ cell tumors can arise in extragonadal sites such as the mediastinum and the retroperitoneum, most germ cell tumors arise in the gonad from undifferentiated germ cells. The variation in the site of these cancers is explained by the embryonic migration of the germ cells from the caudal part of the yolk sac to the dorsal mesentery before their incorporation into the sex cords of the developing gonads.

**Classification**

A histologic classification of ovarian germ cell tumors is presented in Table 32.5. Both a-fetoprotein (AFP) and human chorionic gonadotropin (hCG) are secreted by some germ cell malignancies; therefore, the presence of circulating hormones can be clinically useful in the diagnosis of a pelvic mass and in monitoring the course of a patient after surgery. Placental alkaline phosphatase (PLAP) and lactate dehydrogenase (LDH) are commonly produced by dysgerminomas and may be useful for monitoring the disease. α1-Antitrypsin (AAT) can rarely be detected in association with germ cell tumors. When the histologic and immunohistologic identification of these substances in tumors is correlated, a classification of germ cell tumors emerges.

**Table 32.5. Histologic Typing of Ovarian Germ Cell Tumors**

![Table 32.5](image)

In this scheme, embryonal carcinoma (a cancer composed of undifferentiated cells) synthesizes both hCG and AFP, and this lesion is the progenitor of several other germ cell tumors. More differentiated germ cell tumors, such as the endodermal sinus tumor, which secretes AFP, and the choriocarcinoma, which secretes hCG, are derived from the extraembryonic tissues; the immature teratomas derived from the embryonic cells have lost the ability to secrete these substances. Pure
germinomas do not secrete these markers.

**Epidemiology**

Although 20% to 25% of all benign and malignant ovarian neoplasms are of germ cell origin, only about 3% of these tumors are malignant (2,3). Germ cell malignancies account for fewer than 5% of all ovarian cancers in Western countries. Germ cell malignancies represent up to 15% of ovarian cancers in Asian and African American societies, where epithelial ovarian cancers are much less common.

In the first 2 decades of life, almost 70% of ovarian tumors are of germ cell origin, and one-third of these are malignant (2,3,266). Germ cell tumors account for two-thirds of the ovarian malignancies in this age group. Germ cell cancers also are seen in the third decade, but thereafter they become quite rare.

**Clinical Features**

**Symptoms**

In contrast to the relatively slow-growing epithelial ovarian tumors, germ cell malignancies grow rapidly and often are characterized by subacute pelvic pain related to capsular distention, hemorrhage, or necrosis. The rapidly enlarging pelvic mass may produce pressure symptoms on the bladder or rectum, and menstrual irregularities also may occur in menarcheal patients. Some young patients may misinterpret the early symptoms of a neoplasm as those of pregnancy, and this can lead to a delay in the diagnosis. Acute symptoms associated with torsion or rupture of the adnexa can develop. These symptoms may be confused with acute appendicitis. In more advanced cases, ascites may develop, and the patient can have abdominal distention (268).

**Signs**

For a patient with a palpable adnexal mass, the evaluation can proceed as outlined. Some patients with germ cell tumors will be premenarcheal and may require examination under anesthesia. If the lesions are principally solid or a combination of solid and cystic, as might be noted on an ultrasonographic evaluation, a neoplasm is probable and a malignancy is possible (see Fig. 13.11 and Chapter 13). During the remainder of the physical examination, effort should be directed to searching for signs of ascites, pleural effusion, and organomegaly.

**Diagnosis**

Adnexal masses measuring 2 cm or larger in premenarcheal girls or 8 cm or larger in other premenopausal patients will usually require surgical exploration. For young patients, blood tests should include serum HCG and AFP titers, a complete blood count, and liver function tests. A radiograph of the chest is important because germ cell tumors can metastasize to the lungs or mediastinum. A karyotype should be obtained preoperatively for all premenarcheal girls because of the propensity of these tumors to arise in dysgenetic gonads (267,271). A preoperative CT scan or MRI may document the presence and extent of retroperitoneal lymphadenopathy or liver metastases; however, because these patients require surgical exploration, such extensive and time-consuming evaluation is unnecessary. If postmenarcheal patients have predominantly cystic lesions up to 8 cm in diameter, they may be observed or given oral contraceptives for two menstrual cycles (271,272).

**Dysgerminoma**

Dysgerminoma is the most common malignant germ cell tumor, accounting for about 30% to 40% of all ovarian cancers of germ cell origin (2,3,270). The tumors represent only 1% to 3% of all ovarian cancers, but they represent as many as 5% to 10% of ovarian cancers in patients younger than 20 years. Seventy-five percent of dysgerminomas occur between the ages of 10 and 30 years, 5% occur before the age of 10 years, and they rarely occur after 50 years of age (2,3,268). Because these malignancies occur in young women, 20% to 30% of ovarian malignancies associated with pregnancy are dysgerminomas.

Dysgerminomas are found in both sexes and may arise in gonadal or extragonadal sites. The latter include the midline structures from the pineal gland to the mediastinum and the retroperitoneum. Histologically, they represent abnormal proliferations of the basic germ cell. In the ovary, the germ cells are encapsulated at birth (the primordial follicle), and the unencapsulated or free cells die. If either of the latter processes fails, it is conceivable that the germ cell could free itself of its normal control and multiply indiscriminately.

The size of dysgerminomas varies widely, but they are usually 5 to 15 cm in diameter (2,3). The capsule is slightly bosselated, and the consistency of the cut surface is spongy and gray-brown in color (Fig. 32.15).

![Figure 32.15 Dysgerminoma of the ovary. Note that the lesion is principally solid with some cystic areas. (From Berek JS, Hacker NF, Practical gynecologic oncology, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000:526, with permission.)](image)

The histologic characteristics of the dysgerminoma are very distinctive. The large round, ovoid, or polygonal cells have abundant, clear, very-pale–staining cytoplasm, large and irregular nuclei, and prominent nucleoli (Fig. 32.16). Mitotic figures are seen in varying numbers, although they are usually numerous. Another characteristic feature is the arrangement of the elements in lobules and nests separated by fibrous septa, which are often extensively infiltrated with lymphocytes, plasma cells, and granulomas with epithelial cells and multinucleated giant cells. When necrosis is extensive, the lesion may be confused with tuberculosis. Occasional dysgerminomas may contain syncytiotrophoblastic giant cells and may be associated with precocious puberty or virilization. The presence of these cells does not seem to alter the behavior of the tumor (2,3).
The most frequently used chemotherapeutic regimens for germ cell tumors are BEP (regarded as the treatment of choice for the more immature teratomas, it is logical that these two tumors may coexist. Choriocarcinoma, endodermal sinus tumor, and other extraembryonal lesions are also commonly associated with the dysgerminoma.

Approximately 5% of dysgerminomas are discovered in phenotypic females with abnormal gonads. This malignancy can be associated with patients who have pure gonadal dysgenesis (46,XY, bilateral streak gonads), mixed gonadal dysgenesis (45,XY/46,XY, unilateral streak gonad, contralateral testis), and the androgen insensitivity syndrome (46,XY, testicular feminization). Therefore, for premenarcheal patients with a pelvic mass, the karyotype should be determined (see Chapter 23.)

For most patients with gonadal dysgenesis, dysgerminomas arise in gonadoblastomas, which are benign ovarian tumors that are composed of germ cells and sex cord stroma. If gonadoblastomas are left in situ in patients with gonadal dysgenesis, more than 50% will develop into ovarian malignancies.

About 75% of dysgerminomas are stage I (i.e., confined to one or both ovaries) at diagnosis. About 85% to 90% of stage I tumors are confined to one ovary; 10% to 15% are bilateral. In fact, dysgerminoma is the only germ cell malignancy that has this significant rate of bilaterality. Other germ cell tumors are rarely bilateral.

For patients whose contralateral ovary has been preserved, disease can develop in 5% to 10% of the retained gonads over the next 2 years. This figure includes those not given additional therapy, as well as patients with gonadal dysgenesis.

In the 25% of patients who are diagnosed initially with metastatic disease, the tumor most commonly spreads via the lymphatic system. It can also spread hematogenously or by direct extension through the capsule of the ovary with exfoliation and dissemination of cells throughout the peritoneal surfaces. Metastases to the contralateral ovary may be present when there is no other evidence of spread. An uncommon site of metastatic disease is bone; when metastasis to this site occurs, the lesions are seen principally in the lower vertebrae. Metastases to the lungs, liver, and brain are seen most often in patients with long-standing or recurrent disease. Metastasis to the mediastinum and supraclavicular lymph nodes is usually a late manifestation of disease.

For patients whose karyotype analysis reveals a Y chromosome, both ovaries should be removed, although the uterus may be left in situ for possible future embryo transfer. Whereas cytoreductive surgery is of unproved value, bulky disease that can be readily resected (e.g., an omental cake) should be removed during the initial operation.

Surgery

The minimal surgical operation for ovarian dysgerminoma is a unilateral oophorectomy. If there is a desire to preserve fertility, the contralateral ovary, fallopian tube, and uterus should be left in situ, even in the presence of metastatic disease, because of the sensitivity of the tumor to chemotherapy. If fertility need not be preserved, it may be appropriate to perform a total abdominal hysterectomy and bilateral salpingo-oophorectomy for patients with advanced disease. For patients whose karyotype analysis reveals a Y chromosome, both ovaries should be removed, although the uterus may be left in situ for possible future embryo transfer. Whereas cytoreductive surgery is of unproved value, bulky disease that can be readily resected (e.g., an omental cake) should be removed during the initial operation.

Radiation Therapy

Dysgerminomas are very sensitive to radiation therapy, and doses of 2,500 to 3,500 cGy may be curative, even for gross metastatic disease. Loss of fertility is a problem with radiation therapy, however, so radiation should rarely be used as first-line treatment.

Chemotherapy

Many patients with a dysgerminoma will have a tumor that is apparently confined to one ovary and will be referred for further treatment after unilateral salpingo-oophorectomy without surgical staging. The options for such patients are repeat laparotomy for surgical staging, regular pelvic and abdominal surveillance with CT scans, and adjuvant chemotherapy. Because dysgerminomas are rapidly growing tumors, regular CT surveillance is preferable. Tumor markers (AFP and hCG) should also be monitored in case occult mixed germ cell elements are present.

There have been numerous reports of successful control of metastatic dysgerminomas with systemic chemotherapy, and this technique should now be regarded as the treatment of choice. The most frequently used chemotherapeutic regimens for germ cell tumors are BEP (bepotecin, etoposide, and cisplatin), VBP (bepotecin, vincristine, and cisplatin), and BEV (bepotecin, etoposide, and vinblastine).
bleomycin, and hape cisplatin), and VAC (hape vincristine, actinomycin, and hape cyclophosphamid) (278,279,280,281,282,283,284,285,286,287,288 and 289) (Table 32.6).

### Immature Teratomas

Immature teratomas contain elements that resemble tissues derived from the embryo. Immature teratomatous elements may occur in combination with other germ cell tumors as mixed germ cell tumors. The pure immature teratoma accounts for fewer than 1% of all ovarian cancers, but it is the second most common germ cell tumor type, representing 90% of all pure immature teratomas. Although in the past, surgery for advanced disease followed by pelvic and abdominal irradiation resulted in a 5-year survival rate of 63% to 83%, cure rates of 85% to 90% for this same group of patients are now being reported with the use of VBP, BEP, or EC combination chemotherapy (290,291,292).

#### Prognosis

For patients whose initial disease is stage Ia (i.e., a unilateral encapsulated dysgerminoma), unilateral oophorectomy alone results in a 5-year disease-free survival rate of greater than 95% (277,278). The features that have been associated with a higher tendency to recur include lesions larger than 10 to 15 cm in diameter, age younger than 20 years, and a microscopic pattern that includes numerous mitoses, anaplasia, and a medullary pattern (279,280,281,282,283,284,285,286,287,288). Although in the past, surgery for advanced disease followed by pelvic and abdominal irradiation resulted in a 5-year survival rate of 63% to 83%, cure rates of 85% to 90% for this same group of patients are now being reported with the use of VBP, BEP, or EC combination chemotherapy (278,279,280,281,282,283,284,285,286,287,288).

### Pathology

Immature teratomas contain elements that resemble tissues derived from the embryo. Immature teratomatous elements may occur in combination with other germ cell tumors as mixed germ cell tumors. The pure immature teratoma accounts for fewer than 1% of all ovarian cancers, but it is the second most common germ cell tumor type, representing 90% of all pure immature teratomas. Although in the past, surgery for advanced disease followed by pelvic and abdominal irradiation resulted in a 5-year survival rate of 63% to 83%, cure rates of 85% to 90% for this same group of patients are now being reported with the use of VBP, BEP, or EC combination chemotherapy (278,279,280,281,282,283,284,285,286,287,288).
Of fundamental importance in the understanding of the teratoma is a recognition of the maturation of the various elements. If maturation continues along normal lines, the mature or adult teratoma results, and the prognosis is excellent. Conversely, abnormal maturation of these elements produces undisciplined growth that can be fatal. Teratomas containing immature elements, although relative rate, have been recognized more commonly during the past two decades (Fig. 32.18). Among the tumors with embryonal elements, those containing neural tissues demonstrate most clearly the importance of the ability to mature. Glionmatosis peritonei is the most dramatic demonstration of the significance of maturation, because most patients with these tumors have survived, even with this disseminated disease (3).

Immature teratomas are classified according to a grading system (grades 1 to 3) that is based on the degree of differentiation and the quantity of immature tissue (241). A determination of the amount of undifferentiated neural tissue is of prognostic importance. A grade 1 tumor is one in which less than one low-power microscopic field (LPF) contains immature neural elements, a grade 2 tumor has one to three LPFs with immature elements, and a grade 3 tumor has more than three LPFs with these elements. The prognosis can be correlated with the grade determined by the quantity of these immature neural elements; with a higher grade there is a poorer prognosis (2,3).

Previously, most malignant teratomas were classified as secondary neoplasms developing in a primarily benign teratoma. During the last decade, lesions composed primarily of immature embryonal or extraembryonal elements have become more prevalent, and the basic demonstration of malignancy is the inability of the tissue to mature rather than the presence of individual cell anaplasia (i.e., the mitotic activity may be low). This unique aspect is demonstrated by an absence of aneuploidy in the few cases that have been studied (3).

Malignant change in benign cystic teratomas has been recorded as occurring in 0.5% to 2% of cases, usually in patients over 40 years of age (293). The most common malignancy developing in the initial benign teratoma is squamous cell carcinoma. Other neoplasms have been reported (e.g., melanomas, which may arise from the skin or retinal anlage, and sarcomas, including leiomyosarcomas and mixed mesodermal tumors) (295). Carcinomas may arise from any of the epithelial elements.

**Diagnosis**

The preoperative evaluation and differential diagnosis of immature teratomas are the same as for other germ cell tumors. Some of these lesions will contain calcifications similar to those of mature teratomas, which can be detected by a radiograph of the abdomen or by ultrasonography. Rarely, they are associated with the production of steroid hormones and can be accompanied by sexual pseudoprecocity (296). Tumor markers are negative unless a mixed germ cell tumor is present.

**Treatment**

**Surgery**

For a premenopausal patient whose lesion appears to be confined to a single ovary, unilateral oophorectomy and surgical staging should be performed. For a postmenopausal patient, a total abdominal hysterectomy and bilateral salpingo-oophorectomy may be performed. Contralateral involvement is rare, and routine resection or wedge biopsy of the contralateral ovary is unnecessary (3,293). Any lesions on the peritoneal surfaces should be sampled and submitted for histologic evaluation. The most frequent site of dissemination is the peritoneum and, much less commonly, the retroperitoneal lymph nodes. Bloodborne metastases to organ parenchyma, such as the lungs, liver, or brain, are uncommon. When present, they are usually seen in patients with late or recurrent disease and most often in tumors that are poorly differentiated (i.e., grade 3).

**Chemotherapy**

Patients with stage la, grade 1 tumors have an excellent prognosis, and no adjuvant therapy is required. For patients whose tumors are stage la, grades 2 or 3, adjuvant chemotherapy should be used (281,282 and 283,290,302). Chemotherapy is also indicated for patients who have ascites, regardless of tumor grade. The most frequently used combination chemotherapeutic regimen in the past has been VAC (296,297 and 298). However, in a GOG study, the relapse-free survival rate in patients with incompletely resected disease was only 75% (298). The newer approach has been to incorporate hape cisplatin into the primary treatment of these tumors, and most of the experience has been with the VBP and BEP regimens (302). No direct comparison of these regimens with VAC has been reported, but the BEP combination can save some patients who have persistent or recurrent disease after VAC (302).

The GOG has been prospectively studying three courses of BEP therapy for patients with completely resected stage I, II, and III ovarian germ cell tumors (302). Overall, the toxicity has been acceptable, and 91 of 93 patients whose nonsyndromic germatomaus tumors were treated are clinically free of disease. Thus, the BEP regimen, which is used more extensively for testicular cancer, seems to be superior to the VAC regimen in the treatment of completely resected non dysgerminomatous germ cell tumors of the ovary. Because some tumors can progress rapidly, treatment should be initiated as soon as possible after surgery, preferably within 7 to 10 days.

The switch from VBP to BEP has been prompted by the experience in patients with testicular cancer, in which the replacement of vinblastine with etoposide has been associated with a better therapeutic index (i.e., equivalent efficacy and lower morbidity), especially less neurologic and gastrointestinal toxicity. Furthermore, the use of hape bleomycin seems to be important for this group of patients. In a randomized study of three cycles of hape etoposide plus hape cisplatin with or without hape bleomycin (EP versus BEP) in 180 patients with germ cell tumors of the testes, the BEP regimen had a relapse-free survival rate of 84% compared with 69% for the EP regimen (p = 0.03) (285). In addition, hape cisplatin may be slightly better than hape carboplatin in the setting of metastatic germ cell tumors. Two hundred ninety-two patients with germ cell tumors of the testes were entered into a study of four cycles of hape etoposide plus hape cisplatin (EP) versus four cycles of etoposide plus hape carboplatin (EC). There have been three relapses with the EP regimen versus seven with the EC regimen, although the overall survival of the two groups is identical thus far (286). In view of these results, BEP is the preferred treatment regimen for patients with gross residual disease and has replaced the VAC regimen for patients with completely resected disease.

Patients who have immature teratomas with malignant squamous elements seem to have a poorer prognosis than those whose tumors are without these elements (285). The treatment in these patients is also the BEP regimen.

**Radiation Therapy**

Radiation therapy is generally not used in the primary treatment of patients with immature teratomas. Furthermore, there is no evidence that the combination of chemotherapy and radiation has a higher rate of disease control than chemotherapy alone. Radiation therapy should be reserved for patients with localized persistent
The addition of a second-look operation has been questioned (291-292). It seems not to be justified in patients who have received chemotherapy in an adjuvant setting (i.e., stage Ia, grades 2 and 3), because chemotherapy in these patients is so effective. Second-look laparotomy in patients with macroscopic residual disease is of value at the start of chemotherapy, because there are no reliable tumor markers for this disease and such patients are at higher risk of failure. If a second-look operation is performed, sampling of any peritoneal lesions should be performed and the retroperitoneal lymph nodes should be evaluated carefully. If only mature elements are found during the second-look procedure, chemotherapy should be discontinued. If the presence of persistent immature elements is documented, alternative chemotherapy should be employed. An enlarged contralateral ovary may contain a benign cyst or a mature cystic teratoma, which may be managed with an ovarian cystectomy (266-268).

Prognosis

The most important prognostic feature of the immature teratoma is the grade of the lesion (2,293). In addition, the stage of disease and the extent of tumor at the initiation of treatment have an impact on the curability of the lesion. Patients whose tumors have been incompletely resected before treatment have a significantly lower probability of 5-year survival than those whose lesions have been completely resected (i.e., 94% versus 50%) (269). Overall, the 5-year survival rate for patients with all stages of pure immature teratomas is 70% to 80%, and it is 90% to 95% for patients with surgically determined stage I lesions (290,293,294). The degree or grade of immaturity generally correlates with the metastatic potential and curability. The 5-year survival rates for all stages combined have been reported to be 82%, 62%, and 30% for patients with grades 1, 2, and 3, respectively (293). Occasionally, these tumors are associated with mature or low-grade glial elements that have implanted throughout the peritoneum, and such patients usually have a favorable long-term survival (2,3).

Endodermal Sinus Tumors

Endodermal sinus tumors (EST) have also been referred to as yolk sac carcinomas, because they are derived from the primitive yolk sac (2,3). These lesions are the third most frequent malignant germ cell tumors of the ovary. ESTs occur in patients with a median age of 16 to 18 years (2,3,303,304). About one-third of the patients are premenarcheal at the time of diagnosis. Abdominal or pelvic pain is the most frequent initial symptom, occurring in about 75% of patients, whereas an asymptomatic pelvic mass is documented in 10% of patients (267).

Pathology

The gross appearance of an EST is soft grayish-brown. Cystic areas caused by degeneration are present in these rapidly growing lesions. The capsule is intact in most cases.

The EST is unilateral in 100% of cases; thus, biopsy of the opposite ovary in such young patients is contraindicated. The association of such lesions with gonadal dysgenesis must be appreciated, and chromosomal analysis should be performed preoperatively in premenarcheal patients (3).

Microscopically, the characteristic feature is the endodermal sinus, or hape Schiller-Duval body (Fig. 32.19). The cystic space is lined with a layer of flattened or irregular endoderm into which projects a glomerulus-like tuft with a central vascular core. These structures vary throughout the tumor, and the reticular, myxoid elements represent undifferentiated mesoblast. The lining of the papillary infolding and the cavity is irregular, with an occasional cell containing clear, glassy cytoplasm, simulating the hobnail appearance of the epithelium in clear cell tumors. The association of EST with dysgerminoma must be emphasized if diagnosis and therapy are to be optimal (2,3).

Figure 32.19 Endodermal sinus tumor of the ovary. Note the classic Schiller-Duval body with its central vessel and mantle of endoderm (arrow). (From Berek JS, Hacker NF. Practical gynecologic oncology, 2nd ed. Baltimore: Williams & Wilkins, 1994:151, with permission.)

Most EST lesions secrete AFP and, rarely, they may elaborate detectable AAT. AFP can be demonstrated in the tumor by means of the immunoperoxidase technique. There is a good correlation between the extent of disease and the level of AFP, although discordance also has been observed. The serum level of these markers, particularly AFP, is useful in monitoring the patient's response to treatment (303,304,305,306,307,308 and 309).

Treatment

Surgery

The treatment of the EST consists of surgical exploration, unilateral salpingo-oophorectomy, and a frozen section for diagnosis. The addition of a hysterectomy and contralateral salpingo-oophorectomy does not alter outcome (268,307). Any gross metastases should be removed, if possible, but thorough surgical staging is not indicated because all patients need chemotherapy. At surgery, the tumors tend to be solid and large, ranging in size from 7 to 28 cm (median, 15 cm) in the GOG series (268,302). Bilaterality is not seen in these lesions, and the other ovary is involved with metastatic disease only when there are other metastases in the peritoneal cavity. Most patients have early-stage disease: 71%, stage I; 6%, stage II; and 23%, stage III (309).

Chemotherapy

All patients with ESTs are treated with either adjuvant or therapeutic chemotherapy. Before the routine use of combination chemotherapy for this disease, the 2-year survival rate was only about 25%. After the introduction of the VAC regimen, this rate improved to 60% to 70%, indicating the chemosensitivity of most of these tumors (297,298). Furthermore, with conservative surgery and adjuvant chemotherapy, fertility can be preserved as with other germ cell tumors.

VPB is a more effective regimen in the treatment of EST, particularly in the treatment of measurable or incompletely resected tumors (302). In the GOG series, only about 20% of patients with residual metastatic disease responded completely to the VAC regimen, whereas about 60% of those treated with VPB had a complete response (293). In addition, this regimen may save some patients in whom VAC therapy has failed.

Workers at the Charing Cross Hospital in London have developed the POMB-ACE regimen for high-risk germ cell tumors of any histologic type (310) (Table 32.7). This protocol introduces seven drugs into the initial management, which is intended to minimize the chances of developing drug resistance. Drug resistance is
particularly relevant for patients with massive metastatic disease, and the POMB-ACE regimen may be used as primary therapy for such patients as well as for those with liver or brain metastases. The POMB schedule is only moderately myelosuppressive, so the intervals between each course can be kept to a maximum of 14 days (usually 9 to 11 days), thereby minimizing the time for tumor regrowth between courses. When hape bleomycin is given by a 48-hour infusion, pulmonary toxicity is reduced. With a maximum of 9 years of follow-up, the Charing Cross group has seen no long-term side effects for patients treated with POMB-ACE. Children have developed normally, menstruation has been physiologic, and several have completed normal pregnancies.

Cisplatin-containing combination chemotherapy, preferably BEP or POMB-ACE, should be used as primary chemotherapy for ESTs. The optimal number of treatment cycles has not been established. The GOG protocols have used three to four treatment cycles given every 4 weeks (302,310). Alternatively, three cycles can be given to patients with stage I and completely resected disease, and two further cycles can be given after negative tumor marker status is achieved by patients with macroscopic residual disease before chemotherapy.

Second-look Laparotomy

The value of a second-look operation has yet to be established in patients with an EST. It seems reasonable to omit the operation for patients with pure low-stage lesions and for patients whose AFP values return to normal and remain normal for the balance of their treatment (308,309). There have been reported cases in which the AFP has returned to normal despite persistent measurable disease; some of these cases have been mixed germ cell tumors (309). For patients whose AFP levels do not return to normal, persistent disease can be assumed and alternative chemotherapy (e.g., POMB-ACE) can be offered.

Embryonal Carcinoma

Embryonal carcinoma of the ovary is an extremely rare tumor that is distinguished from a choriocarcinoma of the ovary by the absence of syncytiotrophoblastic and cytotrophoblastic cells. The patients are very young; ages ranged between 4 and 28 years (median, 14 years) in two series (311). Older patients have been reported (312). Embryonal carcinomas may secrete estrogens, with the patient exhibiting symptoms and signs of precocious pseudopuberty or irregular bleeding (2). The clinical picture is otherwise similar to that of the EST. The primary lesions tend to be large, and about two-thirds are confined to one ovary at the time of diagnosis. These lesions frequently secrete AFP and hCG, which are useful for following the response to subsequent therapy (308). The treatment of embryonal carcinomas is the same as for the EST (i.e., a unilateral oophorectomy followed by combination chemotherapy with BEP) (282,306). Radiation does not seem to be useful for primary treatment.

Choriocarcinoma of the Ovary

Pure nongestational choriocarcinoma of the ovary is an extremely rare tumor. Histologically, it has the same appearance as gestational choriocarcinoma metastatic to the ovaries (313). Most patients with this cancer are younger than 20 years. The presence of hCG can be useful in monitoring the patient's response to treatment. In the presence of high hCG levels, isosexual precocity has been seen to occur in about 50% of patients whose lesions appear before menarche (314).

There are only a few limited reports on the use of chemotherapy for nongestational choriocarcinomas, but complete responses have been reported with the MAC (hape methotrexate, actinomycin D, and hape cyclophosphamide) regimen used in a manner described for gestational trophoblastic disease (313) (see Chapter 34). Alternatively, the BEP regimen can be used. The prognosis of ovarian choriocarciomas has been poor, with most patients having metastases to organ parenchyma at the time of diagnosis.

Polyembryoma

Polyembryoma of the ovary is another extremely rare tumor, which is composed of “embryoid bodies.” This tumor replicates the structures of early embryonic differentiation (i.e., the three somatic layers: endoderm, mesoderm, and ectoderm) (2,270). The lesion tends to occur in very young, premenarcheal girls with signs of pseudopuberty and elevated AFP and hCG titers. Anecdotally, the VAC chemotherapy regimens have been reported to be effective (287).

Mixed Germ Cell Tumors

Mixed germ cell malignancies of the ovary contain two or more elements of the lesions described above. In one series (315), the most common component of a mixed malignancy was dysgerminoma, which occurred in 80%, followed by EST in 70%, immature teratoma in 53%, choriocarcinoma in 20%, and embryonal carcinoma in 16%. The most frequent combination was a dysgerminoma and an EST. The mixed lesions may secrete either AFP, hCG, or both or neither of these markers, depending on the components.

These lesions should be managed with combination chemotherapy, preferably BEP. The serum marker, if positive initially, may become negative during chemotherapy, but this finding may reflect regression of only a particular component of the mixed lesion. Therefore, for these patients, a second-look laparotomy may be indicated to determine the precise response to therapy if macroscopic disease was present at initiation of chemotheraphy.

The most important prognostic features are the size of the primary tumor and the relative size of its most malignant component (315). For stage IA lesions smaller than 10 cm, survival is 100%. Tumors composed of less than one-third EST, choriocarcinoma, or grade 3 immature teratoma also have an excellent prognosis, but it is less favorable when these components constitute most of the mixed lesions.

Sex Cord–stromal Tumors

Sex cord–stromal tumors of the ovary account for about 5% to 8% of all ovarian malignancies (23,266,267,316,317,318 and 319). This group of ovarian neoplasms is derived from the sex cords and the ovarian stroma or mesenchyme. The tumors usually are composed of various combinations of elements, including the "female" cells (i.e., granulosa and theca cells), and "male" cells (i.e., Sertoli and Leydig cells), as well as morphologically indifferent cells. A classification of this group of tumors is presented in Table 32.8.

</table>
Granulosa cell tumors, which secrete estrogen, are seen in women of all ages. They are found in prepubertal girls in 5% of cases; the remainder are found in women throughout their reproductive and postmenopausal years (319). Granulosa cell tumors are bilateral in only 2% of patients.

**Pathology**

Granulosa cell tumors range from a few millimeters to 20 centimeters or more in diameter. The tumors are rarely bilateral, and they have a smooth, lobulated surface. The solid portions of the tumor are granular, frequently trabeculated, and are commonly yellow or gray-yellow in color. The granulosa-theca cell tumor is probably the most inaccurately diagnosed lesion of the female gonad. Of 477 ovarian tumors from the Emil Novak Ovarian Tumor Registry diagnosed initially as granulosa-theca cell tumors, almost 15% were reclassified after histologic review. Lesions misdiagnosed as granulosa cell tumors included metastatic carcinomas, teratoid tumors, and poorly differentiated mesothelial tumors (316).

The classic granulosa cell is round or ovoid with scant cytoplasm. The nucleus contains compact, finely granular cytoplasm suggesting hyperchromatism (3). “Coffee bean” grooved nuclei are common, as are mitoses, thus simulating the corresponding elements in the normal, mature follicle. Conversely, if the epithelial elements are bizarre with atypical mitoses, the lesion should not be categorized as a poorly differentiated granulosa cell tumor but instead as an undifferentiated mesothelial neoplasm. In the most common variety, the granulosa cells show a tendency to arrange themselves in small clusters or rosettes around a central cavity, so there is a resemblance to primordial follicles (i.e., hape Call-Exner bodies) (Fig. 32.20). The stroma is similar to the theca and may be luteinized. In children and adolescents, the granular cell tumors are often cystic, contain luteinized cells, and can be associated with precocious puberty.

![Figure 32.20 Granulosa cell tumor of the ovary. Note the classic Call-Exner bodies (arrow) with a minimal stromal component in this tumor of folliculoid pattern. (From Berek JS, Hacker NF. Practical gynecologic oncology. 2nd ed. Baltimore: Williams & Wilkins, 1994:153, with permission.)](image)

**Diagnosis**

Of the rare prepubertal lesions, 75% are associated with sexual pseudoprecocity because of the estrogen secretion (319). For women of reproductive age, most patients have menstrual irregularities or secondary amenorrhea, and cystic hyperplasia of the endometrium is frequently present. For postmenopausal women, abnormal uterine bleeding is the initial symptom. Indeed, the estrogen secretion in these patients can be sufficient to stimulate the development of endometrial cancer. Endometrial cancer occurs in association with granulosa cell tumors in at least 5% of cases, and 25% to 50% are associated with endometrial hyperplasia (3,316,317,318 and 319).

The other symptoms and signs of granulosa cell tumors are nonspecific and the same as most ovarian malignancies. Ascites is present in about 10% of cases, and rarely a pleural effusion is present (316,317,318 and 319). Granulosa tumors tend to be hemorrhagic; occasionally, they rupture and produce a hemoperitoneum.

Granulosa cell tumors are usually stage I at diagnosis but may recur 5 to 30 years after initial diagnosis (318). The tumors may also spread hematogenously, and metastases can develop in the lungs, liver, and brain years after initial diagnosis. When granulosa cell tumors do recur, they can progress quite rapidly. Malignant thecomas are extremely rare, and their signs and symptoms, management, and outcome are similar to those of the granulosa cell tumors (316). Inhibin is secreted by some granulosa cell tumors and is a useful marker for the disease (320,321 and 322).

**Treatment**

The treatment of granulosa cell tumors depends on the age of the patient and the extent of disease. For most patients, surgery alone is sufficient primary therapy; radiation and chemotherapy are reserved for the treatment of recurrent or metastatic disease (319,320,321 and 322).

**Surgery**

Because granulosa cell tumors are bilateral in only about 2% of patients, a unilateral salpingo-oophorectomy is appropriate therapy for stage Ia tumors in children or in women of reproductive age (317). At the time of laparotomy, if a granulosa cell tumor is identified by frozen section, a staging operation is performed, including an assessment of the contralateral ovary. If the opposite ovary appears enlarged, it should be sampled for biopsy. For perimenopausal and postmenopausal women for whom ovarian preservation is not important, a hysterectomy and bilateral salpingo-oophorectomy should be performed. For premenopausal patients in whom the uterus is left in situ, an endometrial biopsy should be performed, because of the possibility of a coexisting adenocarcinoma of the endometrium (319).

**Radiation Therapy**

There is no evidence to support the use of adjuvant radiation therapy for granulosa cell tumors, although pelvic irradiation may help to palliate isolated pelvic recurrences (319).

**Chemotherapy**

There is no evidence that adjuvant chemotherapy will prevent recurrence of disease. Metastatic lesions and recurrences have been treated with a variety of antineoplastic drugs. The most effective chemotherapeutic regimen appears to be BEP. In a GOG study (323), 37% (14 of 30) patients treated with BEP had a negative second-look laparotomy, and completely responding patients had a median time to progression of 24.4 months. The use of hormonal agents such as progestins or antiestrogens has been suggested, but there are no data available to suggest effectiveness (317).

**Prognosis**

Granulosa cell tumors have a prolonged natural history and a tendency toward late relapse, reflecting their low-grade biology. As such, 10-year survival rates of about 90% have been reported, with 20-year survival rates dropping to 75% (317,318 and 319). Most histologic types have the same prognosis, but patients with the more poorly differentiated diffuse or sarcomatoid type tend to do worse (316).

The DNA ploidy of the tumors has recently been correlated with survival. Holland and colleagues (324) reported DNA aneuploidy in 13 of 37 patients (35%) with primary granulosa cell tumors. The presence of residual disease was found to be the most important predictor of progression-free survival, but DNA ploidy was an independent prognostic factor. Patients with residual-negative DNA diploid tumors had a 10-year progression-free survival of 96%.

Granulosa-theca tumors are extremely rare, and their signs and symptoms, management, and outcome are similar to those of the granulosa cell tumors (316). The stroma is similar to the theca and may be luteinized.
Sertoli-Leydig Tumors

Sertoli-Leydig tumors occur most frequently in the third and fourth decades of life; 75% of the lesions are seen in women younger than 40 years. These lesions are extremely rare and account for less than 0.2% of ovarian cancers (2). Sertoli-Leydig cell tumors are most frequently low-grade malignancies, although occasionally a poorly differentiated variety may behave more aggressively.

The tumors typically produce androgens, and clinical virilization is noted in 70% to 85% of patients (325). Signs of virilization include oligomenorrhea followed by amenorrhea, breast atrophy, acne, hirsutism, clitoromegaly, deepening of the voice, and a receding hairline. Measurement of plasma androgens may reveal elevated testosterone and androstenedione, with normal or slightly elevated dehydroepiandrosterone sulphate (2,326). Rarely, the Sertoli-Leydig tumor can be associated with manifestations of estrogenization (i.e., iosexual precocity, irregular or postmenopausal bleeding).

Treatment

Because these low-grade lesions are only rarely bilateral (<1%), the usual treatment is unilateral salpingo-oophorectomy and evaluation of the contralateral ovary for patients who are in their reproductive years (3,319). For older patients, hysterectomy and bilateral salpingo-oophorectomy are appropriate.

There are insufficient data to document the utility of radiation or chemotherapy for patients with persistent disease, but some responses in patients with measurable disease have been reported with pelvic irradiation and the VAC chemotherapy regimen (1,328).

Prognosis

The 5-year survival rate is 70% to 90%, and recurrences thereafter are uncommon (3,326). Most fatalities occur in the presence of poorly differentiated lesions.

Uncommon Ovarian Cancers

There are several varieties of malignant ovarian tumors that together constitute only 0.1% of ovarian malignancies (2). Two of these lesions are the lipoid (or lipid) cell tumors and the primary ovarian sarcomas.

Lipoid Cell Tumors

Lipoid cell tumors are believed to arise in adrenal cortical rests that reside in the vicinity of the ovary. More than 100 cases have been reported, and bilateral disease has been noted in only a few (2). Most are associated with virilization and, occasionally, with obesity, hypertension, and glucose intolerance reflecting corticosteroid secretion. Rare cases of estrogen secretion and iosexual precocity have been reported.

Most of these tumors have benign or low-grade behavior, but about 20%, most of which are initially larger than 8 cm in diameter, are associated with metastatic lesions. Metastases are usually in the peritoneal cavity but rarely occur at distant sites. The primary treatment is surgical extirpation of the primary lesion. There are no data regarding the effectiveness of radiation or chemotherapy for this disease.

Sarcomas

Malignant mixed mesodermal sarcomas of the ovary are extremely rare; only about 100 cases have been reported. Most lesions are heterologous, and 80% occur in postmenopausal women. The signs and symptoms are similar to those of most ovarian malignancies. These lesions are biologically aggressive, and most patients have evidence of metastases.

There is no effective treatment for ovarian sarcomas, and most patients die within 2 years. 

Small Cell Carcinomas

This rare tumor occurs at an average age of 24 years (range 2 to 46 years) (389). The tumors are all bilateral. Approximately two-thirds of the tumors are accompanied by paraendocrine hypercalcemia. This tumor accounts for one-half of all of the cases of hypercalcemia associated with ovarian tumors. About 50% of the tumors have spread beyond the ovaries when they are diagnosed (329).

The management of these malignancies consists of surgery followed by platinum-based chemotherapy or radiation therapy or both. In addition to the primary treatment of the disease, control of the hypercalcemia may require aggressive hydration, loop diuretics, and the use of bisphosphonates or 

Metastatic Tumors

About 5% to 6% of ovarian tumors are metastatic from other organs, most frequently from the female genital tract, the breast, or the gastrointestinal tract (330,331,332,333,334 and 335). The metastases may occur from direct extension of another pelvic neoplasm, by hematogenous spread, lymphatic spread, or transcoelomic dissemination, with surface implantation of tumors that spread in the peritoneal cavity.

Gynecologic

Nonovarian cancers of the genital tract can spread by direct extension or they may metastasize to the ovaries. Tubal carcinoma involves the ovaries secondarily in 13% of cases (2,3), usually by direct extension. Under some circumstances, it is difficult to know whether the tumor originated in the tube or in the ovary when both are involved. Cervical cancer spreads to the ovary only in rare cases (<1%), and most of these are of an advanced clinical stage or are adenocarcinomas. Although adenocarcinoma of the endometrium can spread and implant directly onto the surface of the ovaries in as many as 5% of cases, two synchronous primary tumors probably occur with greater frequency. In these cases, an endometrioid carcinoma of the ovary is usually associated with the adenocarcinoma of the endometrium.

Nongynecologic

The frequency of metastatic breast carcinoma to the ovaries varies according to the method of determination, but the phenomenon is common (Fig. 32.21). In autopsy data of women who died of metastatic breast cancer, the ovaries were involved in 24% of cases, and 80% of the involvement was bilateral (330,331,332 and 333). Similarly, when ovaries are removed to palliate advanced breast cancer, about 20% to 30% of the cases reveal ovarian involvement, 60% of those bilaterally. The involvement of ovaries in early-stage breast cancer seems to be considerably lower, but precise figures are not available. In almost all cases, either ovarian involvement is occult or a pelvic mass is discovered after other metastatic disease becomes apparent.
Krukenberg Tumor

The Krukenberg tumor, which can account for 30% to 40% of metastatic cancers to the ovaries, arises in the ovarian stroma and has characteristic mucin-filled, signet-ring cells (334). The primary tumor is most frequently located in the stomach and less commonly in the colon, breast, or biliary tract. Rarely, the cervix or the bladder may be the primary site. Krukenberg tumors can account for about 2% of ovarian cancers at some institutions, and they are usually bilateral. The lesions are usually not discovered until the primary disease is advanced and, therefore, most patients die of their disease within 1 year. In some cases, a primary tumor is never found.

Other Gastrointestinal Tumors

In other cases of metastasis from the gastrointestinal tract to the ovary, the tumor does not have the classic histologic appearance of a Krukenberg tumor; most of these are from the colon and, less commonly, the small intestine. As many as 1% to 2% of women with intestinal carcinomas will develop metastases to the ovaries during the course of their disease (332). Before exploration for an adnexal tumor in a woman older than 40 years, a barium enema is indicated to exclude a primary gastrointestinal carcinoma with metastases to the ovaries, particularly if there are any gastrointestinal symptoms. Metastatic colon cancer can mimic a mucinous cystadenocarcinoma of the ovary histologically (331,332).

Melanoma

Rare cases of malignant melanoma metastatic to the ovaries have been reported (335). In these circumstances, the melanomas are usually widely disseminated. Removal would be warranted for palliation of abdominal or pelvic pain, bleeding, or torsion.

Carcinoid Tumors

Metastatic carcinoid tumors represent fewer than 2% of metastatic lesions to the ovaries (336). Conversely, only about 2% of patients with primary carcinoids have evidence of ovarian metastasis, and only 40% of them have the carcinoid syndrome at the time of discovery of the metastatic carcinoid. However, in perimenopausal and postmenopausal women explored for an intestinal carcinoid, it is reasonable to remove the ovaries to prevent subsequent ovarian metastasis. Furthermore, the discovery of an ovarian carcinoid should prompt a careful search for a primary intestinal lesion.

Lymphoma and Leukemia

Lymphomas and leukemia can involve the ovary. When they do, the involvement is usually bilateral (337,338). About 5% of patients with Hodgkin's disease will have lymphomatous involvement of the ovaries, but this involvement occurs typically with advanced-stage disease. With Burkitt's lymphoma, ovarian involvement is very common. Other types of lymphoma involve the ovaries much less frequently, and leukemic infiltration of the ovaries is uncommon. Sometimes the ovaries can be the only apparent site of involvement of the abdominal or pelvic viscera with a lymphoma; if this circumstance is found, a careful surgical exploration may be necessary. Intraoperatively, a hematologist-oncologist should be consulted to determine the need for these procedures if frozen section of a solid ovarian mass reveals a lymphoma. In general, most lymphomas no longer require extensive surgical staging, although biopsy of enlarged lymph nodes should generally be performed. In some cases of Hodgkin's disease, a more extensive evaluation may be necessary. Treatment involves that of the lymphoma or leukemia in general. Removal of a large ovarian mass may improve patient comfort and facilitate a response to subsequent radiation or chemotherapy.

Fallopian Tube Cancer

Carcinoma of the fallopian tube accounts for 0.3% of all cancers of the female genital tract (2,3,339,340,341,342 and 343). In histologic features and behavior, fallopian tube carcinoma is similar to ovarian cancer; thus, the evaluation and treatment are also essentially the same (Fig. 32.23). The fallopian tubes are frequently involved secondarily from other primary sites, most often the ovaries, endometrium, gastrointestinal tract, or breast. They may also be involved in primary peritoneal carcinomatosis. Almost all cancers are of epithelial origin, most frequently of serous histology. Rarely, sarcomas have also been reported.
Figure 32.23 Carcinoma of the fallopian tube. This is the mixed papillary and the papillary-alveolar pattern. (From Berek JS, Hacker NF. Practical gynecologic oncology, 2nd ed. Baltimore: Williams & Wilkins, 1994:159, with permission.)

Clinical Features

Tubal cancers are seen most frequently in the fifth and sixth decades, with a mean age of 55 to 60 years (339). There are no known predisposing factors.

Symptoms and Signs

The classic triad of symptoms and signs associated with fallopian tube cancer is (a) a prominent watery vaginal discharge (i.e., hydrops tubae profluens), (b) pelvic pain, and (c) a pelvic mass. However, this triad is noted in fewer than 15% of patients (3).

Vaginal discharge or bleeding is the most common symptom reported by patients with tubal carcinoma and is documented in more than 50% of patients (340). Lower abdominal or pelvic pressure and pain also are noted in many patients. However, the symptoms may be rather vague and nonspecific. For perimenopausal and postmenopausal women with unusual, unexplained, or persistent vaginal discharge, even in the absence of bleeding, the clinician should be concerned about the possibility of occult tubal cancer. Fallopian tube cancer is often found incidentally in asymptomatic women at the time of abdominal hysterectomy and bilateral salpingo-oophorectomy.

On examination, a pelvic mass is present in about 60% of patients, and ascites may be present if advanced disease exists. For patients with tubal carcinoma, the results of dilation and curettage will be negative (342), although abnormal or adenocarcinomatous cells may be seen in cytologic specimens obtained from the cervix in 10% of patients.

Spread Pattern

Tubal cancers spread in much the same manner as epithelial ovarian malignancies, principally by the transcocelomic exfoliation of cells that implant throughout the peritoneal cavity. In about 80% of the patients with advanced disease, metastases are confined to the peritoneal cavity at the time of diagnosis (341).

The fallopian tube is richly permeated with lymphatic channels, and spread to the paraaortic and pelvic lymph nodes is common. Metastases to the paraaortic lymph nodes have been documented in at least 33% of the patients with all stages of disease (343).

Staging

Fallopian tube cancer is staged according to FIGO (339). The staging is based on the surgical findings at laparotomy (Table 32.9). According to this system, about 20% to 25% of patients have stage I disease, 20% to 25% have stage II disease, 40% to 50% have stage III disease, and 5% to 10% have stage IV disease (339). A somewhat lower incidence of advanced disease is seen in these patients than in patients with epithelial ovarian carcinomas, presumably because of the earlier occurrence of symptoms, particularly vaginal bleeding or unusual vaginal discharge.

Table 32.9. Modified FIGO Staging of Fallopian Tube Cancer (Based on Operative Findings Before Debulking and Pathologic Findings)

Treatment

The treatment of this disease is the same as that of epithelial ovarian cancer (339,342,344). Exploratory laparotomy is necessary to remove the primary tumor, to stage the disease, and to resect metastases. After surgery, the most frequently employed treatment is combination chemotherapy, although radiation therapy is also used in selected cases.

Surgery

Patients with tubal carcinoma should undergo total abdominal hysterectomy and bilateral salpingo-oophorectomy (3). If there is no evidence of gross tumor spread, a staging operation is performed. The retroperitoneal lymph nodes should be adequately evaluated, and peritoneal cytologic studies and biopsies should be performed, along with an infracolic omentectomy.

In patients with metastatic disease, an effort should be made to remove as much tumor bulk as possible. The role of cytoreductive surgery in this disease is unclear, but extrapolation from the experience with epithelial ovarian cancer indicates that significant benefit might be expected, particularly if all macroscopic disease can be resected.

Chemotherapy

The most active combination chemotherapy for epithelial ovarian cancer is hape carboplatin and hape paclitaxel, and it is appropriate, therefore, to use the same chemotherapy for patients with epithelial tubal malignancies (3).
Tubal Sarcomas

Tubal sarcomas, particularly malignant mixed mesodermal tumors, have been described but are rare. They occur mainly in the sixth decade and are typically advanced at the time of diagnosis. If all gross disease can be resected, platinum-based combination chemotherapy should be tried. However, survival is generally poor, and most patients die of their disease within 2 years (326).

References

4. Barnhill DR, Kurman RJ, Brady MF, et al. Tubal sarcomas, particularly malignant mixed mesodermal tumors, have been described but are rare. They occur mainly in the sixth decade and are typically considered to be high grade at presentation. If all gross disease can be resected, platinum-based combination chemotherapy should be tried. However, survival is generally poor, and most patients die of their disease within 2 years (326).

Prognosis

The overall 5-year survival for patients with epithelial ovarian carcinomas is about 40%. This number is higher than for patients with ovarian cancer and reflects the somewhat higher proportion of patients diagnosed with early-stage disease. The outlook is clearly related to the stage of disease, but the available data relate to patients who have not been surgically staged. Thus, the reported 5-year survival rate for patients with stage I disease is only about 65%. The 5-year survival rate for patients with stage II disease is 50% to 60%, but it is only 10% to 20% for patients with stages III and IV disease (339).

Rationale Therapy

Although most patients with tubal cancers have been treated with radiation therapy in the past, its role in the management of the disease remains unclear, because patients have not been treated in a consistent manner and the small numbers treated preclude any meaningful conclusions (342). Pelvic irradiation alone was once popular, but this approach seems inappropriate when the pattern of spread of this disease to the upper abdomen is considered (340). Whole-abdominal irradiation with a pelvic boost has been used in patients with no evidence of gross disease in the abdomen (i.e., completely resected disease or microscopic metastases only) (339).

Tubal Carcinomas

Tubal carcinosarcoma, which may arise in the fallopian tube, has been described but is rare. It occurs mainly in the sixth decade and is typically advanced at the time of diagnosis. If all gross disease can be resected, platinum-based combination chemotherapy should be tried. However, survival is generally poor, and most patients die of their disease within 2 years (326).
Chapter 33  Vulvar Cancer  
Christine H. Holschneider  Jonathan S. Berek

Etiology  
Types of Invasive Vulvar Cancer  
Epithelial Cell Carcinoma  
Melanoma  
Blastic/Granulocytic Carcinoma of the Bartholin Gland  
Adenocarcinoma of the Bartholin Gland  
Adenosquamous Carcinoma  
Basal Cell Carcinoma  
Verrucous Carcinoma  
Vulvar Sarcoma  
Rare Vulvar Malignancies  
Metastatic Tumors of the Vulva

With 3,800 new cases and 800 deaths annually in the United States (1), vulvar cancer is uncommon, representing 3% to 5% of malignancies of the female genital tract. Squamous cell carcinomas account for about 90% of all primary vulvar malignancies, whereas melanomas, adenocarcinomas, basal cell carcinomas, and sarcomas are much less common. The incidence of in situ vulvar cancer nearly doubled between the mid-1970s and the mid-1980s, whereas the overall rate of invasive squamous cell carcinoma has remained relatively stable (2). However, in women younger than 50 years there has been a striking increase in the incidence of not only in situ but also invasive squamous cell carcinoma of the vulva (3).

Following the reports of Taussig (4) in the United States and Way (5) in Great Britain, radical vulvectomy and en bloc groin dissection, with or without pelvic lymphadenectomy, has been considered standard treatment for all patients who have operable disease. Postoperative morbidity was high and prolonged hospitalization common. During the past 20 years, a number of significant advances have been made in the management of vulvar cancer. The following changes have markedly decreased the physical and psychological morbidity associated with the treatment:

1. Individualization of treatment for all patients with invasive disease (6,7)
2. Vulvar conservation for patients with unifocal tumors and an otherwise normal vulva (6,7,8,9 and 10)
3. Omission of the groin dissection for patients with T1 tumors and <1mm of stromal invasion (6,7)
4. Elimination of routine pelvic lymphadenectomy (11,12,13,14 and 15)
5. The use of separate incisions for the groin dissection to improve wound healing (16,17)
6. Omission of the contralateral groin dissection in patients with lateral T1 lesions and negative ipsilateral nodes (7,18)
7. The use of preoperative radiation therapy to obviate the need for exenteration in patients with advanced disease (19,20)
8. The use of postoperative radiation therapy to decrease the incidence of groin recurrence in patients with multiple positive groin nodes (15).

Etiology  
The etiology of vulvar cancer has been only partially elucidated and is likely to be multifactorial. Based on histopathologic and environmental factors, there appear to be at least two distinct etiologic entities of squamous cell carcinoma of the vulva.

1. Basaloid or warty types, which tend to be multifocal, occur generally in younger patients and are related to human papillomavirus (HPV) infection, vulvar intraepithelial neoplasia (VIN), and cigarette smoking.
2. Keratinizing types, which tend to be unifocal, occur predominantly in older patients, are not related to HPV, and often are found in areas adjacent to lichen sclerosus and squamous hyperplasia.

High-grade vulvar intraepithelial neoplasia (VIN 3) has been most closely studied as a potential precancerous lesion. The direct progression of VIN to cancer is difficult to document, but 10% to 20% of vulvar carcinoma in situ lesions harbor an occult invasive component (21,22), and VIN is found adjacent to basaloid or warty vulvar squamous cell carcinomas in more than 80% of cases. DNA of HPV has been documented in 89% of patients with VIN 3 and in up to 86% of warty or basaloid type carcinomas of the vulva, but it occurs in less than 10% of the keratinizing type of carcinomas of the vulva (23). Epidemiologic risk factors for the basaloid or warty type squamous cell carcinoma of the vulva are similar to those for cervical cancer and include a history of multiple lower genital tract neoplasias, immunosuppression, and smoking (23,24). Frequently implied as an etiologic variable for the keratinizing carcinoma is the itch–scratch cycle associated with lichen sclerosus and squamous hyperplasia, with atypical changes occurring in the repaired epithelium. In keratinizing carcinoma, associated lichen sclerosus or squamous hyperplasia is found in more than 80% of patients (25,26), yet their causative role remains controversial. Supportive evidence that some of these lesions could be precancerous comes from molecular studies that demonstrate aneuploid DNA content, p53 overexpression, and monoclonal expansion of keratinocytes in lichen sclerosus and associated squamous hyperplasia (27,28). In the past, some studies have reported vulvar cancer to be more common in patients who are obese, have hypertension and diabetes mellitus, or are nulliparous (29,30), but a recent case-control study of vulvar cancer was unable to confirm any of these as risk factors (24).

Types of Invasive Vulvar Cancer  
The varieties of invasive vulvar cancer are shown in Table 33.1.
Table 33.1. Types of Vulvar Cancer

Squamous Cell Carcinoma:

Approximately 90% to 92% of all invasive vulvar cancers are of the squamous cell type. As discussed previously, squamous carcinomas of the vulva can be divided into distinct histologic subtypes designated as basaloid carcinoma, warty carcinoma, and keratinizing squamous carcinoma. Mitoses are noted in these malignancies, but atypical keratinization is the histologic hallmark of invasive vulvar cancer. Most vulvar squamous carcinomas reveal keratinization. Histologic features that correlate with the occurrence of inguinal lymph node metastasis are lymph–vascular space invasion, tumor thickness, depth of stromal invasion, histologic pattern of invasion (spray and stellate versus broad and pushing), and increased amount of keratin.

Figure 33.1 Squamous cell carcinoma of the vulva, keratinizing type. The multiple pearl formations consist of laminated keratin. (From Berek JS, Hacker NF. Practical gynecologic oncology, 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Microinvasive Squamous Carcinoma

Microinvasive carcinoma of the vulva has been defined as a lesion >2 cm in diameter with <1 mm stromal invasion. Depth of stromal invasion is measured vertically from the epithelial–stromal junction (basement membrane) of the most superficial dermal papilla to the deepest point of tumor invasion. When the tumor invades <1 mm, metastasis to the inguinal lymph nodes is extremely rare among reported series. However, when invasion is >1 mm, there is a significant risk of inguinal lymph node metastasis.

Figure 33.2 Early invasive carcinoma of vulva originating from vulvar intraepithelial neoplasia. Multiple irregular nests of malignant cells extend from the base of rete pegs. Desmoplastic stromal reaction and chronic inflammation are useful diagnostic signs of stromal invasion. The depth of stromal invasion is measured from the base of the most superficial dermal papilla vertically to the deepest tumor cells. In this tumor, it is 3.6 mm in depth. (From Berek JS, Hacker NF. Practical gynecologic oncology, 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Clinical Features

Squamous cell carcinoma of the vulva is predominantly a disease of postmenopausal women; the mean age at diagnosis is about 65 years. However, 15% of patients who develop vulvar cancer do so before age 40. There may be a long-standing history of an associated vulvar intraepithelial disorder, such as lichen sclerosus, squamous hyperplasia, or VIN. Up to 27% of patients with vulvar cancer are reported to have a second primary malignancy, most commonly cervical cancer, followed by cancer of the breast, extragenital skin, and gastrointestinal tract.

Most patients are asymptomatic at the time of diagnosis. If symptoms exist, vulvar pruritus, a lump, or a mass are the most common findings. Less frequent symptoms include a bleeding or ulcerative lesion, discharge, pain, or dysuria. Occasionally, a large metastatic mass in the groin may be the initial complaint.

A careful inspection of the vulva should be part of every gynecologic examination. On physical examination, vulvar carcinoma is usually raised and may be fleshy, ulcerated, leukoplakic, or warty in appearance. It may be pigmented, red or white, tender or painless. The lesion may be clinically indistinct, especially in the presence of VIN or vulvar dystrophies. Thus, any lesion of the vulva warrants a biopsy.

Most squamous carcinomas of the vulva occur on the labia majora and minora (60%), but the clitoris (15%) and perineum (10%) also may be primary sites. Approximately 10% of the cases are too extensive to determine a site of origin, and about 5% of the cases are multifocal.

As part of the clinical evaluation, a careful assessment of the extent of the lesion, including whether it's unifocal or multifocal, should be performed. The groin lymph nodes should be evaluated carefully, and a complete pelvic examination should be performed. A cytologic sample should be taken from the cervix for Papnicolaou testing, and colposcopy of the cervix and vagina should be performed because of the common association with other squamous intraepithelial or invasive neoplasms of the lower genital tract.

Diagnosis

Diagnosis requires a wedge biopsy specimen, which usually can be obtained in the office using local anesthesia. If the lesion is only about 1 cm in diameter, excisional biopsy is preferable.

Physician delay is a common problem in the diagnosis of vulvar cancer, particularly if the lesion has a warty appearance. Any confluent warty lesion requires biopsy before medical or ablative therapy is initiated.

Routes of Spread
Vulvar cancer spreads by the following routes:

1. Direct extension, to involve adjacent structures such as the vagina, urethra, and anus
2. Lymphatic embolization to the regional inguinal and femoral lymph nodes
3. Hematogenous spread to distant sites, including the lungs, liver, and bone.

Lymphatic metastases may occur early in the disease. Twelve percent of T₁ tumors have regional metastases (37,41). Initially, spread is usually to the inguinal lymph nodes, which are located between Camper’s fascia and the fascia lata (8). From these superficial groin nodes, the disease will spread to the deep femoral nodes, which are located medially along the femoral vessels (Fig. 33.3). Cloquet’s or Rosenmüller’s node, situated beneath the inguinal ligament, is the most cephalad of the femoral node group. Metastases to the femoral nodes without involvement of the inguinal nodes have been reported (42,43,44 and 45), and intraoperative lymphatic mapping studies find the sentinel node to be deep to the cribiform fascia in 5% of cases (46).

Figure 33.3 Inguinal-femoral lymph nodes. (From Berek JS, Hacker NF. Practical gynecologic oncology, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000, pg 558, with permission.)

From the inguinal-femoral nodes, the cancer spreads to the pelvic nodes, particularly the external iliac group. Although direct lymphatic pathways from the clitoris and Bartholin gland to the pelvic nodes have been described, these channels seem to be of minimal clinical significance (11,47). The lymphatics of the vulva from either side form a rich network of anastomoses along the midline. Lymphatic drainage from the clitoris, anterior labia minora, and perineum is bilateral. For lateral vulvar tumors, metastases to contralateral lymph nodes in the absence of ipsilateral nodal involvement is rare (0.4% for T₁ tumors) (41).

The overall incidence of inguinal-femoral lymph node metastases is reported to be about 30% (9,10,45,46,47,48,49,50 and 51) (Table 33.2). Metastases to pelvic nodes occur in about 12% of cases. Pelvic nodal metastases are rare (0.6 %) in the absence of groin node involvement, but they occur on average in about 16% of cases with positive groin nodes (Table 33.2). The risk increases to 33% in the presence of clinically suspicious groin nodes (12), and to about 50% if there are three or more pathologically positive inguinal-femoral nodes (12,15,38). The incidence of lymph node metastases in relation to depth of invasion is shown in Table 33.3.

Hematogenous spread usually occurs late in the course of vulvar cancer and is rare in the absence of lymph node metastases.

Table 33.3. Nodal Status in T₁ Squamous Cell Carcinoma of the Vulva Versus Depth of Stromal Invasion

**Staging**

Previously, vulvar carcinoma was staged clinically based on tumor size and location, palpable regional lymph node status, and a limited search for distant metastases. The prognostic importance of the lymph node status is significant, yet the accuracy of the clinical assessment of the lymph nodes is limited. Microscopic metastases may be present in nodes that are not clinically suspicious, and suspicious nodes may be enlarged because of inflammation only. When compared with surgical staging, the percentage of error in clinical staging increases from 18% for stage I disease to 44% for stage IV disease (38).

These factors led the Cancer Committee of the International Federation of Gynecology and Obstetrics (FIGO) in 1988 to introduce a surgical staging system for vulvar cancer, which was revised in 1995 to separate T₁ lesions invasive to 1 mm or less as stage Ia (Table 33.4). This surgical staging system offers much improvement over the previous clinical staging system, but there remains need for further refinements. One major problem is that stage III represents a very heterogeneous group of patients. It includes patients ranging from those with a small tumor involving the distal urethra or vagina and negative nodes and those with one microscopically involved groin node, who should have a good prognosis, to those with multiple positive groin nodes, who have a very poor prognosis.
An increasing proportion of patients with early-stage disease—up to 50% of patients in many centers—have tumors with a 5-year survival rate greater than 90%, compared with about 50% for patients with positive lymph nodes (57). The number of positive inguinal-femoral lymph nodes is an important prognostic factor. Patients with only one microscopically involved node have a prognosis comparable to those with negative lymph nodes (55,56), whereas the 2-year survival rate is 20% for patients with three or more metastatic lymph nodes (12). In a Gynecologic Oncology Group (GOG) study, patients with N1 or N2 nodes had a 2-year survival rate of 78%, compared with 52% for patients with N3 nodes and 33% for patients with N4 nodes (13). The survival rate for patients with positive pelvic nodes is about 11% (59). Tumor ploidy is another important prognostic factor. Data from the Norwegian Radium Hospital (59) demonstrate a 5-year crude survival rate of 62% for diploid and 23% for the aneuploid tumors (p < 0.001). In a multivariate Cox regression analysis, tumor ploidy was the second most important prognostic factor after lymph node status.

Prognosis and Survival

Survival of patients with vulvar cancer correlates with FIGO stage. The prognosis for patients with early-stage disease is generally very good (Table 33.5). The single most important prognostic factor is lymph node status, followed by lesion size (57). Histologic grade, tumor thickness, depth of stromal invasion, and lymph–vascular space involvement contribute to the risk of lymph node involvement but are not independent predictors of survival (56). Patients with negative lymph nodes have a 5-year survival rate greater than 90%, compared with about 50% for patients with positive lymph nodes (57). The number of positive inguinal-femoral lymph nodes is an important prognostic factor. Patients with only one microscopically involved node have a prognosis comparable to those with negative lymph nodes (55,56), whereas the 2-year survival rate is 20% for patients with three or more metastatic lymph nodes (12). In a Gynecologic Oncology Group (GOG) study, patients with N1 or N2 nodes had a 2-year survival rate of 78%, compared with 52% for patients with N3 nodes and 33% for patients with N4 nodes (13). The survival rate for patients with positive pelvic nodes is about 11% (59). Tumor ploidy is another important prognostic factor. Data from the Norwegian Radium Hospital (59) demonstrate a 5-year crude survival rate of 62% for diploid and 23% for the aneuploid tumors (p < 0.001). In a multivariate Cox regression analysis, tumor ploidy was the second most important prognostic factor after lymph node status.

Treatment

After the pioneering work of Taussig (4) in the United States and Way (5) in Great Britain, en bloc radical vulvectomy and bilateral dissection of the groin and pelvic nodes became the standard treatment for most patients with operable vulvar cancer. If the disease involved the anus, rectovaginal septum, or proximal urethra, some type of pelvic exenteration was combined with the dissection.

Although the survival rate improved markedly with this aggressive surgical approach, several factors have led to modifications of this treatment plan during the past 20 years. These factors are summarized as follows:

1. An increasing proportion of patients with early-stage disease—up to 50% of patients in many centers—have T1 tumors.
2. There were concerns about the postoperative morbidity and associated long-term hospitalization common with the en bloc radical dissection.
3. Increasing awareness has emerged of the psychosexual consequences of radical vulvectomy.

In order to individualize the patient's care and determine the appropriate therapy, it is necessary to determine independently the primary lesion as well as groin lymph nodes.

Before initiation of therapy, all patients should undergo colposcopy of the cervix, vagina, and vulva. Preinvasive (and rarely invasive) lesions may be present at other sites along the lower genital tract.

Management of the Primary Lesion

Early Vulvar Cancer (T1) The modern approach to the management of patients with T1 carcinoma of the vulva should be individualized (6,7). There is no standard approach applicable to every patient, and emphasis is on performing the most conservative operation that is consistent with cure of the disease.

Radical vulvectomy has been considered the standard treatment for primary vulvar lesions, but this operation is associated with significant surgical morbidity and disturbances of sexual function and body image. Psychosexual sequelae are a major long-term morbidity associated with the treatment of vulvar cancer (8). One study reported that sexual arousal was reduced to the eighth percentile and body image was reduced to the fourth percentile for women who had undergone vulvectomy when compared with healthy adult women (61).

Traditionally, there has been concern that, without an en bloc resection, intervening tissue left between the primary tumor and the regional lymph nodes may contain microscopic tumor foci in draining lymphatics. However, experience with a separate incision technique for node dissection has confirmed that metastases rarely occur in the skin bridge in patients without clinically suspicious nodes in the groin (17).

During the past 20 years, several investigators have advocated a radical local excision rather than a radical vulvectomy for the primary lesion for patients with T1 tumors (5,7,8) and 9). Regardless of whether a radical vulvectomy or a radical local excision is performed, the surgical margins adjacent to the tumor will be the same. An analysis of the available literature indicates that the incidence of local invasive recurrence after radical local excision is not higher than that after radical vulvectomy (6,41,59,62). This finding suggests that in the presence of an otherwise normal-appearing vulva, radical local excision is a safe surgical option, regardless of the depth of invasion. A recent review of 135 patients with all stages of disease assessed the surgical margin that must be obtained to prevent local disease recurrence. In this study, a 1-cm tumor-free surgical margin on the vulvar specimen (0.8-cm on pathologic specimen) resulted in a very high rate of local control (63). Neither clinical tumor size nor the presence of coexisting benign vulvar pathology correlated with local recurrence. It is important to bear in mind that paraffin-embedded tissue shrinks by about 25%. Thus, at the time of radical local excision, at least a 1- to 1.5-cm grossly negative margin, which should extend down to the level of the inferior fascia of the urogenital diaphragm, should be obtained.

When vulvar cancer arises in the presence of VIN or some nonneoplastic epithelial disorder, treatment will be influenced by the patient's age. Elderly patients who often have had many years of chronic itching may not be disturbed by the prospect of a vulvectomy. In younger women, it will be desirable to conserve as much of the
radical local excision is most appropriate for lesions on the lateral or posterior aspects of the vulva (Fig. 33.4). Midline lesions pose special challenges due to their proximity to the clitoris, urethra, or anus. For anterior lesions that involve the clitoris or that are in proximity to it, any type of surgical excision will have psychosexual consequences. In addition, marked edema of the posterior vulva may occur. For young patients with perineal lesions, the primary lesion can be treated with a small field of radiation therapy, possibly with concomitant sensitizing chemotherapy. Small vulvar lesions should respond very well to about 5,000 cGy external radiation, and biopsy can be performed after therapy to confirm the absence of any residual disease (64).

Radical local excision is performed, so it would seem to be both feasible and desirable to extend the indications for vulvar conservation, particularly for younger patients. Tumors that are most suitable to a more conservative resection are those involving the posterior half of the vulva, where preservation of the clitoris and mons pubis is feasible. For patients with more advanced T1 and T2 lesions, management consists of radical vulvectomy and bilateral inguinal-femoral lymphadenectomy. If the disease involves the distal urethra, vagina, or anus, partial resection of these organs will be required. Alternatively, it may be preferable to give preoperative radiation therapy to allow for a less radical resection (see below).

Closure of Large Defects

After radical local excision, primary closure without tension often can be accomplished for smaller defects. However, if a more extensive dissection has been required to treat a large primary lesion, a number of options are available to repair the defect.

1. An area may be left open to granulate, which it will usually do over a period of 6 to 8 weeks (67).
2. Full-thickness skin flaps may be devised (68,69,70 and 71). The rhomboid flap is best suited to covering large defects of the posterior vulva (71), whereas for lateral defects, a mons pubis pedicle flap has been advocated (68).
3. Myocutaneous flaps may be developed to cover the defect. Unilateral or bilateral gracilis myocutaneous grafts are most useful when an extensive area from the mons pubis to the perineal area has been resected. Because the graft brings a new blood supply to the area, it is particularly applicable if the vulva is poorly vascularized from prior surgical resection or radiation (72).
4. If extensive defects exist in the groin and vulva, the tensor fascia lata myocutaneous graft may be the most applicable (73).

Advanced Disease—Large T3 and T4 Primary Tumors

To achieve primary surgical clearance for tumors involving the upper urethra, anus, rectum, or rectovaginal septum, pelvic exenteration is needed in addition to radical vulvectomy and inguinofemoral lymphadenectomy, which carries an extremely high physical and psychological morbidity (61,74). Reported 5-year survival rates are about 50% (75,76,77 and 78). For many of these patients, a combined approach of surgery and radiation therapy offers improved survival and reduced morbidity. Numerous small prospective and retrospective series report on the use of external beam radiation, often with concomitant chemotherapy to shrink the primary tumor. Reported initial response rates to chemoradiation approximate 90% (79,80 and 81). It is important that this chemoradiation is followed by a more limited resection of the tumor bed and lymphadenectomy on an individualized basis. About one-half of the specimens will contain residual tumor (82), and local relapse rates are as high as 50% to 79% with external radiation alone (with or without concomitant chemotherapy) (83,84), emphasizing the need for a combined approach that involves radiation and surgery.

As experience with this combination therapy has evolved, it appears that external beam therapy is generally appropriate for most cases, with more selective use of brachytherapy. The extensiveness of the surgery has also been significantly modified. A more limited vulvar resection is now advocated, and bulky N3 and N4 nodes are resected without full groin dissection to avoid the leg edema associated with groin dissection and radiation. With this combined radiation-surgical approach, 5-year survival rates as high as 76% have been reported (82). With the experience now accrued, preoperative radiation, with or without concurrent chemotherapy, should be regarded as the treatment of first choice for patients with advanced vulvar cancer who would otherwise require some type of pelvic exenteration.

Management of the Lymph Nodes

Groin dissection is associated with postoperative wound infection and breakdown, as well as chronic leg edema. Although the incidence of wound breakdown is reduced significantly when separate incisions are used for the groin dissection (Fig. 33.5) (17), chronic leg edema remains a major problem. When assessing a patient for groin dissection, the following three facts should to be kept in mind:

Figure 33.4 Small (T1) vulvar carcinoma at the posterior fourchette. (From Berek JS, Hacker NF. Practical gynecologic oncology, 3rd ed. Philadelphia: Lippincott Williams & Wilkins 2000. pg. 565, with permission.)

Figure 33.5 Skin incision for groin dissection through a separate incision. A line is drawn 1 cm below and parallel to the groin crease, and a narrow ellipse of
1. The only patients with virtually no risk of lymph node metastases are those whose tumor invades the stroma to <1 mm.
2. Patients who develop recurrent disease in an undissected groin have a >90% mortality (88).
3. Based on the laterality of the vulvar lesions, an ipsilateral or bilateral lymphadenectomy becomes necessary.

**Appropriate groin dissection is the single most important factor in decreasing the mortality for early vulvar cancer.**

**Microinvasive Carcinoma** All patients whose tumors demonstrate more than 1 mm of stromal invasion require inguinal-femoral lymphadenectomy. A wedge biopsy specimen of the primary tumor should be obtained, and the depth of invasion should be determined. If it is smaller than 1 mm on the wedge biopsy specimen, the entire lesion should be locally excised and analyzed histologically to determine the depth of invasion. If there is still no invasive focus larger than 1 mm, groin dissection may be omitted provided there is no lymph–vascular space invasion and there are no clinically suspicious groin lymph nodes. Although an occasional patient with less than 1 mm of stromal invasion has had documented groin node metastases (89), the incidence is so low that it is of no practical significance.

**Inguinal-femoral Lymphadenectomy** If groin dissection is indicated in patients with early vulvar cancer, it should be a thorough inguinal-femoral lymphadenectomy. The GOG recently reported six groin recurrences among 121 patients with T1 N0 tumors after a superficial (inguinal) dissection, even though the removed inguinal nodes were negative (45). Whether all of these recurrences were in the femoral nodes is unclear, but this large multicenter study does indicate that an incomplete groin dissection will increase the number of groin recurrences and, therefore, mortality. Comparable failure rates have been reported by Burke and colleagues (9). Furthermore, GOG data indicate that radiation therapy cannot substitute for groin dissection followed by selective radiation as indicated, even in patients with clinically nonsuspicious lymph nodes (90). This GOG study was closed early because a significantly higher incidence of recurrences occurred in women who were receiving groin radiation therapy only (19% versus 0%). The dose of radiation was 5,000 cGy given in daily 200-cGy fractions to a depth of 3 cm below the anterior skin surface. Although the radiation regimen itself has been criticized extensively, the therapeutic effects of an alternative radiation regimen remain to be determined.

**Unilateral Versus Bilateral Groin Dissection** It is clear that it is not necessary to perform a bilateral groin dissection if the primary lesion is unilateral and the ipsilateral lymph nodes are negative. In a patient with unilateral T1 lesion and negative ipsilateral groin nodes, the risk of contralateral lymph node metastasis is 0.4% (43). However, there is an increase in the risk of contralateral nodal involvement proportional to the number of positive ipsilateral inguinal nodes (15). Thus, it is recommended that patients with any bulky or multiple microscopically positive ipsilateral groin lymph nodes undergo contralateral inguinofemoral lymphadenectomy as well. Bilateral inguinal-femoral lymphadenectomy should be performed for all lesions (clitoris, anterior labia minora, posterior fourchette) or those within 2 cm of the midline, because of the more frequent contralateral lymph flow from these regions (91).

**Management of Pelvic Lymph Nodes** In the past, pelvic lymphadenectomy has been considered part of the routine surgery for invasive vulvar cancer. However, the incidence of pelvic lymph node metastasis is rare in the absence of groin node involvement (Table 33.2), thus a more selective approach is preferred. Patients most prone to pelvic lymph node metastases are those with clinically suspicious three or more pathologically positive groin nodes (11,12,14,38). In these patients, the pelvis requires treatment by pelvic lymphadenectomy or radiation. If a preoperative pelvic imaging study reveals enlarged pelvic lymph nodes, resection of these nodes is performed via an extraperitoneal approach because of the inability of external beam radiation therapy to sterilize bulky positive pelvic nodes.

** Sentinel Node Studies** A number of investigators have explored the use of intraoperative lymphatic mapping using lymphoscintigraphy or blue dye to identify a sentinel node that would predict the presence or absence of regional nodal metastases (34,92,93) and 94). Small preliminary studies suggest that a sentinel node can be identified in most patients. Reliable identification of the sentinel node and foregoing a full node dissection in patients with clinically nonsuspicious groin lymph nodes and a negative sentinel node may significantly reduce the number of patients who undergo unnecessary, extensive lymphadenectomy in the absence of disease. However, until the accuracy of the negative predictive value of an uninvolved sentinel node is documented in well-designed and sufficiently powered clinical trials, complete inguinal-femoral lymphadenectomy remains indicated in all but stage la disease, given the high mortality of recurrence in an undissected groin.

**Postoperative Management**

Despite the age and general medical condition of many elderly patients with vulvar cancer, surgery is usually remarkably well tolerated. Patients should be able to commence eating a low-residue diet on the first postoperative day. In the past, bedrest had been advised for 3 to 5 days postoperatively to allow for immobilization of the wounds and foster healing. Because radical local excisions are being performed with increasing frequency and groin dissections are done through separate incisions, patients generally begin ambulation on postoperative day 1 or 2. Pneumatic calf compression or subcutaneous heparin should be given to help prevent deep venous thrombosis, and active leg movements are to be encouraged. Frequent dressing changes are performed to keep the vulvar wound dry. Metabolic and perineal hygiene is maintained. Suction drainage of each side of the groin is continued until output is minimal to help decrease the incidence of groin seromas. It is not uncommon for suction drainage to continue for 10 or more days. The Foley catheter is removed once the patient is ambulatory. If there is significant periurethral swelling, prolonged bladder drainage may be advisable. If there is breakdown of the vulvar wound, sitz baths or whirlpool therapy is helpful, followed by drying of the perineum with a hair dryer.

**Early Postoperative Complications**

The major immediate morbidity is related to groin wound infection, necrosis, and breakdown. This complication has been reported in as many as 53% to 85% of patients having an en bloc operation (37,38). With the separate-incision approach, the incidence of wound breakdown can be reduced to about 44%; major breakdown occurs in about 14% of patients (17,38,95). With appropriate antibiotics, debridement, and wound dressings, the area will granulate and reepithelialize over the next several weeks and may be managed with home nursing. Whirlpool therapy is effective for areas of extensive breakdown.

Other early postoperative complications include urinary tract infection, seromas in the femoral triangle, deep venous thrombosis, pulmonary embolism, myocardial infarction, hemorrhage and, rarely, ostestis pubis. Lymphocystis or groin seromas occur in about 10% to 15% of cases and should be managed by periodic sterile aspiration. Anesthesia of the anterior thigh resulting from femoral nerve injury is common and usually resolves slowly.

**Late Complications**

One major late complication is chronic lymphedema, which occurs on average in about 30% of patients (37,38 and 39,95,98). Recurrent lymphangitis or cellulitis of the leg develops in about 10% of patients and usually responds to oral antibiotics. Urinary stress incontinence, with or without genital prolapse, occurs in about 10% of patients after radical vulvectomy and may require corrective surgery. Intestinal stenosis can lead to dyspareunia and may require a vertical relaxing incision, which is sutured transversely. An uncommon late complication is femoral hernia, which usually can be prevented intraoperatively by closure of the femoral canal with a suture from the inguinal ligament to Cooper's ligament. Pubic osteomyelitis and rectovaginal or rectoperineal fistulas are rare late complications.

Other major long-term treatment complications associated with the extent of vulvar surgery include depression, altered body image, and sexual dysfunction (61,74). Modifications in the radical extent of the surgical approach and appropriate preoperative and postoperative counseling may help lessen some of the psychological impacts.

**Role of Radiation Therapy**

Radiation therapy traditionally has been considered to have a limited role in the management of patients with vulvar cancer. In the orthovoltage era, local tissue tolerance was poor and vulvar necrosis was common, but with megavoltage therapy, tolerance has improved significantly. Thus, radiation therapy, with or without concurrent chemotherapy, is likely to have an increasingly important role in the management of patients with vulvar cancer. It is important to remember, though, that with a rare exception, radiation therapy alone has little place in the primary management of vulvar cancer. It is generally indicated in conjunction with surgery.

The indications for radiation therapy for patients with primary vulvar cancer are still evolving. At present, radiation seems to be clearly indicated in the following
Preoperatively, in patients with advanced disease who would otherwise require pelvic exenteration (99). Postoperatively, to help prevent local recurrences in patients with involved or close surgical margins (97). As primary therapy for patients with small primary tumors, particularly clitoral or periclitoral lesions in young and middle-aged women, for whom surgical resection would have significant psychological consequences (54).

No additional treatment is recommended if one microscopically positive groin node is found. The prognosis for this group of patients is excellent (12), and only careful observation is required. Even if a unilateral groin dissection has been performed for a lateral lesion, there seems to be no indication for dissection of the other side, because contralateral lymph node involvement is likely only if there are multiple microscopic or any gross ipsilateral inguinal node metastases (12,15).

If clinically evident groin metastases or two or more microscopically positive groin nodes are found, which is unusual in patients with T1 vulvar cancer, the patient is at increased risk of groin and pelvic recurrence and should receive postoperative groin and pelvic irradiation. In 1977, the GOG initiated a prospective trial in which patients with positive groin nodes were randomized to either ipsilateral pelvic node dissection or bilateral pelvic node dissection plus groin irradiation (15). Radiation therapy consisted of 4,500 to 5,000 cGy to the midplane of the pelvis at a rate of 180 to 200 cGy per day. The survival rate for the radiation group (66% at 2 years) was significantly better than the survival rate for the pelvic lymphadenectomy group (54% at 2 years) ($p = 0.03$). The survival advantage was limited to patients with clinically evident groin nodes or more than one positive groin node. Groin recurrence occurred in 3 of 59 patients (5%) treated with radiation, compared with 13 of 55 (23.6%) patients treated with lymphadenectomy ($p = 0.02$). Four patients who received radiation had a pelvic recurrence, compared with one who had lymphadenectomy. These data indicate no benefit from pelvic irradiation combined with pelvic lymphadenectomy for the prevention of pelvic recurrence, but they do highlight the value of prophylactic groin irradiation in preventing groin recurrence in patients with multiple positive groin nodes.

### Recurrent Vulvar Cancer

Approximately two-thirds of recurrences of vulvar cancer occur within the first 2 years from initial therapy (99), with groin recurrences occurring sooner (median time to recurrence 6 months) than vulvar recurrences (median time to recurrence 3 years) (100).

Recurrence of vulvar cancer correlates most closely with the number of positive groin nodes (12). Patients with fewer than three positive nodes, particularly if the nodes are only microscopically involved, have a low incidence of recurrence at any site, whereas patients with three or more positive nodes have a high incidence of local, regional, and systemic recurrences (12,15).

#### Local Recurrence

Margin status at the time of radical resection of the vulvar cancer is the most powerful predictor of local vulvar recurrence, with an almost 50% recurrence risk with margins of less than 0.8 cm (63). Margin status does not, however, predict survival (57). Local vulvar recurrences are likely in patients with primary lesions larger than 4 cm in diameter, especially if lymph–vascular space invasion is present (97,101). When detected early, isolated local failure is usually salvageable by additional surgical therapy (9,17,38,45,102), often with a gracilis myocutaneous graft to cover the defect. Radiation therapy, particularly a combination of external beam therapy plus interstitial needles, at times combined with chemotherapy, has also been used to treat vulvar recurrences (104). One study reported on 10 patients treated in this manner, nine of whom were still alive with a mean follow-up of 28 months (105). However, 6 of the 10 patients developed severe radionecrosis at a median of 8.5 months after radiation, and the authors concluded that, although this treatment was highly effective, it also had a high degree of morbidity.

#### Regional and Distant Recurrence

Regional and distant recurrences are difficult to manage and are associated with a poor prognosis (97,99,100). Radiation therapy may be used in conjunction with surgery for groin recurrence, whereas chemotherapeutic agents that have activity against squamous carcinomas may be offered for distant metastases. The literature on the use of chemotherapy for recurrent vulvar cancer consists of mainly small series. The most extensively studied regimens contain bleomycin and methotrexate, with or without cisplatin or CCNU (a nitrosourea) and bleomycin and mitomycin C (106,107), but response rates are low and the duration of response is usually disappointing. Long-term survival is very uncommon with regional or distant recurrence.

#### Melanoma

Vulvar melanomas are rare, with an incidence of 0.1 to 0.19 per 100,000 women (108,109). They account for 4% to 10% of all cases and are the second most common form of vulvar malignancy (36). Most melanomas arise de novo (110), but they may arise from a preexisting junctional nevus. Vulvar melanomas occur predominantly in postmenopausal white women. The incidence of cutaneous melanomas worldwide is increasing significantly. Vulvar melanomas appear to behave in a manner similar to that of other cutaneous melanomas (311,112 and 113).

Most patients with vulvar melanoma have no symptoms except for a pigmented lesion that may be enlarging. Some patients have itching or bleeding, and a few have a groin mass. Vulvar melanomas occur most frequently on the labia minora or the clitoris (Fig. 33.6), and extension into the urethra or vagina at discovery is not uncommon. Any pigmented lesion on the vulva should be excised or, if the lesion is large, sampled for biopsy unless it is known to have been present and unchanged for some years. Most vulvar nevi are junctional and may be precursor lesions to melanoma; thus, any nevus of the vulva should be removed.

---

**Histopathology**

There are three basic histologic types of vulvar melanoma (Fig. 33.7).
Figure 33.7 Vulvar melanoma. Spindle-shaped melanoma cells form interlacing bundles, and some contain melanin pigment (left lower corner). Epidermal invasion is evident in the form of Pagetoid migration (left upper corner). (From Berek JS, Hacker NF. Practical gynecologic oncology, 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

1. The mucosal lentigious melanoma is a flat freckle that may become quite extensive but tends to remain superficial.
2. The most common type is the superficial spreading melanoma, which tends to remain relatively superficial early in its development.
3. The nodular melanoma, which is the most aggressive, is characterized by a raised lesion that penetrates deeply and may metastasize widely.

In the largest series reported to date, more than one-fourth of the cases of melanomas were macroscopically amelanotic (108). Vulvar melanoma tends to spread early, not only lymphatically but also hematogenously.

### Staging

The FIGO staging used for squamous lesions is not applicable to melanomas, because the lesions are usually much smaller and the prognosis is related to the depth of tumor invasion rather than to the diameter of the lesion (111,115,127). The leveling system established by Clark and others (117) for cutaneous melanomas is less readily applicable to vulvar lesions because of the different skin morphology. The vulvar skin lacks a well-defined papillary dermis. Breslow (118) measured the thickest portion of the melanoma from the surface of intact epithelium to the deepest point of invasion. This system is more adequate for the vulva. Chung and colleagues (115) proposed a modified system that retained Clark’s definitions for levels I and V but arbitrarily defined levels II, III, and IV, using measurements in millimeters. The 1992 American Joint Committee on Cancer (AJCC) staging for melanoma combined the Clark and Breslow systems with clinical staging (119). A comparison of these systems is shown in Table 33.6.

### Treatment

With better understanding of the prognostic significance of the microstaging, some individualization of treatment has developed. However, treatment of vulvar melanoma continues to be controversial, in part because of the lack of large retrospective studies, which makes it difficult to draw conclusions regarding the behavior and best treatment of vulvar melanoma. Currently used treatments are guided by experience from cutaneous melanoma in general and squamous cell carcinomas of the vulva. Paralleling the trend toward more conservative surgical management of cutaneous melanoma, there is a shift toward more conservative management of vulvar melanoma (122,115,120,121).

It is generally accepted that lesions with less than 1 mm of invasion may be treated with radical local excision alone (115,116). With more invasive lesions, en bloc resection of the primary tumor and regional groin nodes has traditionally been recommended. In the last 15 years, however, radical vulvectomy has been performed less frequently and survival does not seem to be compromised (122). One study reported on 32 patients with vulvar melanoma who underwent local excision (n = 14), simple vulvectomy (n = 7), or radical resection (n = 11) (123). No group had a superior survival rate, although the overall survival rate at 5 years was only 25%. More recently, another study reported on 59 patients who underwent radical vulvectomy and 19 who underwent more conservative resections (112). Survival was not improved by the more radical approach, and they recommended radical local excision for the primary tumor, with groin dissection for tumors with a thickness of more than 1 mm. Current literature on cutaneous melanoma suggests that a 1-cm margin of skin and subcutaneous tissue is sufficient for the treatment of superficial localized melanoma (Breslow tumor thickness <0.76 mm), whereas a 2-cm margin suffices for intermediate-thickness lesions (1 to 4 mm) (124,125).

Because melanomas commonly involve the clitoris and labia minora, the vaginourethral margin of resection is a common site of failure, and care should be taken to obtain an adequate “inner” resection margin (126). A 10-year survival rate of 61% has been shown for lateral lesions, compared with 37% for medial lesions (p = 0.027) (111).

Controversy exists as to which patients may benefit from inguinal-femoral lymphadenectomy. A prospective study by the GOG demonstrated that the risk of inguinal-femoral lymph node metastasis correlated with the Breslow microstage (113). As with cutaneous melanoma, it appears that for superficial lesions (Breslow tumor thickness <0.76 mm) the risk for nodal spread is so low that routine lymphadenectomy is not indicated as long as the nodes appear clinically to be free of disease. For intermediate-thickness (1 to 4 mm) cutaneous melanoma, a randomized controlled trial of elective lymph node dissection versus observation showed a 5-year survival advantage for patients who underwent elective lymph node dissection, who were younger than 60 years, and whose tumors were characterized by 1- to 2-mm thickness and no ulcerations (127). Patients with deeply invasive cutaneous melanomas (>4-mm tumor thickness) have a high risk of regional and systemic metastases and are unlikely to benefit from regional lymphadenectomy (128). Given some of the epidemiologic, histologic, and prognostic differences between vulvar and cutaneous melanoma (114), extrapolation of these data to the vulva should be done with caution. Specific to patients with vulvar melanoma, there is a small body of literature to suggest that there may be a clinical benefit in elective groin lymphadenectomy and the resection of clinically positive nodes (111,112).

Pelvic node metastases do not occur in the absence of groin node metastases (129,120,130). In addition, the prognosis for patients with positive pelvic nodes is so poor that there seems to be no value in performing pelvic lymphadenectomy for this disease.

Chemotherapy and immunotherapy for vulvar melanoma have disappointing results. Interferon-alpha has been used with some improvement in survival rates for patients with deep invasive (>4 mm) cutaneous melanomas and those with lymph node metastases, but morbidity is significant (131,132). Estrogen receptors have been demonstrated in human melanomas (133), and an occasional response to tamoxifen has been reported (134,135). Cancer vaccines are currently under investigation (136).
Prognosis

The behavior of melanomas can be quite unpredictable, but the overall prognosis is poor. The reported 5-year survival rate for vulvar melanoma ranges from 25% (123) to 50% (108,109). Because vulvar melanoma has a propensity for late recurrences, 5-year survival may not reflect cure. Prognosis is best predicted by microstaging. Patients with lesions invading to 1 mm or less have a good prognosis, but as depth of invasion increases, the prognosis worsens (Table 33.7). Tumor volume has been reported to correlate with prognosis; patients whose lesions have a volume under 100 mm$^3$ have an excellent prognosis (130). Additional prognostic factors are the patient’s age, AJCC stage, presence of multifocal or satellite lesions, tumor ulceration, central tumor location, histologic growth pattern, lymph–vascular space involvement, and aneuploidy (108,111,112 and 113,138).

Table 33.8. Survival of Patients with Bartholin Gland Carcinoma

Bartholin Gland Carcinoma

Epidemiology

Primary carcinoma of the Bartholin gland is a rare form of vulvar cancer, which accounts for about 2% to 7% of vulvar malignancies (141). Because of its rarity, individual experience with the tumor is limited, and recent management for management must be based on the review of small published series. To date, only about 300 cases have been reported (47,141,142). Bartholin gland carcinoma is 5 times more common in postmenopausal than in premenopausal women (143).

Histopathology

The bilateral Bartholin glands are greater vestibular glands situated posterolaterally in the vulva. Their main duct is lined with stratified squamous epithelium, which changes to transitional epithelium as the terminal ducts are reached. Because tumors may arise from the gland or the duct, a variety of histologic types occur, including adenocarcinomas, squamous carcinomas and, rarely, transitional cell, adenosquamous, and adenoid cystic carcinomas.

Classification of a vulvar tumor as a Bartholin gland carcinoma has typically required that it fulfill Honan's criteria, which are as follows:

1. The tumor is in the correct anatomic position.
2. The tumor is located deep in the labium majus.
3. The overlying skin is intact.
4. There is some recognizable normal gland present.

Strict adherence to these criteria will result in underdiagnosis of some cases. Large tumors may ulcerate through the overlying skin and obliterate the residual normal gland. Although transition between normal and malignant tissue is the best criterion, some cases will be diagnosed on the basis of their histologic characteristics and anatomic location.

Signs and Symptoms

The most common initial symptom of Bartholin gland carcinoma is a vulvar mass or perineal pain. About 10% of patients have a history of inflammation of the Bartholin gland and malignancies may be mistaken for benign cysts or abscesses. Therefore, delay of diagnosis is common, particularly for premenopausal patients. The differential diagnosis of any pararectovaginal neoplasm should include cloacogenic carcinoma and secondary neoplasm (142).

Treatment

Traditionally, treatment has been radical vulvectomy with bilateral groin and pelvic node dissection (144). However, there seems to be no indication for dissection of the pelvic nodes in the absence of positive groin nodes, and good results have been reported with hemivulvectomy or radical local excision for the primary tumor (142). Because these lesions are deep in the vulva, extensive dissection is required in the ischiorectal fossa; even then, surgical margins are often close. Postoperative radiation to the vulva decreased the likelihood of local recurrence from 27% (6 of 22 patients) to 7% (1 of 14 patients) (142). If the ipsilateral groin nodes are positive, bilateral groin and pelvic irradiation may decrease regional recurrence. If the tumor is fixed to the inferior pubic ramus or involves adjacent structures, such as the anal sphincter or rectum, preoperative radiation and chemotherapy is preferable to avoid ultraradical surgery.

Prognosis

Because of the deep location of the gland, disease tends to be more advanced than squamous carcinomas at the time of diagnosis but, stage for stage, the prognosis is similar. Five-year disease-free survival rates by stage are summarized in Table 33.8.

Table 33.8. Survival of Patients with Bartholin Gland Carcinoma

Adenoid Cystic Carcinoma of the Bartholin Gland
The adenoid cystic variety accounts for 15% of Bartholin gland carcinomas. It is less likely to metastasize to lymph nodes and carries a somewhat better prognosis (47,146) (Fig. 33.8). Local recurrences are common, however, and metastases may occur, particularly to the lungs. The slowly progressive nature of these tumors and the tendency for late recurrences is reflected in the disparity between progression-free interval and survival curves (146).

**Other Adenocarcinomas**

Adenocarcinomas of the vulva usually arise in a Bartholin gland or occur in association with Paget's disease. They may rarely arise from the skin appendages, paraurethral glands, minor vestibular glands, aberrant breast tissue, endometriosis, or a misplaced cloacal remnant (147).

**Adenosquamous Carcinoma**

A particularly aggressive type of carcinoma is the adenosquamous carcinoma. This tumor has a number of synonyms, including cylindroma, pseudoglandular squamous cell carcinoma, adenoid squamous cell carcinoma, and adenoanaplastic carcinoma of the sweat gland of Lever. The tumor has a propensity for perineurial invasion, early lymph node metastasis, and local recurrence. One study noted a crude 5-year survival rate of 5.5% (1 of 18) for adenosquamous carcinoma of the vulva, compared with 62.3% (48 of 77) for patients with squamous cell carcinoma (148). Treatment should be radical vulvectomy and bilateral groin dissection. Postoperative radiation therapy may be appropriate.

**Basal Cell Carcinoma**

Basal cell carcinomas represent about 2% of vulvar cancers. As with other basal cell carcinomas, vulvar lesions commonly appear as a "rodent ulcer" with rolled edges, although nodules and macules are other morphologic varieties that occur. Most lesions are smaller than 2 cm in diameter and are usually situated on the anterior labia majora. Giant lesions occasionally occur (149). Basal cell carcinoma usually affects postmenopausal white women and is locally aggressive. Symptoms are frequently present for a prolonged period and most frequently include pruritus, soreness, and irritation (150). It is diagnosed by biopsy, and radical local excision is generally adequate treatment. Metastasis to regional lymph nodes has been reported but is rare (151,152 and 153). The local recurrence rate is about 10% to 20% (150,154). Basal cell carcinoma of the vulva is associated with a high incidence of antecedent or concomitant malignancies elsewhere (150). In a series of 28 women with vulvar basal cell carcinoma, 10 patients had other basal cell carcinomas, and 10 patients suffered from other primary malignancies (150).

About 3% to 5% of basal cell carcinomas contain a malignant squamous component, the so-called basosquamous carcinoma. These lesions are more aggressive and should be treated as squamous carcinomas (153). Another subtype of basal cell carcinoma is the adenoid cystic carcinoma which must be differentiated from the more aggressive adenoid cystic carcinoma arising in a Bartholin gland or the skin (153).

**Verrucous Carcinoma**

Verrucous carcinoma is a variant of squamous cell carcinoma and has distinctive clinical and pathologic characteristics (155). Although most commonly found in the oral cavity, verrucous lesions may be found on any moist membrane composed of squamous epithelium (156). In the female genital tract, these lesions may develop on the cervix, vulva, and vagina. The cause of the lesion in the female genital tract is not fully understood, but associated HPV-6 and HPV-11 have been found (157).

Grossly, the tumors have a cauliflower-like appearance; microscopically, they contain multiple papillary fronds that lack the central connective tissue core that characterizes condylomata acuminata (Fig. 33.9). The gross and microscopic features of a verrucous carcinoma are very similar to those of the giant condyloma of Buschke-Loewenstein, and they probably represent the same disease entity (147). Adequate biopsy from the base of the lesion is required to differentiate a verrucous carcinoma from a benign condyloma acuminatum or a squamous cell carcinoma with a verrucous growth pattern.

**Figure 33.8. Adenoid cystic tumor of the Bartholin gland.** Basaloid cells form cribriform, sieve-like spaces containing mucinous material. The hyaline stroma is another distinct feature of this tumor. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

**Figure 33.9 Verrucous carcinoma of the vulva.** Note the exophytic hyperkeratotic papillary fronds and endophytic bulky rete pegs with smooth borders. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Verrucous carcinomas usually occur in postmenopausal women, and they are slow-growing but locally destructive lesions. Even bone may be invaded. Metastasis to regional lymph nodes is rare but has been reported (159). Radical local excision is the basic treatment, although any palpably suspicious groin nodes should be evaluated with fine-needle aspiration cytology or excisional biopsy. Usually, enlarged nodes will be caused by inflammatory hypertrophy (159). If the nodes contain metastases, radical vulvectomy and bilateral inguinal-femoral lymphadenectomy are indicated.

Several small studies failed to document any therapeutic advantage with radiation therapy (159,160). In addition, there is concern that radiation may induce anaplastic transformation with subsequent regional and distant metastasis (151). One study reported a corrected 5-year survival rate of 94% for 17 patients treated with surgery alone, compared with 42% for 7 patients treated with surgery and radiation (159). The latter patients had, however, more advanced disease. If there is a recurrence, further surgical excision is the treatment of choice, which occasionally may necessitate some type of exenteration.
Vulvar Sarcoma

Sarcomas represent 1% to 2% of vulvar malignancies and constitute a heterogeneous group of tumors. Leiomyosarcomas are the most common, and other histologic types include fibrosarcomas, neurofibrosarcomas, liposarcomas, rhabdomyosarcomas, angiosarcomas, epithelioid sarcomas, and malignant schwannomas (147).

Leiomyosarcomas usually appear as enlarging, often painful masses, usually in the labium majus. Smooth muscle tumors of the vulva that show at least three of the following four criteria should be regarded as sarcomas: (a) diameter >5 cm, (b) infiltrating margins, (c) 5 or more mitotic figures per 10 high-power fields, (d) moderate-to-severe cytological atypia (162). The absence of one, or even all, of these features does not guarantee against recurrence (163). Lympathic metastases are uncommon, and radical local excision is the usual treatment.

Epithelioid sarcomas characteristically develop in the soft tissues of the extremities of young adults but rarely may occur on the vulva. In a description of two cases and review of three other reports, the authors concluded that these tumors may mimic a Bartholin cyst, thus leading to inadequate initial treatment (164). They also believed that vulvar epithelioid sarcomas behave more aggressively than their extragenital counterparts, with four of the five patients dying of metastatic disease. They suggested that early recognition and wide excision should improve the prognosis.

Rhodobasoscaromas are the most common soft tissue sarcoma in childhood, and 20% involve the pelvis or genitourinary tract (165). Dramatic gains have been made in the treatment of these tumors during the past 20 years. Previously, radical pelvic surgery was the standard approach, but results were poor. More recently, a multimodal approach has evolved, and survival rates have improved significantly, with a corresponding decrease in morbidity. In a report of the experience of the Intergroup Rhodobasoscarcoma Study I and II (1972 to 1984) with primary tumors of the female genital tract, nine patients aged 1 to 19 years had primary vulvar tumors, and these tumors were often regarded as a form of Bartholin gland infection before biopsy (166). They were all managed with chemotherapy (vincristine, or actinomycin D, or both) and surgery. When local excision of the tumor, with or without inguinal-femoral lymphadenectomy, was carried out before or after the chemotherapy. Seven of the nine patients were free of disease 4 or more years from diagnosis, one patient was free of disease when lost to follow-up at 5 years, and one patient was alive with disease.

Rare Vulvar Malignancies

In addition to the previously mentioned tumors, a number of malignancies more commonly seen in other areas of the body may rarely occur as isolated vulvar tumors.

Lymphomas

The genital tract may be involved primarily by malignant lymphomas but, more commonly, involvement is a manifestation of systemic disease. In the lower genital tract, the cervix is most often involved, followed by the vulva and the vagina (147). Most patients are in their third to sixth decade of life, and about three-fourths of the cases involve diffuse large cell or histiocytic non-Hodgkin's lymphomas. The remainder are nodular or Burkitt's lymphomas (134). Treatment is by surgical excision followed by chemotherapy and radiation or both, and the overall 5-year survival rate is about 70% (167).

Endometrial Sinus Tumor

There have been four case reports of endometrial sinus tumor of the vulva, and three of the four patients died of distant metastases (147,168). All patients were in their third decade of life, but none was treated with modern chemotherapy.

Merkel Cell Carcinoma

Merkel cell carcinomas are primary small cell carcinomas of the skin, which resemble oat cell carcinomas of the lung. They metastasize widely and have a very poor prognosis (169,170). They should be locally excised and treated with cisplatin-based chemotherapy.

Dermatofibrosarcoma Protubersan

This rare, low-grade cutaneous malignancy occasionally involves the vulva. It has a marked tendency for local recurrence but a low risk of systemic spread (171). Radical local excision should be sufficient treatment.

Metastatic Tumors of the Vulv

Eight percent of vulvar tumors are metastatic (147). The most common primary site is the cervix, followed by the endometrium, kidney, and urethra. Most patients in whom vulvar metastases develop have advanced primary tumors when diagnosed, and in about one-fourth of the patients the primary lesion and the vulvar metastasis are diagnosed simultaneously (172).

References

Gestational trophoblastic disease (GTD) is among the rare human tumors that can be cured even in the presence of widespread dissemination (1,2). This classification includes a spectrum of interrelated tumors, including complete and partial hydatidiform mole, placental-site trophoblastic tumor, and choriocarcinoma, which have varying propensities for local invasion and metastasis. Although persistent gestational trophoblastic tumors (GTTs) most commonly follow a molar pregnancy, they may ensue after any gestational event, including therapeutic or spontaneous abortion, ectopic pregnancy, or term pregnancy. Advances in the understanding of the pathogenesis, natural history, and treatment of GTD and the current approach to management are reviewed.

Hydatidiform Mole

Epidemiology

Estimates of the incidence of GTD vary dramatically in different regions of the world. For example, the incidence of molar pregnancy in Japan (2 per 1,000 pregnancies) has been reported to be about threefold higher than the incidence in Europe or North America (about 0.6 to 1.1 per 1,000 pregnancies) (3). The variation in the incidence rates of molar pregnancy may in part result from differences between reporting population-based versus hospital-based data. The incidences of both complete and partial mole have been investigated in Ireland by reviewing all products of conception from first- and second-trimester abortions (4). Based on a complete pathologic review, the incidence of complete and partial mole was found to be 1 per 1,945 and 1 per 695 pregnancies, respectively.

Case-control studies have been undertaken to identify risk factors for both complete and partial molar pregnancy. The high incidence of molar pregnancy in some populations has been attributed to nutritional and socioeconomic factors. Case-control studies from Italy and the United States have shown that low dietary intake of carotene may be associated with an increased risk of complete molar pregnancy (5,6). Areas with a high incidence of molar pregnancy also have a high frequency of vitamin A deficiency. Dietary factors, therefore, may partly explain regional variations in the incidence of complete mole. Maternal age older than 35 years has consistently been shown to be a risk factor for complete mole. Ova from older women may be more susceptible to abnormal fertilization. In one study, the risk for complete mole was increased 2.0-fold for women older than 35 years and 7.5-fold for women older than 40 years (7). Limited information is available concerning risk factors for partial molar pregnancy. However, the epidemiologic characteristics of complete and partial mole may differ. There is no association between maternal age and the risk for partial mole (7). The risk for partial mole has been reported to be associated with the use of oral contraceptives and a history of irregular menstruation, but not with dietary factors (8).

Complete Versus Partial Hydatidiform Mole

Hydatidiform moles may be categorized as either complete or partial moles on the basis of gross morphology, histopathology, and karyotype (Table 34.1).

Table 34.1. Features of Complete and Partial Hydatidiform Moles
Pathology Complete moles lack identifiable embryonic or fetal tissues, and the chorionic villi exhibit generalized hydatidiform swelling and diffuse trophoblastic hyperplasia (Fig. 34.1).

Figure 34.1 Photomicrograph of complete mole demonstrating diffusely hydropic chorionic villi and diffuse trophoblastic hyperplasia.

Chromosomes Cytogenetic studies have demonstrated that complete hydatidiform moles usually have a 46,XX karyotype, and the molar chromosomes are entirely of paternal origin (Fig. 34.2) (9). It appears that complete moles usually arise from an ovum that has been fertilized by a haploid sperm, which then duplicates its own chromosomes. The ovum nucleus may be either absent or inactivated (10). Although most complete moles have a 46,XX chromosomal pattern, about 10% have a 46,XY karyotype (11). Chromosomes in a 46,XY complete mole also appear to be entirely of paternal origin, although mitochondrial DNA is of maternal origin (12).

Figure 34.2 The karyotype of complete hydatidiform mole.

Partial Hydatidiform Mole

Pathology Partial hydatidiform moles are characterized by the following pathologic features (13) (Fig. 34.3):

1. Chorionic villi of varying size with focal hydatidiform swelling, cavitation, and trophoblastic hyperplasia
2. Marked villous scalloping
3. Prominent stromal trophoblastic inclusions
4. Identifiable embryonic or fetal tissues.

Chromosomes Partial moles generally have a triploid karyotype (69 chromosomes); the extra haploid set of chromosomes usually is derived from the father (Fig. 34.4) (14). One study reported that 93% of partial moles were triploid (14), whereas another found 90% to be triploid (15). When a fetus is present in conjunction with a partial mole, it generally exhibits the stigmata of triploidy, including growth restriction and multiple congenital malformations such as syndactyly and hydrocephaly (Fig. 34.5).

Figure 34.4 The karyotype of partial hydatidiform mole.
Preevacuation hCG levels were measured in 30 patients and were higher than 100,000 mIU/ml in only two patients (6.6%).

Hyperthyroidism. The initial clinical diagnosis was an incomplete or missed abortion in 74 patients (91.3%) and hydatidiform mole in only five patients (6.2%).

Respiratory distress is usually diagnosed in patients with excessive uterine size and markedly elevated hCG levels. These patients may have chest pain, dyspnea, tachycardia, and chest radiographic evaluation may demonstrate bilateral pulmonary infiltrates. Respiratory distress usually resolves within 72 hours with cardiopulmonary support. In some circumstances, patients may require mechanical ventilation. Respiratory insufficiency may result from trophoblastic embolization or from the cardiopulmonary complications of thyroid storm, preeclampsia, and massive fluid replacement.

Thyroid storms may be manifest by hyperthermia, delirium, convulsions, tachyphlethma, high-output heart failure, or cardiovascular collapse. Administration of b-adrenergic blocking agents prevents or rapidly reverses many of the metabolic and cardiovascular complications of thyroid storm. After molar evacuation, thyroid function test results return rapidly to normal.

If hyperthyroidism is suspected before the induction of anesthesia for molar evacuation, b-adrenergic blocking agents should be administered because anesthesia or surgery may precipitate thyroid storm. Thyroid storms may be manifest by hyperthermia, delirium, convulsions, tachyphlethma, high-output heart failure, or cardiovascular collapse. Administration of b-adrenergic blocking agents prevents or rapidly reverses many of the metabolic and cardiovascular complications of thyroid storm. After molar evacuation, thyroid function test results return rapidly to normal.

Prominent theca lutein ovarian cysts may cause symptoms of marked pelvic pressure, and they may be decompressed by laparoscopic or ultrasonographically directed aspiration. If acute pelvic pain develops, laparoscopy should be performed to assess possible cystic torsion or rupture.

Partial Hydatidiform Mole

Patients with partial hydatidiform mole usually do not have the dramatic clinical features characteristic of complete molar pregnancy. In general, these patients have the signs and symptoms of incomplete or missed abortion, and partial mole can be diagnosed after histologic review of the tissue obtained by curettage.

In a survey of 81 patients with a partial mole, the main initial sign was vaginal bleeding, which occurred in 59 patients (72.8%) (22). Excessive uterine enlargement and preeclampsia were present in only three patients (3.7%) and two (2.5%) patients, respectively. No patients had theca lutein ovarian cysts, hyperemesis, or preeclampsia. The initial clinical diagnosis was an incomplete or missed abortion in 74 patients (91.3%) and hydatidiform mole in only five patients (6.2%). Preevacuation hCG levels were measured in 30 patients and were higher than 100,000 mIU/ml in only two patients (6.6%).

Natural History

Complete Hydatidiform Mole

Clinical Features

Increasingly, patients with complete molar pregnancy are being diagnosed earlier in pregnancy and are being treated before they develop the classic clinical signs and symptoms. This may be due to changes in clinical practice, such as the frequent use of vaginal probe ultrasonography in early pregnancy in women with vaginal staining and even asymptomatic women. Following is a description of the classic and current clinical features of complete molar pregnancy based on the authors’ experience (16).

Complete Hydatidiform Mole

Vaginal Bleeding Vaginal bleeding is the most common symptom causing patients to seek treatment for complete molar pregnancy. Previously, it was reported to occur in 97% of cases, whereas currently it is reported to occur in 84% of patients (17). Molar tissues may separate from the decidua and disrupt maternal vessels, and large volumes of retained blood may distend the endometrial cavity. Because vaginal bleeding may be considerable and prolonged, one-half of these patients had anemia (hemoglobin <10 g/100 ml). Currently anemia is present in only 5% of patients.

Excessive Uterine Size Excessive uterine enlargement relative to gestational age is one of the classic signs of a complete mole, although it was present in only about one-half of patients. The endometrial cavity may be expanded by both chorionic tissue and retained blood. Excessive uterine size is generally associated with markedly elevated levels of human chorionic gonadotropin (hCG), because uterine enlargement results in part from trophoblastic overgrowth. Currently, excessive uterine size is present at diagnosis in only 28% of patients.

Preeclampsia Preeclampsia was once observed in 27% of patients with a complete hydatidiform mole. However, at one center between 1988 and 1993, only 1 of 74 patients with complete mole had preeclampsia at the initial visit (17). Although preeclampsia is associated with hypertension, proteinuria, and hyperreflexia, eclamptic convulsions rarely occur. Preeclampsia develops almost exclusively in patients with excessive uterine size and markedly elevated hCG levels. Hydatidiform mole should be considered whenever preeclampsia develops early in pregnancy.

Hyperemesis Gravidarum Hyperemesis requiring antimetic or intravenous replacement therapy once occurred in one-fourth of women with a complete mole, particularly those with excessive uterine size and markedly elevated hCG levels. Severe electrolyte disturbances may develop and require treatment with parenteral fluids. Currently, only 8% of patients have hyperemesis.

Hyperthyroidism Clinically evident hyperthyroidism was once observed in 7% of patients with a complete molar gestation. These women may have tachycardia, warm skin, and tremor, and the diagnosis can be confirmed by detection of elevated serum levels of free thyroxine (T_4) and triiodothyronine (T_3). Between 1988 and 1993, none of the author’s 74 patients with complete mole had clinical evidence of hyperthyroidism.

If hyperthyroidism is suspected before the induction of anesthesia for molar evacuation, b-adrenergic blocking agents should be administered because anesthesia or surgery may precipitate thyroid storm. Thyroid storms may be manifest by hyperthermia, delirium, convulsions, tachyphlethma, high-output heart failure, or cardiovascular collapse. Administration of b-adrenergic blocking agents prevents or rapidly reverses many of the metabolic and cardiovascular complications of thyroid storm. After molar evacuation, thyroid function test results return rapidly to normal.

Prominent theca lutein ovarian cysts may cause symptoms of marked pelvic pressure, and they may be decompressed by laparoscopic or ultrasonographically directed aspiration. If acute pelvic pain develops, laparoscopy should be performed to assess possible cystic torsion or rupture.

Partial Hydatidiform Mole

Patients with partial hydatidiform mole usually do not have the dramatic clinical features characteristic of complete molar pregnancy. In general, these patients have the signs and symptoms of incomplete or missed abortion, and partial mole can be diagnosed after histologic review of the tissue obtained by curettage.

In a survey of 81 patients with a partial mole, the main initial sign was vaginal bleeding, which occurred in 59 patients (72.8%) (22). Excessive uterine enlargement and preeclampsia were present in only three patients (3.7%) and two (2.5%) patients, respectively. No patients had theca lutein ovarian cysts, hyperemesis, or preeclampsia. The initial clinical diagnosis was an incomplete or missed abortion in 74 patients (91.3%) and hydatidiform mole in only five patients (6.2%). Preevacuation hCG levels were measured in 30 patients and were higher than 100,000 mIU/ml in only two patients (6.6%).
Complete moles have a potential for local invasion and dissemination. After molar evacuation, local uterine invasion occurs in 15% of patients and metastasis occurs in 4% (19).

A review of 858 patients with complete hydatidiform mole revealed that two-fifths of the patients had the following signs of marked trophoblastic proliferation at the time they sought treatment (19):

1. hCG level >100,000 mIU/ml
2. Excessive uterine enlargement
3. Theca lutein cysts 6 cm in diameter.

Patients with any one of these signs were considered at high risk. After molar evacuation, local uterine invasion occurred in 31% and metastases developed in 8.8% of the 352 high-risk patients. For the 506 low-risk patients, local invasion was found in only 3.4%, and metastases developed in 0.6%.

Older patients are also at increased risk of developing postmolar GTT. One study reported that persistent tumor developed after a complete molar pregnancy in 37% of women older than 40 years (23), whereas in another study this finding occurred in 56% of women older than 50 years (23,24).

Partial Hydatidiform Mole

Persistent tumor, usually nonmetastatic, develops in approximately 4% of patients with a partial mole, and chemotherapy is required to achieve remission (25). Patients who develop persistent disease have no distinguishing clinical or pathologic characteristics (26). Additionally, it has been reported that 11 (85%) of 13 patients with partial moles who developed persistent tumor had a triploid karyotype (27).

Diagnosis

Ultrasoundography is a reliable and sensitive technique for the diagnosis of complete molar pregnancy. Because the chorionic villi exhibit diffuse hydropic swelling, complete moles produce a characteristic vesicular ultrasonographic pattern.

Ultrasoundography also may contribute to the diagnosis of partial molar pregnancy by demonstrating focal cystic spaces in the placental tissues and an increase in the transverse diameter of the gestational sac (28). When both of these criteria are present, the positive predictive value for partial mole is 90%.

Treatment

After molar pregnancy is diagnosed, the patient should be evaluated carefully for the presence of associated medical complications, including preeclampsia, hyperthyroidism, electrolyte imbalance, and anemia. After the patient's condition has been stabilized, a decision must be made concerning the most appropriate method of evacuation.

Hysterectomy

If the patient desires surgical sterilization, a hysterectomy may be performed with the mole in situ. The ovaries may be preserved at the time of surgery, even though prominent theca lutein cysts are present. Large ovarian cysts may be decompressed by aspiration. Hysterectomy does not prevent metastasis; therefore, patients still require follow-up with assessment of hCG levels.

Suction Curettage

Suction curettage is the preferred method of evacuation, regardless of uterine size, for patients who desire to preserve fertility. It involves the following steps:

1. Oxytocin infusion—This procedure is begun in the operating room before the induction of anesthesia.
2. Cervical dilation—As the cervix is being dilated, the surgeon frequently encounters increased uterine bleeding. Retained blood in the endometrial cavity may be expelled during cervical dilation. However, active uterine bleeding should not deter the prompt completion of cervical dilation.
3. Suction curettage—Within a few minutes of commencing suction curettage, the uterus may decrease dramatically in size, and the bleeding is generally well controlled. The use of a 12-mm cannula is strongly advised to facilitate evacuation. If the uterus is larger than 14 weeks of gestation, one hand should be placed on top of the fundus, and the uterus should be massaged to stimulate uterine contraction and reduce the risk of perforation.
4. Sharp curettage—When suction evacuation is believed to be complete, gentle sharp curettage is performed to remove any residual molar tissue.

Because trophoblast cells express RhD factor, patients who are Rh negative should receive Rh immune globulin at the time of evacuation.

Prophylactic Chemotherapy

The use of prophylactic chemotherapy at the time of molar evacuation is controversial (29). The debate concerns the wisdom of exposing all patients to potentially toxic treatment when only about 20% are at risk of developing persistent tumor.

In a study of 247 patients with complete molar pregnancy who received prophylactically a single course of actinomycin D at the time of evacuation, local uterine invasion subsequently developed in only 10 patients (4%), and no patients experienced metastasis (29). Furthermore, all 10 patients with local invasion achieved remission after only one additional course of chemotherapy. Prophylactic chemotherapy, therefore, not only prevented metastasis but also reduced the incidence and morbidity of local uterine invasion.

In a prospective randomized study of prophylactic chemotherapy in patients with a complete mole, a significant decrease in persistent tumor was detected in patients with high-risk mole who received prophylactic chemotherapy (47% versus 14%) (30). Prophylaxis may be particularly useful in the management of high-risk complete molar pregnancy, especially when hormonal follow-up is unavailable or unreliable.

Follow-up

Human Chorionic Gonadotropin

After molar evacuation, patients should be monitored with weekly determinations of h-subunit hCG levels until these levels are normal for 3 consecutive weeks, followed by monthly determinations until the levels are normal for 6 consecutive months. The average time to achieve the first normal hCG level after evacuation is about 9 weeks (31). At the completion of follow-up, pregnancy may be undertaken.

Contraception

Patients are encouraged to use effective contraception during the entire interval of hCG follow-up. Because of the potential risk of uterine perforation, intrauterine devices should not be inserted until the patient achieves a normal hCG level. If the patient does not desire surgical sterilization, the choice is to use either oral contraceptives or barrier methods.

The incidence of postmolar persistent tumor has been reported to be increased among patients who used oral contraceptives before gonadotropin remission (32).
However, more recent data indicate that oral contraceptives do not increase the risk of postmolar trophoblastic disease (33,34). It appears that oral contraceptives may be used safely after molar evacuation during the entire interval of hormonal follow-up.

**Persistent Gestational Trophoblastic Tumor**

**Nonmetastatic Disease**

Locally invasive GTT develops in about 15% of patients after molar evacuation and infrequently after other gestations (3). These patients usually are seen clinically with the following symptoms:

1. Irregular vaginal bleeding
2. Theca lutein cysts
3. Uterine subinvolution or asymmetric enlargement
4. Persistently elevated serum hCG levels.

The trophoblastic tumor may perforate through the myometrium, causing intraperitoneal bleeding, or erode into uterine vessels, causing vaginal hemorrhage. Bulky, necrotic tumor may involve the uterine wall and serve as a nidus for infection. Patients with uterine sepsis may have a purulent vaginal discharge and acute pelvic pain.

After molar evacuation, persistent GTT may exhibit the histologic features of either hydatidiform mole or choriocarcinoma. After a nonmolar pregnancy, however, persistent GTT always has the histologic pattern of choriocarcinoma. Histologically, choriocarcinoma is characterized by sheets of anaplastic syncytiotrophoblast and cytotrophoblast without chorionic villi.

**Placental-site Trophoblastic Tumor**

Placental-site trophoblastic tumor is an uncommon but important variant of choriocarcinoma that consists predominantly of intermediate trophoblast (35). Relative to their mass, these tumors produce small amounts of hCG and human placental lactogen (hPL), and they tend to remain confined to the uterus, metastasizing late in their course. In contrast to other trophoblastic tumors, placental-site tumors are relatively insensitive to chemotherapy.

**Metastatic Disease**

Metastatic GTT occurs in about 4% of patients after evacuation of a complete mole, but it is seen more often when GTT develops after nonmolar pregnancies (1). Metastasis is usually associated with choriocarcinoma, which has a tendency toward early vascular invasion with widespread dissemination. Because trophoblastic tumors often are perfused by fragile vessels, they are frequently hemorrhagic. Symptoms of metastases may result from spontaneous bleeding at metastatic foci. The most common sites of metastases are lung (80%), vagina (30%), pelvis (20%), liver (15%), and brain (10%).

**Pulmonary**

At the time of diagnosis, lung involvement is visible on chest radiographs of 80% of patients with metastatic GTT. Patients with pulmonary metastasis may have chest pain, cough, hemoptysis, dyspnea, or an asymptomatic lesion on chest radiograph. Respiratory symptoms may be acute or chronic, persisting over many months.

GTT may produce four principal pulmonary radiographic patterns:

1. An alveolar or “snowstorm” pattern
2. Discrete rounded densities
3. Pleural effusion
4. An embolic pattern caused by pulmonary arterial occlusion.

Because respiratory symptoms and radiographic findings may be dramatic, the patient may be thought to have a primary pulmonary disease. Some patients with extensive pulmonary involvement have minimal, if any, gynecologic symptoms because the reproductive organs may be free of trophoblastic tumor. Unfortunately, the diagnosis of GTT may be confirmed only after thoracotomy has been performed, particularly in patients with a nonmolar antecedent pregnancy. Pulmonary hypertension may develop in patients with GTT secondary to pulmonary arterial occlusion by trophoblastic emboli. The development of early respiratory failure requiring intubation is associated with a dismal clinical outcome (36-37).

**Vaginal**

Vaginal metastases occur in 30% of the patients with metastatic tumor. These lesions are usually highly vascular and may bleed vigorously if a sample is taken for biopsy. Metastases to the vagina may occur in the fornices or suburethrally and may produce irregular bleeding or a purulent discharge.

**Hepatic**

Liver metastases occur in 10% of patients with disseminated trophoblastic tumor. Hepatic involvement is encountered almost exclusively in patients with protracted delays in diagnosis and extensive tumor burdens. Epigastric or right upper quadrant pain may develop if metastases stretch the hepatic capsule. Hepatic lesions may be hemorrhagic, causing hepatic rupture and exsanguinating intraperitoneal bleeding.

**Central Nervous System**

Metastatic trophoblastic disease involves the brain in 10% of patients. Cerebral involvement is generally seen in patients with advanced disease; virtually all patients with brain metastasis have concurrent pulmonary or vaginal involvement or both. Because cerebral lesions may hemorrhage spontaneously, patients may develop acute focal neurologic deficits.

**Staging**

An anatomic staging system for GTT has been adopted by the International Federation of Gynecology and Obstetrics (FIGO) (Table 34.2). It is hoped that this staging system will encourage the objective comparison of data among various centers.
Table 34.2. Staging of Gestational Trophoblastic Tumors

Stage I: Patients have persistently elevated hCG levels and tumor confined to the uterine corpus.

Stage II: Patients have metastases to the vagina and pelvis or both.

Stage III: Patients have pulmonary metastases with or without uterine, vaginal, or pelvic involvement. The diagnosis is based on a rising hCG level in the presence of pulmonary lesions on chest radiograph.

Stage IV: Patients have advanced disease and involvement of the brain, liver, kidneys, or gastrointestinal tract. These patients are in the highest risk category, because they are most likely to be resistant to chemotherapy. The histologic pattern of choriocarcinoma is usually present, and disease commonly follows a nonmolar pregnancy.

Prognostic Scoring System

In addition to anatomic staging, it is important to consider other variables to predict the likelihood of drug resistance and to assist in selecting appropriate chemotherapy (38). A prognostic scoring system proposed by the World Health Organization reliably predicts the potential for resistance to chemotherapy (Table 34.3).

Table 34.3. Scoring System Based on Prognostic Factors

When the prognostic score is higher than 7, the patient is categorized as high risk and requires intensive combination chemotherapy to achieve remission. Patients with stage I disease usually have a low-risk score, and those with stage IV disease have a high-risk score. The distinction between low and high risk applies mainly to patients with Stage II or III disease.

Diagnostic Evaluation

Optimal management of persistent GTT requires a thorough assessment of the extent of the disease prior to the initiation of treatment. All patients with persistent GTT should undergo a careful pretreatment evaluation, including the following:

1. Complete history and physical examination
2. Measurement of the serum hCG value
3. Hepatic, thyroid, and renal function tests
4. Determination of baseline peripheral white blood cell and platelet counts.

The metastatic workup should include the following:

1. Chest radiograph or computed tomography (CT) scan
2. Ultrasonography or CT scan of the abdomen and pelvis
3. CT or magnetic resonance imaging (MRI) scan of the head.

When the pelvic examination and chest radiographic findings are negative, metastatic involvement of other sites is uncommon.

Liver ultrasonography and CT scanning will document most hepatic metastases in patients with abnormal liver function tests. CT or MRI scan of the head has facilitated the early diagnosis of asymptomatic cerebral lesions (39). Chest CT scans may demonstrate micrometastases not visible on a chest radiograph.

In patients with choriocarcinoma or metastatic disease, hCG levels may be measured in the cerebrospinal fluid (CSF) to exclude cerebral involvement if the results of CT scanning of the brain are normal. The ratio of plasma-to-CSF hCG tends to be lower than 60 in the presence of cerebral metastases (40). However, a single plasma-to-CSF hCG ratio may be misleading, because rapid changes in plasma hCG levels may not be reflected promptly in the CSF (41).

Pelvic ultrasonography appears to be useful in detecting extensive trophoblastic uterine involvement and may also aid in identifying sites of resistant uterine tumor (42). Because ultrasonography can accurately and noninvasively detect extensive uterine tumor, it may help identify patients who would benefit from hysterectomy.

Management of Persistent GTT

A protocol for the management of GTT is presented in Table 34.4.
Table 34.4. Protocol for Treatment of GTT

Stage I

In patients with stage I disease, the selection of treatment is based primarily on whether the patient desires to retain fertility.

Hysterectomy plus Chemotherapy

If the patient does not wish to preserve fertility, hysterectomy with adjuvant single-agent chemotherapy may be performed as primary treatment. Adjuvant chemotherapy is administered for three reasons:

1. To reduce the likelihood of disseminating viable tumor cells at surgery
2. To maintain a cytotoxic level of chemotherapy in the bloodstream and tissues in case viable tumor cells are disseminated at surgery
3. To treat any occult metastases that may already be present at the time of surgery.

Chemotherapy can be administered safely at the time of hysterectomy without increasing the risk of bleeding or sepsis. In a series of 30 patients treated with primary hysterectomy and a single course of adjuvant chemotherapy, all have achieved complete remission with no additional therapy.

Hysterectomy is also performed in all patients with stage I placental-site trophoblastic tumor. Because placental-site tumors are resistant to chemotherapy, hysterectomy for presumed nonmetastatic disease is the only curative treatment. To date, only a small number of patients with metastatic placental-site tumor have been reported to be in sustained remission as a result of chemotherapy (43).

Chemotherapy Alone

Single-agent chemotherapy is the preferred treatment in patients with stage I disease who desire to retain fertility. When primary single-agent chemotherapy was administered to 468 patients with stage I GTT, 431 patients (92.1%) attained complete remission. The remaining 37 resistant patients subsequently achieved remission after combination chemotherapy or surgical intervention.

When patients are resistant to single-agent chemotherapy and desire to preserve fertility, combination chemotherapy should be administered. If the patient is resistant to both single-agent and combination chemotherapy and wants to retain fertility, local uterine resection may be considered. When local resection is planned, a preoperative ultrasonography, MRI, or arteriography may help to define the site of the resistant tumor.

Stages II and III

Low-risk patients are treated with primary single-agent chemotherapy, and high-risk patients are treated with primary intensive combination chemotherapy.

Vaginal and Pelvic Metastasis

In one series, 27 treated patients with stage II disease achieved remission. Single-agent chemotherapy induced complete remission in 16 (84.2%) of 19 low-risk patients. In contrast, only two of eight high-risk patients achieved remission with single-agent treatment; the others required combination chemotherapy.

Vaginal metastases may bleed profusely because they are highly vascular and friable. When bleeding is substantial, it may be controlled by packing the vagina or by wide local excision. Infrequently, arteriographic embolization of the hypogastric arteries may be required to control hemorrhage from vaginal metastases.

Pulmonary Metastasis

Of 143 patients treated with stage III disease, 142 (99%) attained complete remission. Gonadotropin remission was induced with single-agent chemotherapy in 80 of 97 (82.5%) patients with low-risk disease. All patients who were resistant to single-agent treatment subsequently achieved remission with combination chemotherapy.

Thoracotomy Thoracotomy has a limited role in the management of stage III disease. If a patient has a persistent viable pulmonary metastasis despite intensive chemotherapy, however, thoracotomy may be attempted to excise the resistant focus. A thorough metastatic workup should be performed before surgery to exclude other sites of persistent disease. Evidence of fibrotic pulmonary nodules may persist indefinitely on chest radiographs, even after complete gonadotropin remission has been attained. In patients undergoing thoracotomy for resistant disease, chemotherapy should be administered postoperatively to treat potential occult sites of micrometastasis.

Hysterectomy

Hysterectomy may be required in patients with metastatic disease to control uterine hemorrhage or sepsis. Furthermore, in patients with extensive uterine tumor, hysterectomy may substantially reduce the trophoblastic tumor burden and thereby limit the need for multiple courses of chemotherapy.

Follow-up

All patients with stage I through stage III disease should receive follow-up with:

1. Weekly measurement of hCG levels until they are normal for 3 consecutive weeks
2. Monthly measurement of hCG values until levels are normal for 12 consecutive months
3. Effective contraception during the entire interval of hormonal follow-up.

Patients with stage IV disease are at greatest risk of developing rapidly progressive and unresponsive tumors despite intensive multimodal therapy. They should preferably be referred to centers with special expertise in the management of trophoblastic disease.

Stage IV

All patients with stage IV disease should be treated with primary intensive combination chemotherapy and the selective use of radiation therapy and surgery. Before 1975, only 6 of 20 patients (30%) treated with stage IV disease attained complete remission, whereas after that time, 14 of 18 patients (77.8%) achieved remission.
Further chemotherapy is withheld as long as the hCG level is falling progressively. If the hCG level does not decline by 1 log within 18 days after completion of the first treatment, additional single-agent chemotherapy is not administered at any predetermined or fixed interval. If the hCG level plateaus for more than 3 consecutive weeks or begins to rise again, the need for additional treatment is considered.

The response to two consecutive courses of chemotherapy is defined as a fall in the hCG level by 1 log after a course of chemotherapy. If the response to the first treatment is inadequate, the dosage of the patient is increased from 1.0 mg/kg per day to 1.5 mg/kg per day for each of the 4 treatment days. If MTX-FA induced remission in 147 of 162 patients (87.6%); of these patients, 132 (81.5%) required only one course of MTX-FA to attain remission. Subsequently, it has been confirmed that MTX-FA is both effective and safe in the management of GTT.

In: Berek JS, Hacker NF, eds. shape Practical gynecologic oncology, 3rd ed. Philadelphia: Lippincot Williams & Wilkins, 2000:632, with permission.)

**Chemotherapy**

**Single-agent Treatment**

Single-agent chemotherapy with either actinomycin D (Act-D) or MTX has achieved comparable and excellent remission rates in both nonmetastatic and low-risk metastatic GTT. Several protocols using these agents are available. Act-D can be given every other week as a 5-day regimen or in a pulsatile fashion; similarly, MTX can be given either in a 5-day regimen or pulsatile weekly. No study has compared all of these protocols with regard to success. An optimal regimen should maximize the response rate while minimizing morbidity and cost.

The administration of methotrexate with folic acid (MTX-FA) in GTT to limit systemic toxicity was first reported in 1964. Subsequently, it has been confirmed that MTX-FA has been the preferred single agent in the treatment of GTT. An evaluation of 185 patients treated in this manner revealed that complete remission was achieved in 162 patients (87.6%); of these patients, 132 (81.5%) required only one course of MTX-FA to attain remission. MTX-FA induced remission in 147 of 163 patients (90.2%) with stage I GTT and in 15 of 22 patients (68.2%) with low-risk stages II and III GTT. Resistance to therapy was more common in patients with chorioncarcinoma, metastasis, and pretreatment serum hCG levels higher than 50,000 mIU/ml. After treatment with MTX-FA, thrombocytopenia, granulocytopenia, and hepatotoxicity developed in only 3 (1.6%), 11 (5.9%), and 26 (14.1%) patients, respectively. Thus, MTX-FA achieved an excellent therapeutic outcome with minimal toxicity and attained this goal with limited exposure to chemotherapy.

The serum hCG level is measured weekly after each course of chemotherapy, and the hCG regression curve serves as the primary basis for determining the need for additional treatment.

After the first treatment:

1. Further chemotherapy is withheld as long as the hCG level is falling progressively.
2. Additional single-agent chemotherapy is not administered at any predetermined or fixed interval.

A second course of chemotherapy is administered under the following conditions:

1. If the hCG level plateaus for more than 3 consecutive weeks or begins to rise again
2. If the hCG level does not decline by 1 log within 18 days after completion of the first treatment.

If the patient's response to the first treatment was adequate and a second course of MTX-FA is required, the dosage of MTX is unaltered. An adequate response is defined as a fall in the hCG level by 1 log after a course of chemotherapy.

If the response to the first treatment is inadequate, the dosage of MTX is increased from 1.0 mg/kg per day to 1.5 mg/kg per day for each of the 4 treatment days. If the response to two consecutive courses of MTX-FA is inadequate, the patient is considered to be resistant to MTX, and Act-D is promptly substituted. If the hCG levels do not decline by 1 log after treatment with Act-D, the patient also is considered resistant to Act-D as a single agent. She must then be treated intensively with...
Combination Chemotherapy

Triple Therapy

Triple therapy with MTX, Act-D, and cyclophosphamide is inadequate as an initial treatment in patients with metastasis and a high-risk prognostic score. Collectively, data from various centers indicate that triple therapy induced remission in only 21 (49%) of 43 patients with metastasis and a high-risk score (score >7) (49 and 51).

Etoposide has been reported to induce complete remission in 56 (95%) of 60 patients with nonmetastatic and low-risk metastatic GTT (52). A new combination regimen described in 1984 included etoposide, MTX, Act-D, cyclophosphamide, and vincristine (EMA-CO) and had an 83% remission in patients with metastasis and a high-risk score (53). Another study (54) confirmed that primary EMA-CO induced complete remission in 76% of the patients with metastatic GTT and a high-risk score (54). Still another study reported that EMA-CO induced complete sustained remission in 61 (94%) of 65 patients with high-risk (score >5) GTT (55). Furthermore, remission occurred with EMA-CO in 13 (86%) of 15 patients with brain metastasis (44).

The EMA-CO regimen is generally well tolerated, and treatment seldom has to be suspended because of toxicity. The EMA-CO regimen is the preferred primary treatment in patients with metastasis and a high-risk prognostic score. However, the optimal combination drug protocol for management of GTT has not yet been clearly defined. If patients experience resistance to EMA-CO, they may then be treated successfully by substituting etoposide and cisplatin on day 8 (EMA-EP). EMA-EP has induced remission alone or with surgery in 16 (76%) of 21 patients who were resistant to EMA-CO (56). The optimal combination drug protocol will most likely include etoposide, MTX, and Act-D and perhaps other agents administered in the most dose-intensive manner.

Duration of Therapy

Patients who require combination chemotherapy must be treated intensively to attain remission. Combination chemotherapy should be given as often as toxicity permits until the patient achieves three consecutive normal hCG levels. After normal hCG levels are attained, at least two additional courses of chemotherapy are administered to reduce the risk of relapse.

Subsequent Pregnancies

Pregnancies After Hydatidiform Mole Patients with hydatidiform moles can anticipate normal reproduction in the future (67). From 1965 until 1999, patients who were treated for complete mole had 1,239 subsequent pregnancies that resulted in 850 term live births (68.6%), 93 premature deliveries (7.5%), 11 ectopic pregnancies (0.9%), 7 stillbirths (0.5%), and 17 repeat molar pregnancies (1.4%). First- and second-trimester spontaneous abortions occurred in 205 (16.5%) and 18 (1.5%) pregnancies, respectively. Major and minor congenital malformations were detected in 38 infants (4.0%), and primary cesarean delivery was performed in 56 of 345 (16.2%) term or preterm births from 1979 to 1999. Although data regarding pregnancies after partial mole are limited (205 subsequent pregnancies), the information is reassuring (57). Patients with both complete and partial mole should be reassured that they are at no increased risk of complications in later gestations.

When a patient has had a molar pregnancy, she is at an increased risk of having a molar gestation in subsequent conceptions (59). After one molar pregnancy, the risk of having molar disease in a future gestation is about 1%. Of 29 patients with at least two documented molar pregnancies, every possible combination of molar pregnancy was observed. After two molar pregnancies, these 29 patients had 34 later conceptions resulting in 19 (55.9%) term deliveries, 7 (20.6%) moles (6 complete, 1 partial), 3 spontaneous abortions, 3 therapeutic abortions, 1 intrauterine fetal death, and 1 ectopic pregnancy. In six patients, the medical records indicated that the patient had a different partner at the time of different molar pregnancies (59).

Therefore, for any subsequent pregnancy, it seems prudent to undertake the following approach:

1. Perform pelvic ultrasonographic examination during the first trimester to confirm normal gestational development.
2. Obtain a thorough histologic review of the placenta or products of conception.
3. Obtain an hCG measurement 6 weeks after completion of the pregnancy to exclude occult trophoblastic neoplasia.

Pregnancies After Persistent GTT Patients with GTT who are treated successfully with chemotherapy can expect normal reproduction in the future. Patients who were treated with chemotherapy at the authors’ institution from 1965 to 1999 had 522 subsequent pregnancies that resulted in 358 term live births (68.6%), 30 preterm deliveries (5.6%), 8 ectopic pregnancies (1.1%), 8 stillbirths (1.5%), and 6 repeat molar pregnancies (1.1%) (57). First- and second-trimester spontaneous abortions occurred in 81 (15.5%) and 7 (1.4%) pregnancies, respectively. Major and minor congenital malformations were detected in 10 infants (2.5%). Primary cesarean delivery was performed in 57 (19.4%) of 294 subsequent term and preterm births from 1979 to 1999. It is particularly reassuring that the frequency of congenital anomalies is not increased, although chemotherapeutic agents are known to have teratogenic and mutagenic potential.

References

Breast cancer accounts for approximately one-third of all cancers in women and is second only to lung cancer as the leading cause of cancer deaths in 
women. Breast cancer, however, has the highest incidence rate of all cancers. According to estimates from the American Cancer Society, in the United States during
2002 there will be 203,500 new cases of breast cancer and 39,600 deaths from this disease in women (1). During the past 50 years, the incidence of breast cancer in
this country has increased significantly; nearly one in every eight women in the United States will develop breast cancer. Fortunately, the mortality rate actually

Predisposing Factors

Less than 1% of all breast cancers occur in women less than 25 years of age. After 30 years of age, however, there is a sharp increase in the incidence of breast
cancer. Except for a short plateau between the ages of 45 and 50 years, the incidence increases steadily with age (2).

Family History

Only 20% of women who develop breast cancer have a family history of the disease. Any family history of breast cancer increases the overall relative risk (3). However, the risk is not increased significantly in women whose mothers or sisters had breast cancer after menopause, whereas women whose mothers or sisters had bilateral breast cancer premenopaually have at least a 40% to 50% lifetime risk. If the patient's mother or sister had unilateral breast cancer premenopaually, her
lifetime risk of developing breast cancer is approximately 30%. The increased incidence in this group is probably due to inherited oncogenes.

Approximately 5% to 10% of all breast cancers have an inherited basis. All inherited genes are autosomal dominant but have variable penetrance. Males can carry the gene 50% of the time. Carriers of these germine mutations have up to a 4%-per-year risk of developing breast cancer and a lifetime risk of up to 85% (4). The most common gene mutations are the BRCA1 (chromosome 17q21) and BRCA2 (chromosome 13q12–13) gene deletions. These mutations are rare in the general
public (0.1%) but are more commonly identified in Jews of Ashkenazi descent (1% to 2%) (5). Testing should be performed only if there is a high likelihood that results
will be positive, can be interpreted accurately, and will be used to influence decisions regarding medical management of the patient and family.

Diet, Obesity, and Alcohol

Marked geographic differences in the incidence of breast cancer may be related to diet, in particular with regard to variations in fat intake (6). It is not clear, however,
that a high-fat diet is a specific risk factor, because most studies have not clearly separated obesity from other known risk factors (7). Alcohol consumption may
increase the risk of breast cancer, but again this relationship is not clear (8).

Reproductive and Hormonal Factors

The risk of breast cancer increases with the length of a woman's reproductive phase (9). Thus, the median age at menarche is lower for women who develop breast
cancer, and either natural or artificial early menopause protects against the development of breast cancer (10). Artificial menopause as a result of oophorectomy
lowers the risk of breast cancer farther than does early natural menopause. There is no clear association between the risk of breast cancer and menstrual irregularity
and duration of menses. There is some evidence that these reproductive factors, although decreasing the risk of developing breast cancer, may adversely affect a
patient's prognosis (11).

Lactation does not affect the incidence of breast cancer, but women who have never been pregnant have a higher risk of breast cancer than those who are
multiparous. Also, women who bear their first child later in life have a higher incidence of breast cancer than do younger primigravida females (12).

A well-controlled study from the Centers for Disease Control and Prevention showed that oral contraceptive use does not increase the risk of breast cancer,
regardless of duration of use, family history, or coexistence of benign breast disease (13). However, a recent pooled analysis from 54 epidemiologic studies showed
current users of oral contraceptives had a small, but real, increased risk when compared with nonusers. Ten years after discontinuation, the risk of past users declined to that of the normal population (14).

Although short-term estrogen treatment for menopausal symptoms probably does not increase the risk of breast cancer, prolonged use (longer than 10 years) or higher dosages of estrogen may increase the risk. Current data suggest that postmenopausal estrogen administration is a risk factor (15). The current consensus is that, postmenopausally, estrogen should be given in a relatively low dose either cyclically or in combination with progestins when the uterus is present. Although estrogens may slightly increase the incidence of breast cancer, this risk should be weighed against the possible benefits in preventing osteoporosis and heart disease.

History of Cancer

Women with a history of breast cancer have an approximately 50% risk of developing microscopic breast cancer and about a 20% risk of developing clinically apparent cancer in the contralateral breast, which occurs at a rate of 1% to 2% per year (16). Lobular carcinoma has a higher incidence of bilaterality than does ductal carcinoma. A history of endometrial carcinoma, ovarian carcinoma, or colon cancer has also been associated with an increased risk of breast cancer.

Diagnosis

Breast cancer most commonly arises in the upper outer quadrant, where there is more breast tissue. Breast masses are most often discovered by the patient and less frequently by the physician during routine breast examination. The increasing use of screening mammography has expanded the ability to detect nonpalpable abnormalities. Rare metastatic breast cancer may be found as an axillary mass without obvious malignancy.

Mammography and physical examination, the standard screening modalities, are complementary. In the past, most cases of breast cancer were discovered as a palpable mass. However, 10% to 50% of cancers detected mammographically are not palpable. Conversely, physical examination detects 10% to 20% of cancers not seen on mammography (17). The purpose of screening is to detect cancers when they are small (<1 cm) and have the highest potential for surgical cure. It may have the added benefit of reducing breast cancer mortality for women age 50 and older who undergo annual screening mammography. Data for screening of women under 40 have been more controversial. However, recent data from the Gothenburg screening trial showed a 45% reduction in mortality for women screened between the ages 40 and 49 (18). Because of these findings, it is recommended that all women undergo screening mammography starting at age 40, along with clinical breast examination and breast self-examination. No other tests, such as ultrasonography, magnetic resonance imaging (MRI), computed tomography (CT) scans, sestamibi scans, positron emission tomography (PET) scans, or serum blood markers, are effective screening modalities, and these tests should be used only when indicated. Screening guidelines recommended by the American College of Radiology and the American Cancer Society are presented in Table 35.1.

Table 35.1. Official Screening Recommendations

Masses are easier to palpate in older women with fatty breasts than in younger women with dense, often nodular breasts. An area of thickening amid normal nodularity may be the only clue to an underlying malignancy. Skin dimpling, nipple retraction, or skin erosion is usually obvious, but these are later-stage disease signs. Algorithms for the evaluation of breast masses in premenopausal and postmenopausal women are presented in Chapter 18.

A dominant breast mass must be considered a possible carcinoma, and biopsy is essential for diagnosis. About 30% to 40% of lesions believed clinically to be malignant will be benign on histologic examination (19). Conversely, 20% to 25% of clinically benign-appearing lesions will be proven malignant by biopsy (20).

Biopsy Techniques

For patients with obvious malignancy, it may be reasonable to obtain a biopsy specimen and a frozen section immediately before mastectomy or other definitive treatment. It is preferable for the patient to be involved in the planning of her therapy. Initial biopsy is better followed by subsequent definitive treatment in the two-step approach. This approach allows the physician to discuss alternative forms of therapy with the patient who has a malignancy, and it gives the patient an opportunity to obtain a second opinion before undergoing definitive treatment.

Fine-needle Aspiration Cytology

Fine-needle aspiration (FNA) cytology is performed with a 20- or 22-gauge needle. The technique has a high level of diagnostic accuracy, with a 10% to 15% false-negative rate and rare, but persistent, false-positive results (21). Fine-needle aspiration cytology results can be useful in discussing alternatives with the patient. Negative FNA cytologic results do not exclude malignancy and usually are followed by excisional biopsy or careful observation. In young women, it is prudent to follow a benign-appearing mass for one or two menstrual cycles. Furthermore, confirmation of a clinically apparent fibroadenoma with FNA can serve as the basis for observational follow-up without excision.

Open Biopsy

Open biopsy may be performed if FNA cytology has not been performed or if the results are negative or equivocal. An unequivocal histologic diagnosis of cancer should be obtained before treatment of breast cancer is undertaken. Cytologic diagnosis may be relied on if the mass clinically or mammographically appears to be malignant. In equivocal cases, a partial mastectomy can be performed, and a frozen section can be obtained to confirm the diagnosis of cancer before the axillary dissection is started. An alternative to open biopsy is removal of a core of tissue through a Vim-Silverman-type cutting needle. If a definitive diagnosis is not obtained, these procedures must also be followed by open biopsy.

Open biopsy can usually be performed in an outpatient setting with the patient under light sedation, in conjunction with the use of local anesthesia, in the following manner:

1. The patient is positioned and the location of the mass confirmed.
2. Local anesthesia is used to infiltrate the skin and subcutaneous tissue surrounding the palpable mass.
3. An incision is made directly over the mass. Planning should include an ellipse of skin to be either excised with the mastectomy or placed cosmetically so that partial mastectomy can be performed through the same incision. Paraareolar incisions are appropriate only for lesions in proximity to the nipple–areolar complex.
4. After the skin and underlying tissue are incised, the mass is gently grasped with Allis forceps or with a stay suture and moved into the operative field.
5. The mass should be excised completely whenever possible. Large masses that are difficult to excise totally with local anesthesia can be incised. When an incisional biopsy is used, a frozen section should be obtained to confirm that tissue is malignant. Such masses, however, are preferably sampled with FNA or core biopsy.

6. Once the mass is removed, adequate hemostasis is achieved and the incision is closed. A cosmetically superior result will be achieved if the breast parenchyma is not reapproximated deeply. The most superficial subcutaneous fat can be reapproximated with fine absorbable sutures. The skin should be closed with a subcuticular suture and adhesive strips to achieve the most cosmetically pleasing result. Usually a drain is not necessary.

### Mammographic Localization Biopsy

Biopsy of nonpalpable lesions is a potentially difficult procedure that requires close cooperation between the surgeon and the mammographer. The mammographer places a needle or specialized wire into the breast parenchyma at or near the site of the suspected abnormality. Many mammographers will also inject a biologic dye to assist localization further. The surgeon then reviews the films with the mammographer and localizes the abnormality with respect to the tip of the wire or needle. An incision is made directly over this area, and a small portion of the breast that is suspected of containing the abnormality is excised. A mammogram of the surgical specimen is obtained to ensure that the abnormality has been excised. Often, the mammographer can place a needle in the specimen at the site of the abnormality to facilitate histologic evaluation and ensure that the pathologist examines the site of the abnormality.

### Stereotactic Core Biopsy

Mammographic units with computerized stereotactic modifications can be used to localize abnormalities and perform needle biopsy without surgery. Under mammographic guidance, a biopsy needle is inserted into the lesion and a core of tissue is removed for histologic examination. Ultrasound may also be used to obtain a core biopsy of a nonpalpable lesion. Because it is less invasive and less expensive than mammographic localization biopsy, core biopsy is preferred for accessible lesions.

### Pathology and Natural History

Breast cancer may arise in the intermediate-sized ducts or terminal ducts and lobules. In most cases, the diagnosis of lobular and intraductal carcinoma is based more on histologic appearance than site of origin. The cancer may be either invasive (infiltrating ductal carcinoma, infiltrating lobular carcinoma) or in situ (ductal carcinoma in situ or lobular carcinoma in situ). Morphologic subtypes of infiltrating ductal carcinoma can be described as scirrhous, tubular, medullary, and mucinous.

Infiltrating ductal carcinoma of unspecified type accounts for 60% to 70% of the breast cancers in the United States (22). Mammographically, it is characterized by a stellate density or by microcalcifications. Macroscopically, there are gritty, chalky streaks within the tumor that most likely represent a desmoplastic response; microscopically, there is invasion of the surrounding stroma and fat. There is often a fibrotic response surrounding the invasive carcinoma.

Other types of infiltrating ductal carcinoma are far less common. Medullary carcinoma, which accounts for approximately 5% to 8% of breast carcinomas, arises from larger ducts within the breast and has a dense lymphocytic infiltrate. The tumor appears to be a slow-growing, less aggressive malignancy than the infiltrating ductal carcinoma.

Mucinous (colloid) carcinoma accounts for 5% of all breast cancers. Grossly, the tumor may have areas that appear mucinous or gelatinous. Infiltrating comedo carcinoma accounts for 1% of breast malignancies. It is an invasive cancer characterized by foci of necrosis that exude a comedonecrosis-like substance when biopsied. Usually, comedocarcinomas are in situ malignancies. Papillary carcinoma is predominantly a noninvasive ductal carcinoma; when invasive components are present, it should be specified as invasive papillary carcinoma. Tubular carcinoma is a well-differentiated breast cancer that accounts for 1% of all breast malignancies. Tubular carcinomas tend to have a better prognosis than infiltrating ductal carcinomas and rarely metastasize to axillary lymph nodes. Adenoid cystic carcinomas are extremely rare and are similar histologically to those seen in the salivary glands. They tend to be well differentiated and slow to metastasize.

### Growth Patterns

The growth potential of breast cancer and the patient's resistance to malignancy vary widely with the individual and the stage of disease. The doubling time of breast cancer can range from several weeks for rapidly growing tumors to months or years for slowly growing ones. If the doubling time of a breast tumor was constant and a tumor originated from one cell, a doubling time of 100 weeks would result in a 1-cm tumor in about 8 years (Fig. 35.1) (23). During the preclinical phase, tumor cells may be circulating throughout the body.

![Figure 35.1 Growth rate of breast cancer indicating long preclinical phase. (From Guillino PM. Natural history of breast cancer: progression from hyperplasia to neoplasia as predicted by angiogenesis. Cancer 1977;39:2697–2703, with permission.)](image)

Because of the long preclinical tumor growth phase and the tendency of infiltrating lesions to metastasize early, many clinicians view breast cancer as a systemic disease at the time of diagnosis. Although cancer cells may be released from the tumor prior to diagnosis, variations in the tumor's ability to grow in other organs and the host's response to the tumor may inhibit dissemination of the disease. Many women with breast cancer can be treated successfully with surgery alone, and some women have been cured even in the presence of palpable axillary disease. Thus, a pessimistic attitude that breast cancer is systemic and incurable at the time of diagnosis is unwarranted. A more realistic approach may be to view breast cancer as a two-component disease: one is the primary tumor in the breast, with all the inherent problems of local and regional extension and primary tumor control, and the other consists of the systemic metastases with their life-threatening consequences.

Although the natural history of breast cancer can involve metastases to any organ, involvement of bone, lungs, or liver occurs in 85% of women with metastatic breast cancer (24,25 and 26). If any of these sites is involved, metastases to other organs are highly likely. The use of systemic chemotherapy affects the sites of metastases, and currently metastases are occurring in more unusual sites with greater frequency.

### Staging

After the diagnosis of breast cancer has been established, either cytologically or histologically, the clinical stage of disease should be determined. The Columbia Clinical Staging System was widely used for many years (27) but has been replaced by the tumor–nodes–metastases (TNM) system recommended by the International Union Against Cancer (UICC) and the American Joint Committee on Cancer (28). This system allows both preoperative clinical staging and postoperative pathologic staging (Table 35.2 and Table 35.3).
Table 35.2. Tumor–Nodes–Metastasis (TNM) System for Staging of Breast Cancer

Table 35.3. Staging of Breast Carcinoma

Preoperative Evaluation

The extent of preoperative workup varies with the initial stage of the disease (29). For most patients with small tumors, no palpable lymph nodes (TNM stage I), and no symptoms of metastasis, the preoperative evaluation should consist of bilateral mammography, chest radiograph, complete blood count, and screening blood chemistry tests. Bone, CT, and MRI scanning are not necessary unless symptoms or abnormal blood chemistry suggest bone or liver metastasis. For patients with clinical stage II disease, a bone scan should be obtained, but a CT scan of the liver is not necessary unless symptoms or liver function tests suggest liver metastasis. Patients with clinical stage III or IV disease should undergo both bone and liver scanning. A bone marrow biopsy should be performed if there is obvious bone marrow dysfunction but metastases are not evident on a bone scan.

Treatment

Mastectomy

Traditionally, treatment of breast cancer has been surgical, but the type of operation employed has remained a controversial and highly emotional issue. During the nineteenth century, surgical treatment of breast cancer was haphazard, varying from local excision alone to total mastectomy. Halsted devised the radical mastectomy in an attempt to treat carcinoma of the breast as a local infiltrative process (30). Thus, radical mastectomy removes the entire breast, the underlying pectoral muscles, and the contiguous axillary lymph nodes in continuity (31) ([Fig. 35.2A](#)). Haagensen and Bodian reported a 51-year experience with radical mastectomy. Their data, which included 1,036 patients with a follow-up of 47 years, remain unequalled in evaluating any single method of treating breast cancer (32).

During the twentieth century, extensions and modifications of the radical mastectomy procedure were devised that involved removal of more local and regional tissue. Supraclavicular node dissections were added to the radical mastectomy (33). In addition, supraclavicular, mediastinal, and internal mammary lymph node dissections were performed (34).

Urban added *en bloc* internal mammary lymph node dissection to the standard radical mastectomy (35). This technique became popular and is the operation commonly referred to as the extended radical mastectomy. The extended radical mastectomy did not enhance overall survival rates (36). About 5% to 10% of patients in whom axillary lymph nodes are not involved will have involvement of internal mammary nodes. Locally destructive surgery is not justified, however, based on current understanding of the biologic behavior of breast cancer.

Modified Radical Mastectomy

Modified radical mastectomy preserves the pectoralis major muscle (37,38) ([Fig. 35.2B](#)). The breast is removed in a manner similar to that of the radical mastectomy; however, removal of the skin and the axillary lymph node dissection are not as extensive, and there is no need for skin grafting. There is no difference in survival rates between radical mastectomy and modified radical mastectomy, but the latter procedure has a better functional and cosmetic result (39). Modified radical mastectomy has replaced radical mastectomy and remains the procedure most often performed for breast cancer despite the proven equivalence of breast conservation therapy.

Total Mastectomy

Total mastectomy is the removal of the entire breast, nipple, and areolar complex without the underlying muscles or axillary lymph nodes. Axillary nodes are not
removed intentionally. However, low-lying lymph nodes in the upper outer portion of the breast and low axilla usually are included in the specimen. Total mastectomy has local control rates comparable with those of radical or modified radical mastectomy but has a higher risk of axillary recurrence. Because the axillary lymph nodes are not examined microscopically, this operation generally is less desirable than modified radical mastectomy. Regional recurrence will occur in at least 15% to 20% of patients treated with total mastectomy alone.

Adjuvant Radiation Therapy

McWhirther developed the combination of total mastectomy with radiation therapy (40). Many have advocated adjuvant radiation therapy in combination with various operative procedures. Studies claiming improvements in overall survival usually are flawed by the use of historical controls and inaccurate preoperative staging. Earlier trials, both prospective randomized studies and historical control studies, show that adjuvant radiation therapy improves local control but not survival rates (41,42,43 and 44). In contrast, a recent randomized control study demonstrated a 9% absolute increase in 10-year overall survival (45). The researchers concluded that the addition of postoperative radiation to mastectomy and chemotherapy prolongs survival in high-risk premenopausal women with breast cancer.

In a prospective randomized trial performed by the National Surgical Adjuvant Breast Project (NSABP), the roles of postoperative radiation therapy and axillary treatment were examined (46). Patients were randomly assigned to therapy consisting of total mastectomy, radical mastectomy, or total mastectomy with radiation therapy. This trial showed no difference in survival rates among the three groups of patients, whereas radiation therapy and axillary treatment improved local and regional control.

Conservative Therapy with or without Radiation Therapy

Radiation therapy alone, without excision of the tumor, is associated with a high local failure rate (47,48,49 and 50). Similarly, local excision without radiation has a high local failure rate. A major prospective randomized trial compared radical surgery with a combination of conservative surgery and modern radiotherapeutic techniques (51,52). Patients were randomly assigned to treatment with either standard Halsted radical mastectomy or a combination of quadrantectomy, axillary lymph node dissection, and postoperative radiation therapy. Only patients in whom tumors were smaller than 2 cm and not centrally located and who had no clinical evidence of axillary lymph node disease (T1 N0 M0) were considered for this trial. All 701 women in the study were comparable in age, tumor size, menopausal status, and histologic involvement of the axillary lymph nodes (52). After more than 15 years of follow-up, there has been no statistically significant difference between the two groups in either local control or overall survival rates.

The NSABP conducted a trial that extended these observations and provided further information (53). Eligible patients could have a primary tumor 4 cm, with or without palpable axillary lymph nodes, provided that the lymph nodes were not fixed (i.e., stage I or stage II, T1 or T2, and N0 or N1). Patients were assigned randomly to one of three groups: (a) modified radical mastectomy; (b) segmental mastectomy (lumpectomy) and axillary lymph node dissection; or (c) segmental mastectomy, axillary lymph node dissection, and postoperative radiation therapy. Unlike the quadrantectomy, segmental mastectomy or “lumpectomy” consists of removing only the tumor and a small rim of normal surrounding tissue and is cosmetically superior (54,55). Patients were considered ineligible if they were found to have microscopic involvement of the margins. A total of 1,843 women were randomized among the three treatment arms, and the groups were comparable. The lowest local recurrence rate was seen among patients treated with segmental mastectomy and postoperative radiation therapy. Of these patients, 90% were free of local recurrence after 8 years of observation, whereas 39% of the patients undergoing segmental mastectomy without radiation therapy had a local recurrence. Although the addition of radiation therapy clearly improved the local control rate, no significant difference in overall survival rates or disease-free survival could be seen among the three treatment arms; there was a trend, however, in favor of patients who received radiation. This NSABP study clearly shows that the combination of segmental mastectomy, axillary lymph node dissection, and postoperative radiation therapy was as effective as modified radical mastectomy for the management of patients with stage I and II breast cancer. These findings have since been updated; after 12 years of follow-up, no difference was seen in survival among the three groups (56). The high local recurrence rate without radiation therapy makes limited surgery alone generally unacceptable except in unusual circumstances.

Axillary lymph node status and the number of involved nodes is the most important prognostic indicator for patients with primary breast cancer (55,56 and 57). For these reasons, axillary lymphadenectomy is used to detect and quantify the extent of nodal metastasis (58). Axillary lymph node dissection (ALND) is performed routinely on all patients with breast cancer for the purposes of staging and the planning of adjuvant chemotherapy. Axillary dissection is associated with a very low risk of regional recurrence (1% to 3%) but at the cost of significant morbidity (59). The rate of acute complication is 20% to 30%. Similarly, the risk of chronic lymphedema is reportedly as high as 20% to 30% (60). Limiting the dissection to level I nodes or random sampling is associated with unacceptably high false-negative rates (61).

Only one-third of patients with a clinically negative axilla will be found to have nodal metastasis after histopathologic examination of all lymph nodes (62). This means that two-thirds of patients will undergo the morbidity of ALND without proven benefit.

In 1991, intraoperative lymphatic mapping and selective lymph node sampling was introduced in an effort to address these problems (63). The concept behind sentinel lymph node dissection (SLND) is best described by the definition of a sentinel node (SN). The SN is the lymph node that has the greatest potential to harbor metastasis if present. The SLND accurately predicts the status of the entire nodal basin by removing only one or two lymph nodes with minimal morbidity. If the SN is found to be negative, this directed approach can be used to distinguish patients who would not benefit from ALND and its morbidity. In a study of 107 patients with T1 and T2 breast cancer who underwent SLND followed by ALND, the SLN was successfully identified in 100 patients (93.5%). There were no false-negative results and the sentinel node accurately predicted axillary status in all 100 patients.

The technique of SLND has been validated by a number of authors using a variety of techniques (64,65). The information obtained from SLND appears to be equivalent to that of ALND in the few small trials conducted to date. Furthermore, a recent prospective study demonstrated that in node-negative patients undergoing SLND only, the recurrence rate in the axilla was zero at a median follow-up of 39 months (66). The degree of accuracy in predicting axillary metastasis, combined with a very low morbidity rate, makes SLND an attractive alternative to ALND.

Adjuvant Systemic Therapy

For many patients, local and regional control of breast cancer is achieved readily with surgery and radiation therapy alone. About 90% of patients will never experience a local recurrence; however, patients may still develop metastatic disease. The goal of adjuvant systemic therapy is to eliminate occult metastases during the early postoperative period while theoretically they are most vulnerable to anticancer agents (67). This approach, in turn, reduces the risk of local and distant recurrence.

It is currently well accepted that adjuvant systemic therapy will prolong survival in selected breast cancer patients. However, in patients with favorable tumors...
and a low risk of recurrence and subsequent death, such as those who have node-negative cancers smaller than 1 cm or node-negative cancers smaller than 2 cm, with grade 1 histology, this benefit is small and may not justify the risks of systemic therapy. Adjuvant systemic therapy reduces the odds of death by about 25% per year in both node-negative and node-positive patients (68). Because this risk reduction is relatively constant, patients with favorable, node-negative disease have a much smaller absolute benefit as compared with patients who have node-positive disease and a high risk of recurrence. For patients with node-negative disease, the absolute benefit may only be a few percent versus 10% to 20% for those with node-positive disease.

Cytotoxic chemotherapy and hormonal therapy have inherent risks that must be considered when choosing which patients should receive them. Not only are there known acute side effects with current standard regimens, but also there is growing evidence that patients who undergo chemotherapy more frequently report chronic neurocognitive deficits (69). The impact of these deficits remains undefined. Similarly, systemic therapy with tamoxifen has an appreciable long-term morbidity. Adverse effects include an increased incidence of uterine cancer, vaginal dryness, and hot flashes. Choosing the patients who should receive adjuvant therapy can be a difficult decision. This decision entails analyzing a variety of prognostic and predictive factors, identifying patients at risk for recurrence, and quantifying that risk.

In general, adjuvant chemotherapy is currently recommended for women with a greater than 10% chance of relapse within 10 years. In practice, systemic adjuvant therapy is offered to many patients with early-stage breast cancer. The choice of therapy generally depends on an evaluation of specific risk factors.

Factors that determine the patient’s risk of recurrence are nodal involvement, tumor size, estrogen and progesterone receptor status, nuclear grade, histologic type, proliferative rate, and a variety of biologic markers. These prognostic factors and their effects on recurrence are summarized in Table 35.4. The assumption is made that patients with high-risk prognostic factors are more likely to benefit from adjuvant cytotoxic or hormonal therapy; thus, these patients are generally offered such treatment.

Hormone receptor status is an important predictor not only of prognosis but also of response to hormonal therapy. Several studies demonstrated that patients who are estrogen and progesterone positive have overall improved survival (71,72). The status of these receptors should be known when determining the need for and choice of adjuvant therapy.

Histologic grade appears to predict overall survival as well. Those patients with favorable, well-differentiated tumors tend to fare better than those with poorly differentiated ones (Table 35.5). In a British study of 1,168 women, histologic grade was an independent predictor of overall survival at 10 years. Among multiple factors analyzed, only tumor size, lymph node status, and histologic grade had independent significance (73).

It is generally accepted that patients with lymph node metastasis have a higher risk of recurrence than patients with node-negative disease. The 10-year survival rate for women with palpable metastatic axillary lymph nodes who receive no systemic therapy is only about 50% to 60%. Even when they are not clinically palpable, lymph node metastases portend an unfavorable course. The number of lymph nodes involved and the presence of extracapsular invasion are important indicators of poor prognosis.

Another important prognostic indicator of relapse is tumor size. In an evaluation of 767 patients with node-negative disease who underwent radical or modified radical mastectomy without adjuvant chemotherapy, the relapse rate in patients with tumors larger than 1 cm or special tumor types larger than 3 cm (tubular, mucinous or papillary) was 27% at 10 years (70). For tumors smaller than 1 cm, the relapse rate was only 9% at 10 years.

Specific tumor biologic markers are now gaining research interest because of their possible role in predicting which patients will respond to chemotherapy regimens. The most research has been performed with HER-2/neu. In an NSABP study, patients with HER-2/neu overexpression fared worse if they were not treated with anthracycline-based regimens (74). Another study showed that the addition of Trastuzumab (Herceptin), an antibody directed against the HER-2/neu receptor, significantly increased the response rate to therapy over standard chemotherapy alone in the presence of metastases (75). Current research is focusing on the role of trastuzumab as adjuvant therapy. Other prognostic indicators such as p53, Ki-67, and S-phase fraction are also being investigated.

Over the course of several decades, more than 100 prospective, randomized trials have been conducted examining the role of adjuvant chemotherapy in breast cancer (76). From this work, a variety of systemic regimens have emerged. Systemic therapy includes cytotoxic agents and hormonal agents, used alone or in combination. Following is a brief description of the more commonly used regimens. A comprehensive review of all available modalities is beyond the scope of this chapter but is readily available in standard medical oncology texts.

Initially, trials involved a single perioperative course of chemotherapy in an attempt to eradicate circulating tumor cells. The Nissen-Meyer study from Norway showed that a single course of cyclophosphamide improved overall survival rates (77). Subsequently, numerous trials have shown the benefit of adjuvant chemotherapy for certain subgroups of patients (76). In the initial NSABP adjuvant trial, a 2-year course of melphalan was shown to be superior to no treatment (79). Subsequent trials have shown the enhanced beneficial effect of multiple drugs and a combination of hormonal manipulation with chemotherapy (80).

Historically, the most frequently used adjuvant combination chemotherapy has been CMF: cyclophosphamide, methotrexate, and 5-fluorouracil (5-FU). In the original study by Bonadonna and associates, patients with positive axillary lymph nodes were randomized to receive either 12 monthly cycles of CMF or no therapy after radical mastectomy (81). A statistically significant benefit was found with CMF for premenopausal patients, especially those with one to three positive nodes. A subsequent study showed six cycles of CMF to be as effective as 12 cycles (82). However, no significant effect was seen for postmenopausal women. This was thought to be because postmenopausal women were less likely to tolerate the full course of CMF (83). After 20 years of follow-up, this trial demonstrated a
Adjuvant systemic therapy is not recommended for patients with favorable, small nonpalpable tumors or palpable tumors smaller than 1 cm. The Premenopausal women with lymph node involvement should be treated with adjuvant combination chemotherapy. Postmenopausal women who have lymph node metastasis and negative hormone receptor levels may be treated with adjuvant chemotherapy. Postmenopausal patients who have negative lymph nodes and positive hormone receptor levels should receive adjuvant chemotherapy because of the eligibility criteria of many large trials. Because of the inherent toxicity of chemotherapeutic regimens, patients under age 70 years must be carefully selected with regard to treatment.

High-risk patients with hormone-resistant disease may benefit from cytotoxic systemic therapy. In patients over age 70 years, there are little data available regarding the benefits of adjuvant cytotoxic therapy because of the eligibility criteria of many large trials. Because of the inherent toxicity of chemotherapeutic regimens, patients in this age group must be carefully selected with regard to treatment.

Caution should be exercised when using chemotherapeutic agents. Patients in whom the risk of recurrence is low are likely to derive little overall benefit from the use of adjuvant systemic therapy, whereas those with an overall high risk of recurrence are likely to receive the greatest benefit. When the risk of recurrence is extremely low, as would be expected for tumors smaller than 1 cm with no lymph node metastasis, the reduction in the risk of recurrence may not justify the side effects of the therapy. Hormonal manipulation used alone and in combination with cytotoxic regimens is beneficial in select groups of women. Tamoxifen, an estrogen analogue, offers substantial benefits in both premenopausal and postmenopausal women. Taken at a dose of 20 mg per day for 5 years, tamoxifen reduces the annual odds of recurrence by about 50% and the annual odds of death by about 25%. These benefits were seen in women with estrogen receptor–positive disease despite the presence or absence of chemotherapy (69). The possibility of substituting tamoxifen for radiotherapy in patients with small (<1 cm) tumors is also being evaluated prospectively.

There are data to suggest that tamoxifen, when used in combination with cytotoxic chemotherapy, improves survival in women with positive axillary lymph nodes and positive estrogen receptor expression (63). In patients with node-negative, estrogen receptor–positive disease, the addition of tamoxifen to chemotherapy improved disease-free survival after 5 years of follow-up (94). In NSABP study B-14, 2,544 patients with estrogen receptor–positive tumors and no axillary metastases were randomized, double blinded to either tamoxifen (10 mg orally twice daily for 5 years) or a placebo control. After a 4-year median follow-up, the disease-free survival rate for the 1,318 patients treated with tamoxifen was 82% compared with 77% for the 1,326 patients treated with placebo (p = 0.00001). An advantage existed for both premenopausal and postmenopausal women.

The Early Breast Cancer Trialists’ Collaborative Group performed a metaanalysis of adjuvant systemic therapy for breast cancer. They analyzed randomized trials involving adjuvant systemic hormonal, cytotoxic, or immune therapy administered to more than 75,000 women with stage I or II carcinoma. The investigators concluded that, for postmenopausal women with estrogen receptor–positive tumors, tamoxifen in a dose of 20 mg daily for at least 2 years had a significant beneficial effect on disease-free survival rates. This beneficial effect lasted up to 10 years. Data demonstrated a decreased incidence of carcinoma in the contralateral breast and a decreased death rate from heart disease.

### General Recommendations

Adjuvant systemic therapy, either with tamoxifen or multiple-chemotherapy agents, lowers the incidence of recurrence by about 30%. It is important to understand that the proportional reduction in risk of relapse is relatively constant regardless of absolute risk (95) (Table 35.6). As mentioned earlier, adjuvant cytotoxic chemotherapy appears to affect the natural history of patients with axillary node–negative breast cancer. A 2000 consensus statement from the National Institutes of Health on early-stage breast cancer advised that all patients be considered for clinical trials and offered the opportunity to participate (96). Furthermore, node-negative patients who are not candidates for clinical trials should be made aware of the benefits and potential risks of adjuvant systemic therapy. Most high-risk patients with node-negative disease are now being treated with adjuvant cytotoxic therapy.

In postmenopausal women, chemotherapy is about one-half as effective as tamoxifen in the adjuvant setting (97). For most postmenopausal women with hormone-responsive disease (estrogen- and progesterone-responsive positivity), including node-positive patients, tamoxifen alone may be adequate therapy. High-risk patients with hormone-resistant disease may benefit from cytotoxic systemic therapy. In patients over age 70 years, there are little data available regarding the benefits of adjuvant cytotoxic therapy because of the eligibility criteria of many large trials. Because of the inherent toxicity of chemotherapeutic regimens, patients in this age group must be carefully selected with regard to treatment.

Caution should be exercised when using chemotherapeutic agents. Patients in whom the risk of recurrence is low are likely to derive little overall benefit from the use of adjuvant systemic therapy, whereas those with an overall high risk of recurrence are likely to receive the greatest benefit. When the risk of recurrence is extremely low, as would be expected for tumors smaller than 1 cm with no lymph node metastasis, the reduction in the risk of recurrence may not justify the side effects of the drugs. Current studies are under way to investigate whether this assumption is true.

The current recommendations for adjuvant systemic therapy in breast cancer are summarized as follows:

1. Premenopausal women with lymph node involvement should be treated with adjuvant combination chemotherapy. Tamoxifen may be added to the regimen for patients with estrogen receptor–positive tumors following cytotoxic therapy.
2. Premenopausal women without evidence of axillary lymph node involvement but with risk factors such as large (>1 cm), aneuploid, or estrogen receptor–negative tumors should be treated with combination chemotherapy. Tamoxifen should be added for patients with estrogen receptor–positive tumors.
3. Postmenopausal patients who have negative lymph nodes and positive hormone receptor levels should receive adjuvant tamoxifen therapy. Those with positive lymph nodes may receive tamoxifen alone, multidrug cytotoxic therapy, or a combination thereof.
4. Postmenopausal women who have lymph node metastasis and negative hormone receptor levels may be treated with adjuvant chemotherapy.
5. Adjuvant systemic therapy is not recommended for patients with favorable, small nonpalpable tumors or palpable tumors smaller than 1 cm. The toxicity of chemotherapy and its effect on quality of life must be carefully evaluated, especially in older postmenopausal women.

### Prognosis

The treatment of advanced, metastatic breast cancer is largely palliative. For most physicians who treat this disease, quality of life issues are paramount when
choosing which type of therapy is offered. In patients with locally advanced disease in conjunction with distant metastasis, palliative radiotherapy may be advised. Palliative radiotherapy is most widely used in the treatment of certain soft tissue or bony metastases to control pain or avoid fracture. This approach is best exemplified in the treatment of isolated bone metastases, chest wall recurrences, brain metastases, and spinal cord compression.

Systemic disease may be controlled by hormonal or cytotoxic therapy. Because the quality of life during a remission induced by endocrine manipulation usually is superior to a remission following cytotoxic chemotherapy, it usually is preferable to try endocrine manipulation first. Disseminated disease may respond favorably after endocrine therapy such as functional organ ablation (ovary, pituitary, adrenal glands) or administration of drugs that block hormonal function. A favorable response occurs in about one-third of patients with metastatic disease. For those patients whose tumors express estrogen receptors, this response rate may be as high as 60%. Because only 5% to 10% of women whose tumors do not contain estrogen receptors respond to treatment, they should not receive hormonal therapy except in unusual cases such as elderly patients who are unable to tolerate cytotoxic therapy (98).

Cytotoxic chemotherapy should be considered for the treatment of metastatic breast cancer in the following instances: (a) if organ involvement is potentially life-threatening (brain, lung, or liver) (b) if hormonal treatment is unsuccessful or the disease has progressed after an initial response to hormonal manipulation, or (c) if the tumor is estrogen receptor-negative. The most useful single chemotherapeutic agent is a taxane or taxane/cisplatin combination (99). Clinical trials are under way to examine a variety of combinations for stage IV disease. The side effects of nausea and vomiting, which can be devastating, are now well controlled with central-acting antiemetics. The importance of controlling these side effects cannot be overemphasized.

Special Breast Cancers

Paget's Disease

Sir James Paget described a nipple lesion similar to eczema and recognized that this nipple change was associated with an underlying breast malignancy (100). The erosion results from invasion of the nipple and surrounding areola by characteristic large cells with irregular nuclei, now called Paget cells. The origin of these cells has been much debated by pathologists. However, they are probably extensions of an underlying carcinoma into the major ducts of the nipple–areolar complex. There may be no visible changes associated with the initial invasion of the nipple. Often, the patient will notice a nipple discharge, which is actually a combination of serum and blood from the involved ducts.

The overall prognosis for patients with Paget's disease depends on the underlying malignancy. In patients who have an intraductal carcinoma alone, the prognosis is favorable, whereas in those with infiltrating duct carcinoma metastatic to the regional lymph nodes, the prognosis is poor. Traditionally, treatment has almost always been total mastectomy and lymph node dissection, although radiotherapy with resection of the tumor and nipple–areolar complex is being performed (101).

Inflammatory Carcinoma

Inflammatory carcinoma of the breast initially appears to be an acute inflammation with redness and edema. Inflammatory cancer, rather than infiltrating ductal carcinoma, should be diagnosed when more than one-third of the breast is involved with erythema and edema and when biopsy of this area shows metastatic cancer in the subcutaneous lymphatics. There may be no distinct palpable mass, because the tumor infiltrates through the breast with ill-defined margins, or there may be a dominant mass. There may even be satellite nodules within the parenchyma. Most of the tumors are poorly differentiated, and mammographically the breast shows skin thickening with an infiltrative process.

Except for biopsy of the lesion, surgery usually should not be used in the initial management of inflammatory carcinoma. Mastectomy in the face of inflammatory carcinoma usually fails locally and does not improve survival rates. The best results are achieved with a combination of chemotherapy and radiation therapy. Mastectomy may be indicated for patients who remain free of distant metastatic disease after initial chemotherapy and radiation (102-103).

In Situ Carcinomas

Both lobular carcinoma and ductal carcinoma may be confined by the basement membrane of the ducts. These carcinomas do not invade the surrounding tissue and, theoretically, lack the ability to spread. Indeed, lobular carcinoma in situ is not a malignancy. Untreated it may not become a new cancer, whereas ductal carcinoma in situ will. A more appropriate nomenclature for lobular carcinoma in situ is lobular neoplasia, and it should be considered a risk factor for the development of cancer in estrogen-receptor-positive women. For those with the usual natural history, they represent a special form of breast cancer. If treated by biopsy alone, 25% to 30% of patients with lobular carcinoma in situ will subsequently develop invasive cancer.

Lobular Carcinoma In Situ

Most women with lobular carcinoma in situ are premenopausal. The tumor typically is not a discrete mass, but rather is a multifocal lesion within one or both breasts found incidentally at biopsy of a mass or mammographic assessment of an abnormality not related to the lobular carcinoma in situ. Lobular carcinoma in situ usually is managed with excisional biopsy followed by careful observation and mammography. It should not be considered a malignancy but rather a risk factor for malignancy. Patients should be informed that they have a higher risk of developing invasive breast cancer. Occasionally, a patient may request bilateral prophylactic mastectomy.

Ductal Carcinoma In Situ

Ductal carcinoma in situ is more common in postmenopausal women. It may manifest as a palpable mass with features typical of an invasive ductal carcinoma but usually is detected mammographically as a cluster of branched or Y-shaped microcalcifications. By definition, the intraductal disease does not invade beyond the basement membrane. Unlike patients with lobular carcinoma in situ, however, at least 30% to 50% of patients with ductal carcinoma in situ will develop invasive cancer within the same breast when treated by excisional biopsy alone (105).

Although modified radical mastectomy has been standard treatment for intraductal carcinoma, more conservative surgery, with or without radiation therapy, can yield good results (106). In NSABP B17, 818 patients were randomly assigned to treatment with excision alone or excision followed by radiation therapy (107). The mean extent of ductal carcinoma in situ lesions was 13 mm, and 88% were larger than 20 mm. All lesions were completely resected with negative margins. After a median follow-up of 43 months, the actuarial 5-year local recurrence rate was 10.4% without radiation versus 7.5% with radiation (p = 0.055) for noninvasive cancers, and 10.5% without radiation versus 2.9% with radiation (p > 0.001) for invasive cancers. Of 83 recurrences, only 9 (11%) were not in the index quadrant. A recent reanalysis with a mean follow-up of 90 months confirmed these results (108). These data suggest that segmental mastectomy offers excellent local control.

Auxiliary metastases occur in fewer than 5% of patients, indicating that an invasive component has been missed during biopsy. For small, true ductal carcinoma in situ, axillary dissection is not indicated. About 5% of patients whose initial biopsy results show intraductal carcinoma will be found to have infiltrating ductal carcinoma when treated with mastectomy. The incidence of contralateral breast cancer in women with intraductal carcinoma is the same as in those with invasive ductal carcinoma (5% to 8%) (109).

Breast Cancer in Pregnancy

Breast cancer complicates approximately one in 3,000 pregnancies (110-111 and 112). It is the second most common malignancy seen in association with pregnancy, surpassed only by cervical cancer (113). Initial studies suggested a significantly worse prognosis for patients with breast cancer diagnosed during pregnancy, but recent data indicate that the hormonal changes associated with pregnancy seem to have little, if any, influence on prognosis. When pregnant patients are matched stage for stage with nonpregnant patients, survival rates seem equivalent (114).

The treatment of breast cancer in pregnant women must be highly individualized. Considerations include the patient's age and desire to have the child. The overall prognosis should be considered, especially when axillary lymph nodes are involved, because adjuvant chemotherapy can be teratogenic or lethal, particularly during the first trimester, but may be given later in the pregnancy. It is not known whether interruption of pregnancy alters the prognosis for patients with potentially curable
Localized disease found during the first or second trimester of pregnancy is probably best treated with definitive surgery and radiation therapy similar to that done for nonpregnant patients. Radiation therapy is relatively safe to give provided the abdomen is shielded. Adjunctive chemotherapy can be given after the first trimester, however, most oncologists prefer not to give it to pregnant women. Localized tumors found during the third trimester of pregnancy must be managed on an individual basis. Initially, tumors should be excised early in the third trimester. A recent study evaluated the effect of subsequent pregnancy on overall survival of breast cancer patients. Although approximately 40% of the women in the study had node-negative disease, 5- and 10-year survival rates were better in women who became pregnant than in matched pair controls who did not. This study suggests that subsequent pregnancy does not adversely affect the prognosis of early-stage breast cancer. Theoretically, it may be that only women with estrogen receptor-positive or progesterone-positive tumors would be affected detrimentally, but this possibility has not been studied. Because recurrences are most frequent within the first 2 to 3 years after diagnosis, patients with receptor-positive tumors and advanced-stage disease probably should wait before becoming pregnant again if ever.
